NORINYL® 1+50

tablets (norethindrone 1 mg with mestranol 0.05 mg)

Special Note

Oral contraceptives have been marketed in the United States since 1960. Reported pregnancy rates vary from product to product. The effectiveness of the sequential products appears to be somewhat lower than that of the combination products. Both types provide almost completely effective contraception.

An increased risk of thromboembolic disease associated with the use of hormonal contraceptives has now been shown in studies conducted in both Great Britain and the United States. Other risks, such as those of elevated blood pressure, liver disease and reduced tolerance to carbohydrates, have not been quantitated with precision.

Long term administration of both natural and synthetic estrogens in subprimate animal species in multiples of the human dose increases the frequency for some animal carcinomas. These data cannot be transposed directly to man. The possible carcinogenicity due to the estrogens can neither be affirmed nor refuted at this time. Close clinical surveillance of all women taking oral contraceptives must be continued.

Indications

NORINYL 1+50 21-DAY is indicated for oral contraception.

Contraindications

1. Thrombophlebitis, thromboembolic disorders, cerebral apoplexy, or a past history of these conditions.
2. Markedly impaired liver function.
3. Known or suspected carcinoma of the breast.
4. Known or suspected estrogen dependent neoplasia.
5. Undiagnosed abnormal genital bleeding.
6. Known or suspected pregnancy.

Warnings

1. The physician should be alert to the earliest manifestations of thrombotic disorders (thrombophlebitis, cerebrovascular disorders, pulmonary embolism, and retinal thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. Retrospective studies of morbidity and mortality in Great Britain and studies of morbidity in the United States have shown a statistically significant association between thrombophlebitis, pulmonary embolism, and cerebral thrombosis and embolism and use of oral contraceptives. There have been three principal studies in Britain[1,2,3] leading to this conclusion, and one[4] in this country. The estimate of the relative risk of thromboembolism in the study by Vessey and Doll[3] was about sevenfold, while Sartwell and associates in the United States found a relative risk of 4.4, meaning that the users are several times as likely to undergo thromboembolic disease without evident cause as non-users. The American study also indicated that the risk did not persist after discontinuation of administration, and that it was not enhanced by long continued administration. The American study was not designed to evaluate a difference between products. However, the study suggested that there might be an increased risk of thromboembolic disease in users of sequential products. This risk cannot be quantitated, and further studies to confirm this finding are desirable.
2. Discontinue medication pending examination if there is sudden partial or complete loss of vision, or if there is a sudden onset of proptosis, diplopia or migraine. If examination reveals papilledema or retinal vascular lesions, medication should be withdrawn.
3. Since the safety of NORINYL 1+50 21-DAY in pregnancy has not been demonstrated, it is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule the possibility of pregnancy should be considered at the time of the first missed period.
4. A small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The long range effect to the nursing infant cannot be determined at this time.
5. Hepatic cell adenomas have been reported in women on oral contraceptives. The adenoma may present as an abdominal mass or with the signs and symptoms of an acute abdomen. A bleeding hepatic cell adenoma should be considered if the patient has abdominal pain or evidence of intra-abdominal bleeding.

The norethindrone/mestranol 1+50 combination. From the company that developed it.

Precautions

1. The pretreatment and periodic physical examinations should include special reference to liver, breasts and pelvic organs, including Papanicolaou smear since estrogens have been known to produce tumors, some of them malignant, in five species of subprimate animals.
2. Endocrine and possibly liver function tests may be affected by treatment with NORINYL 1+50 21-DAY. Therefore, if such tests are abnormal in a patient taking NORINYL 1+50 21-DAY, it is recommended that they be repeated after the drug has been withdrawn for 2 months.
3. Under the influence of estrogen-progestogen preparations, pre-existing uterine fibromyomata may increase in size.
4. Because these agents may cause some degree of fluid retention, conditions which might be influenced by this factor, such as epilepsy, migraine, asthma, cardiac or renal dysfunction, require careful observation.
5. In breakthrough bleeding, and in all cases of irregular bleeding per vaginam, nonfunctional causes should be borne in mind. In undiagnosed bleeding per vaginam, adequate diagnostic measures are indicated.
6. Patients with a history of psychic depression should be carefully observed and the drug discontinued if the depression recurs to a serious degree.
7. Any possible influence of prolonged NORINYL 1+50 21-DAY therapy on pituitary, ovarian, adrenal, hepatic or uterine function awaits further study.
8. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. The mechanism of this decrease is obscure. For this reason, diabetic patients should be carefully observed while receiving NORINYL 1+50 21-DAY therapy.
9. The age of the patient constitutes no absolute limiting factor, although treatment with NORINYL 1+50 21-DAY may mask the onset of the climacteric.
10. The pathologist should be advised of NORINYL 1+50 21-DAY therapy when relevant specimens are submitted.
11. Susceptible women may experience an increase in blood pressure following administration of contraceptive steroids.

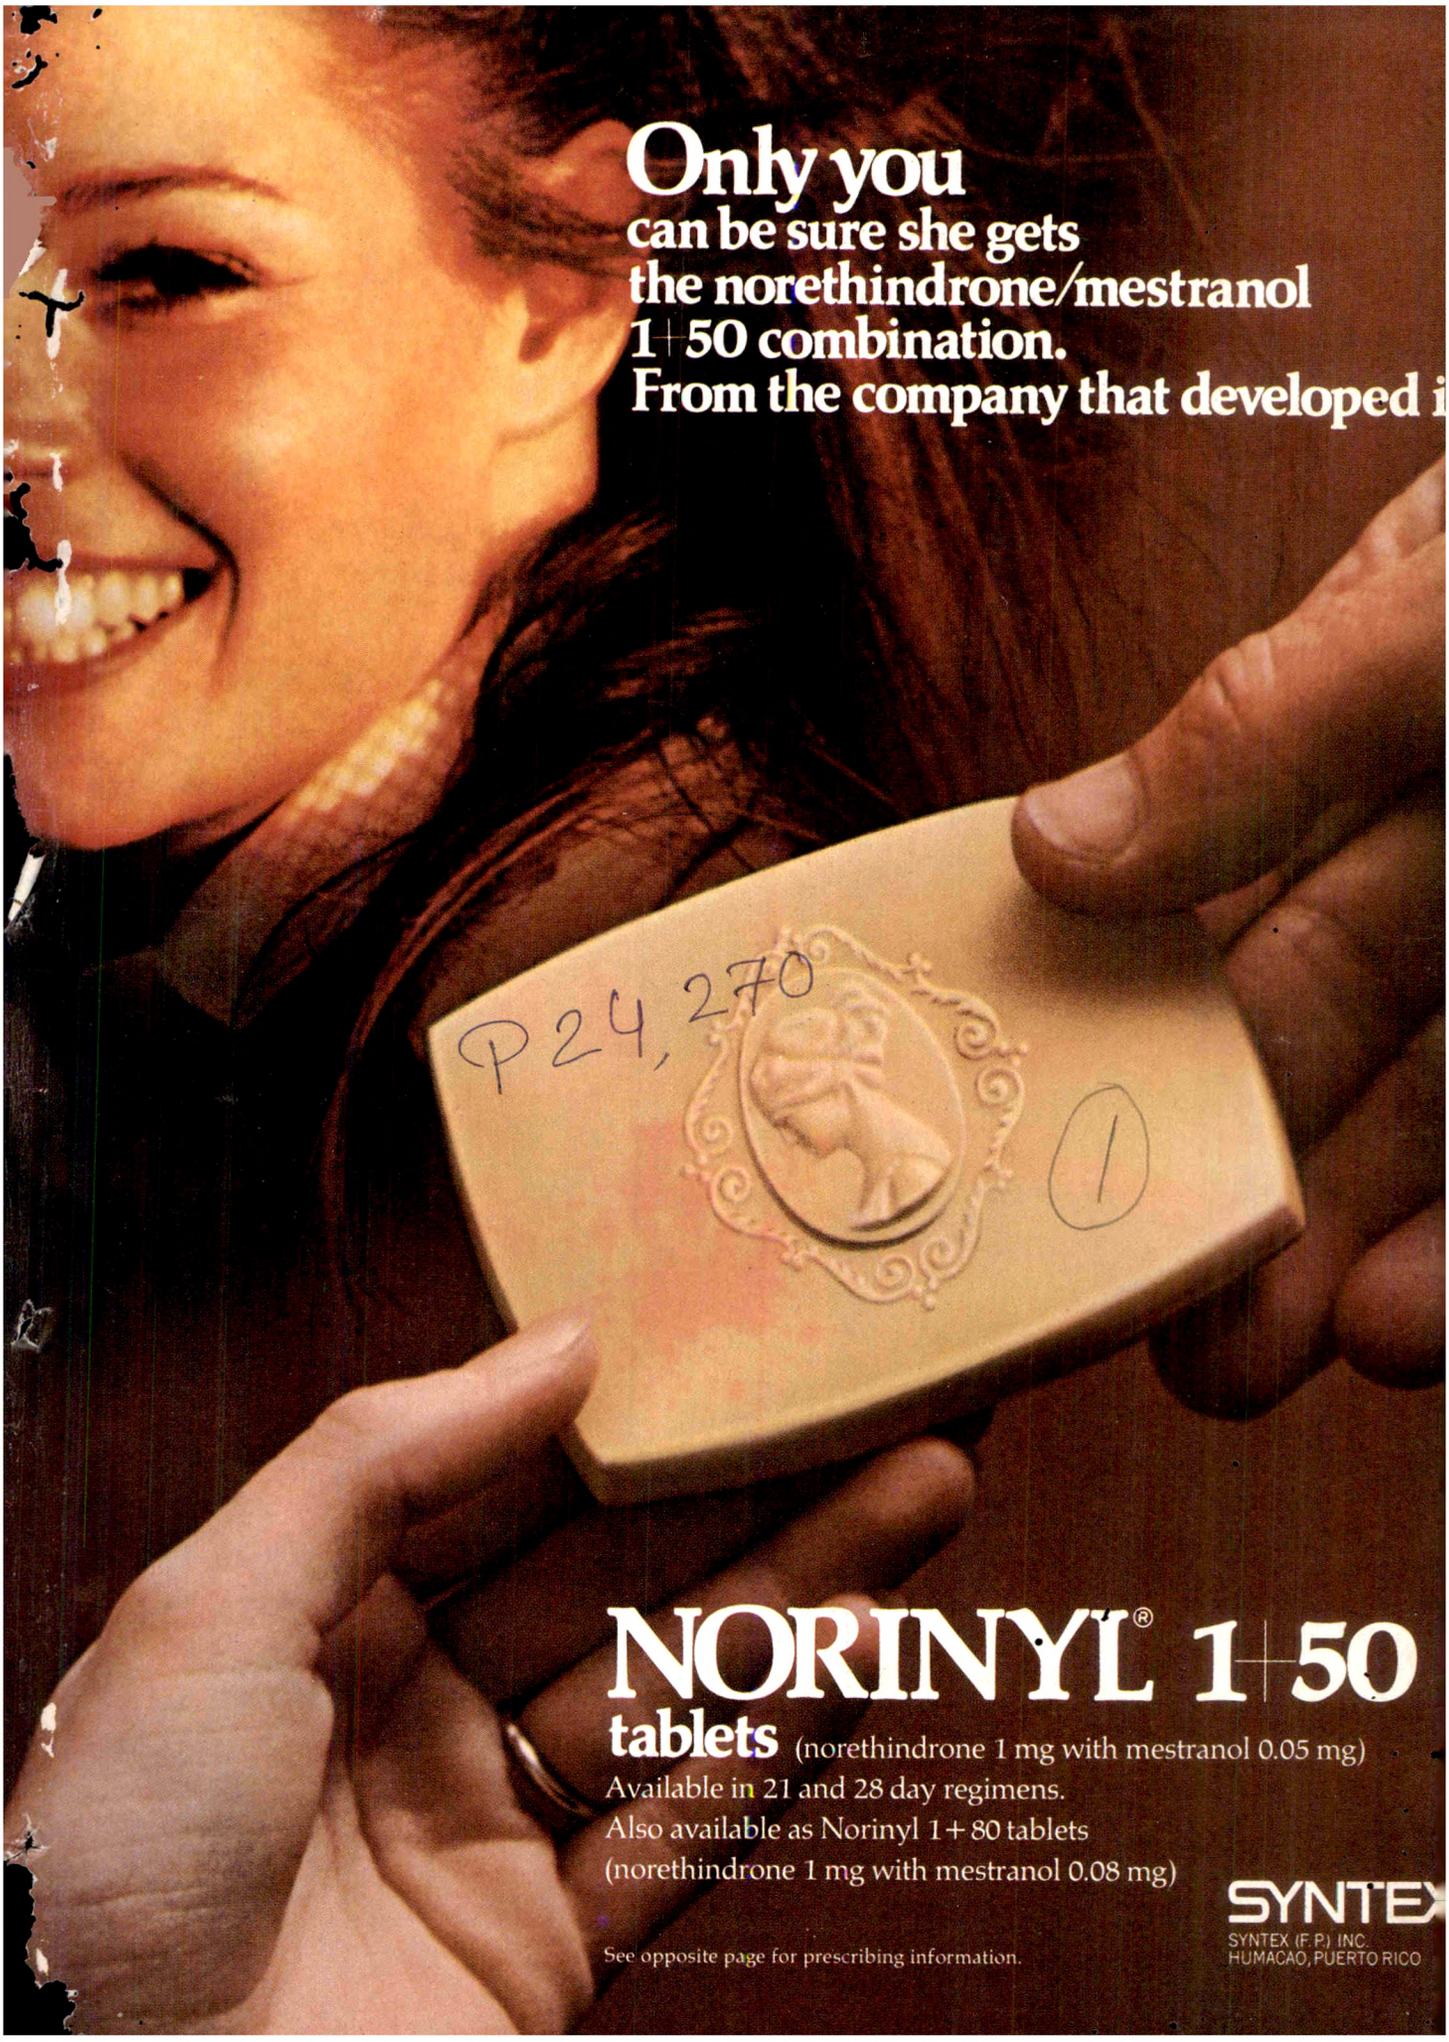
Adverse Reactions Observed in Patients Receiving Oral Contraceptives

A statistically significant association has been demonstrated between use of oral contraceptives and the following serious adverse reactions: thrombophlebitis, pulmonary embolism, cerebral thrombosis.

Although available evidence is suggestive of an association, such a relationship has been neither confirmed nor refuted for the following serious adverse reactions: neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions are known to occur in patients receiving oral contraceptives: nausea, vomiting, gastrointestinal symptoms (such as abdominal cramps and bloating), breakthrough bleeding, spotting, change in menstrual flow, amenorrhea during and after treatment, edema, chloasma or melasma, breast changes: tenderness, enlargement and secretion, change in weight (increase or decrease), changes in cervical erosion and cervical secretions, suppression of lactation when given immediately post-partum, cholestatic jaundice, migraine, rash (allergic), rise in blood pressure in susceptible individuals, mental depression.

Although the following adverse reactions have been reported in users of oral contraceptives, an association has been neither confirmed nor refuted: anovulation post treatment, premenstrual-like syndrome, changes in libido, changes in appetite, cystitis-like syndrome, hirsutism, loss of scalp hair, erythema multiforme, headache, nervousness, dizziness, fatigue, backache, erythema nodosum, hemorrhagic eruption, itching.



The following laboratory results may be altered by the use of oral contraceptives: hepatic function: increased sulfobromophthalein retention and other tests, coagulation tests: increase in prothrombin factors VII, VIII, IX, and X, thyroid function: increase in PBI, and butanol extractable protein bound iodine and decrease in T^3 uptake values, metyrapone test, pregnanediol determination.

The Comfortable Life

relief of symptoms of postmenopausal estrogen deficiency

PREMARIN with Methyltestosterone may often help older estrogen-deficient women to be more comfortable in their daily activities.

The effect of combined estrogen/androgen in PREMARIN with Methyltestosterone often improves tone of aging muscles, helps arrest osteoporotic changes, and relieves associated bone pain.

PREMARIN with Methyltestosterone helps impart a sense of well-being. Patients often feel better, enjoy better appetite and sleep patterns. Unwanted side effects are minimized because of the opposing action of the two hormones on sex-linked tissues.

BRIEF SUMMARY *(For full prescribing information, see package circular.)*
PREMARIN® (Conjugated Estrogens, U.S.P.)
with Methyltestosterone
Each red tablet contains:
Premarin® (Conjugated Estrogens, U.S.P.) ..... 0.625 mg.
Methyltestosterone ..... 5.0 mg.
Each yellow tablet contains:
Premarin® (Conjugated Estrogens, U.S.P.) ..... 1.25 mg.
Methyltestosterone ..... 10.0 mg.
Preparation of Conjugated Estrogens, U.S.P. combined with methyltestosterone. The opposing action of the two hormones helps keep side effects to a minimum.
Indications: Menopause *(Female)*; Bone Disorders (Osteoporosis, Paget's Disease, Nonunion and Delayed Union of Fractures in the Elderly, and as an Adjunct to Prolonged Corticosteroid Therapy)—*(Male or Female)*.
Contraindication: *In the male,* carcinoma of the prostate, because of the methyltestosterone component.
Precautions: *In the female,* to avoid continuous stimulation of breast and uterus, cyclic therapy is recommended (3 week regimen with 1 week rest period—Withdrawal bleeding may occur during this 1 week rest period). *In the male:* A careful check should be made on the status of the prostate gland when therapy is given for protracted intervals.
Adverse Reactions: In addition to withdrawal bleeding, breast tenderness or hirsutism may occur.
Dosage and Administration: Menopause *(Female)*: 1 or 2 *yellow* tablets daily. (See *Precautions.*) Bone Disorders (Osteoporosis, Paget's Disease, Nonunion and Delayed Union of Fractures in the Elderly, and as an Adjunct to Prolonged Corticosteroid Therapy)—*(Male or Female)*: 1 *yellow* tablet daily. (See *Precautions.*)
How Supplied: No. 878 (*red* tablet) and No. 879 (*yellow* tablet)—In bottles of 100 and 1,000 tablets.

To help keep activity in their lives

PREMARIN® CONTAINS NATURAL ESTROGENS EXCLUSIVELY
(CONJUGATED ESTROGENS, U.S.P.)
with Methyltestosterone

Ayerst®
AYERST LABORATORIES
New York, N.Y. 10017

7437

No. 3
As potent as the pain it relieves.

e.g. postpartum pain

NOT TOO LITTLE
- as potent as the pain you need to relieve in patients with fractures, sprains, strains, wounds, contusions, and the pain of surgical convalescence
- unlike acetaminophen/codeine combinations, it does not sacrifice anti-inflammatory action

NOT TOO MUCH
- potent—yet not excessive
- addiction liability low

NOT TOO EXPENSIVE
- brand-name quality, yet reasonable in cost
- readily available in both hospital and local pharmacies

CONVENIENCE
- telephone Rx in most states, up to 5 refills in 6 months at your discretion (where state law permits)

E[illegible]PIRIN® COMPOUND
W[illegible]TH CODEINE NO. 3

codeine phosphate* (32.4 mg) gr ½
Each tablet also contains: aspirin gr 3½, phenacetin gr 2½, caffeine gr ½. *Warning—may be habit-forming.

If you demand Zeiss quality in the hospital, don't settle for less in your office.

The Zeiss Wall Mount

1. has a unique balancing system for unprecedented stability at any point within its range,

2. extends as far as 4½ feet,

3. folds back against the wall,

4. has a built-in two-intensity transformer,

5. accepts both the Zeiss Colposcope 1 and Colposcope 9.

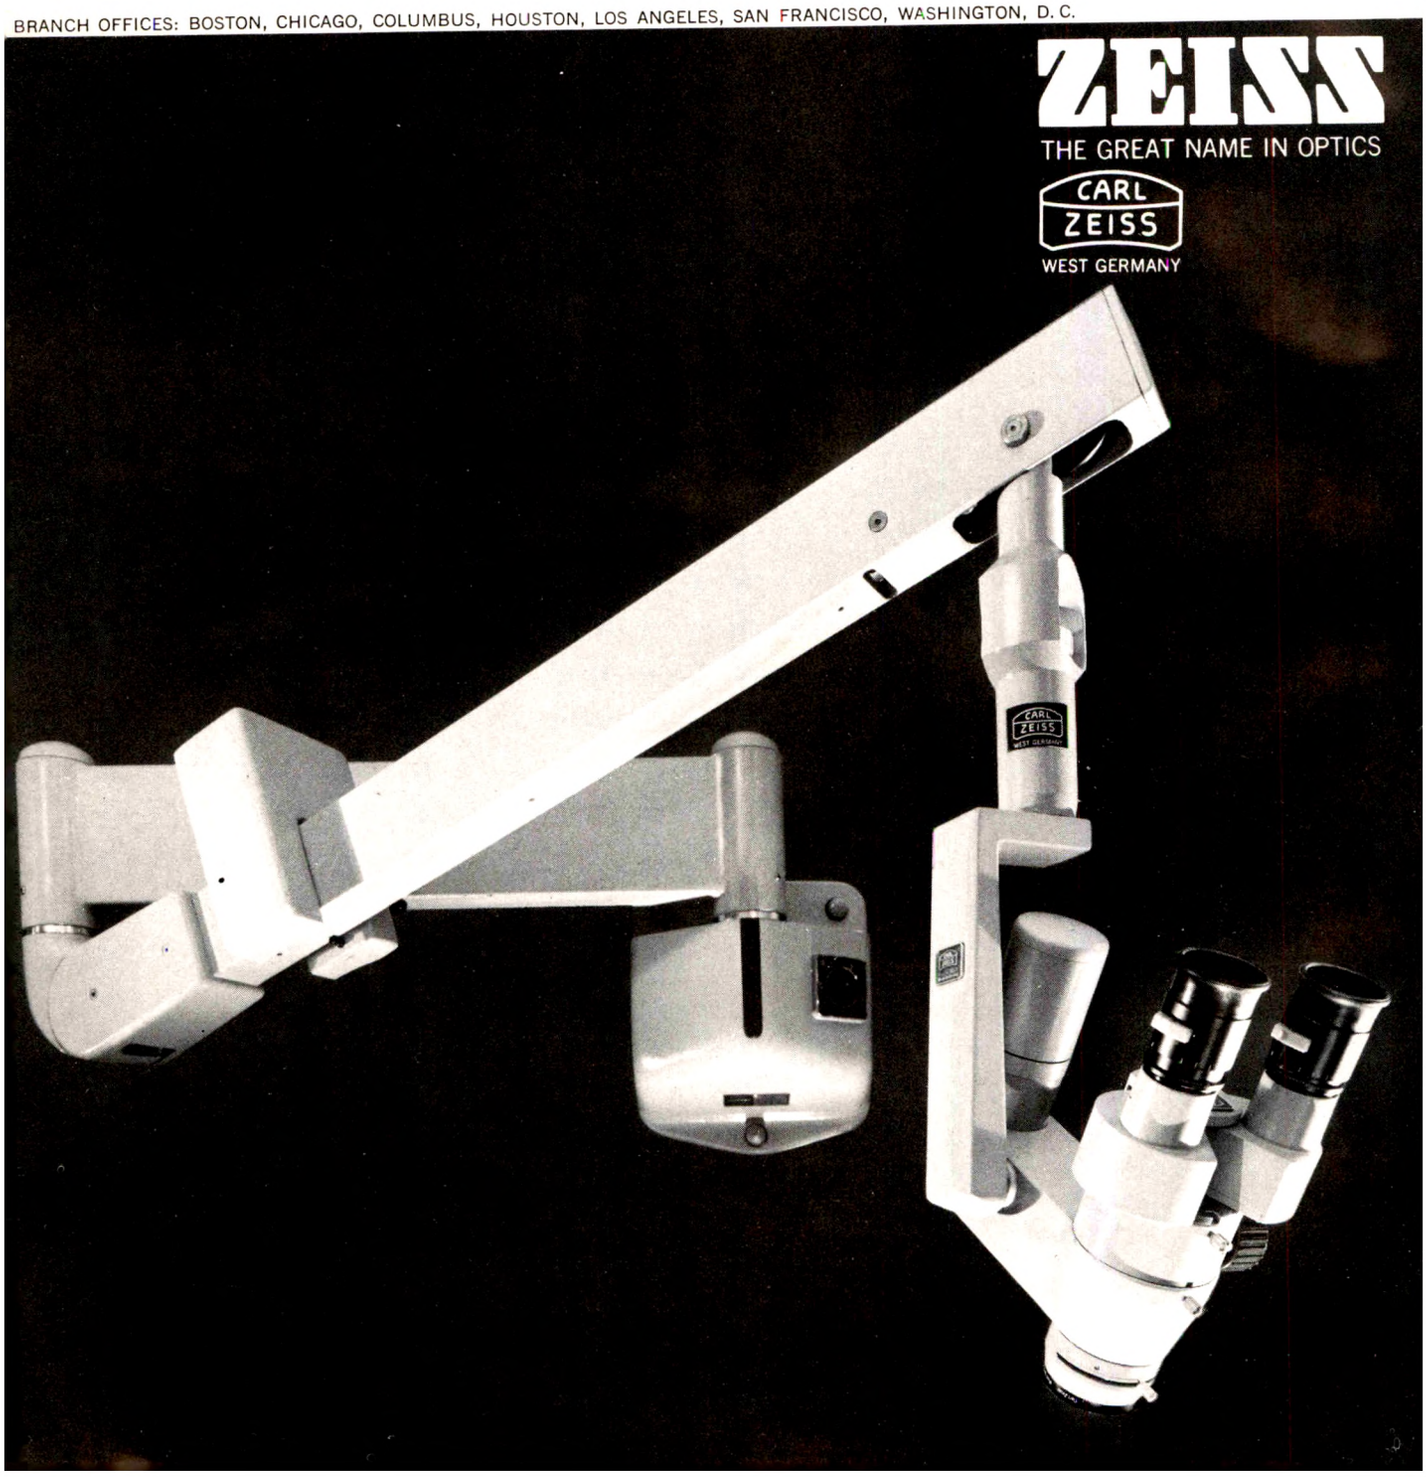
It puts Zeiss optics and mechanical excellence always within your reach, but never in your way.

The Zeiss Colposcope 9 with

1. a wide choice of working distances and magnifications,

2. a 3-step magnification changer, 2-lens objective changer, and other great optional Zeiss accessories,

3. through-the-lens illumination



4. straight binocular tubes,

5. combines with the Wall Mount to make the ideal office colposcope system.

The causes of vaginitis are multiple

You can depend on AVC... therapy that combats major vaginal pathogens and provides rapid symptomatic relief.*

*__Indications:__ Based on a review of AVC by the National Academy of Sciences–National Research Council and/or other information, FDA has classified the indications as follows:

"Probably" effective: For the relief of symptoms of vulvovaginitis where isolation of the specific organism responsible (usually *Trichomonas vaginalis*, *Candida albicans*, or *Hemophilus vaginalis*) is not possible.

NOTE: When the offending organism is known, treatment with a specific agent known to be active against that microorganism is preferred.

"Possibly" effective: For the treatment of trichomoniasis, vulvovaginal candidiasis, and vaginitis due to *Hemophilus vaginalis* or other susceptible bacteria.

Final classification of the less-than-effective indications requires further investigation.

__Contraindications:__ Known sensitivity to sulfonamides.

__Precautions/Adverse Reactions:__ The usual precautions for topical and systemic sulfonamides should be observed because of the possibility of absorption. Burning, increased local discomfort, skin rash or other manifestations of sulfonamide toxicity are reasons to discontinue treatment.

__Dosage:__ 1 applicatorful (about 6 g.) or 1 suppository intravaginally once or twice daily.

__Supplied:__ Cream–4 ounce tube with applicator. Suppositories–Box of 16 with inserter.

ANTISEPTIC SECURITY

in Ob/Gyn practice

Prompt, broad-spectrum action of BETADINE Microbicides provides topical antiseptic security for patients, physicians and nurses

BETADINE Solution Microbicidal Applicator, the only 8½″ long, disposable antiseptic-impregnated swabstick, is indicated for degerming hard-to-reach sites, such as the cervix, vulvovaginal, perineal and anorectal areas

BETADINE Solution, for prepping skin, vagina and perineum, and for general antiseptic use on skin, mucosa and wounds

BETADINE Surgical Scrub, for preoperative scrubbing and for hand and skin degerming (In the rare instance of local irritation or sensitivity, discontinue use in the individual)

BETADINE Douche, for treating vaginal moniliasis, *T. vaginalis* vaginitis and nonspecific infectious vaginitis (*H. vaginalis* vaginitis)... also ideal for routine cleansing, due to its degerming and deodorizing properties

Editorial communications

Submission of contributions. Manuscripts should in general be sent to a particular Editor according to the following plan: If it is from the southeastern quadrant of the United States or from Canada, or if it has been presented before one of the official sponsoring societies, to Dr. Brewer; if from the northeastern quadrant (including Ohio), or if it is a Clinical Opinion or a Letter to the Editors, to Dr. Zuspan; if from the north central states, any of the United States west of the Mississippi, Hawaii, Alaska, or abroad, to Dr. Quilligan.

All articles published in this Journal must be contributed to it exclusively. Articles previously published in another language are not acceptable.

It is assumed by the Editors that articles emanating from a particular institution are submitted with the approval of the requisite authority, including all matters pertaining to human studies.

Statements and opinions expressed in the articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or publisher and the Editor(s) and publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the publisher guarantee, warrant, or endorse any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

Manuscripts. Manuscripts should be typewritten on one side of the paper only, with double spacing and liberal margins. The original and one copy of the manuscript are required. References should be placed at the end of the article and should conform to the style of the Cumulated Index Medicus, viz., name of author, article title, name of periodical, volume, page, and year. Authors are encouraged to limit references to *16, except* for Communications in Brief, limited to *2,* Current Investigation and Clinical Opinion, limited to *6,* and Current Developments for which there is *no* limit. Illustrations accompanying manuscripts should be numbered, provided with suitable legends, and marked lightly on the back with the author's name. Authors should indicate on the manuscript the approximate position of tables and text figures.

Tables should be typed on separate sheets of paper, not in the text, with one table to a page. They should be numbered in sequence and each must be referred to at an appropriate point in the text. Captions of the tables should be brief, yet indicate clearly the purpose or content of each table. Rows and columns in the table should precisely define the nature of the data in each. Abbreviations in tables should be used as little as possible and if abbreviations are used they should be explained in a footnote to the table.

An abstract of 50 to 150 words, to be published as an introduction, should accompany each manuscript.

A footnote should be included which gives the name and complete mailing address of the person to whom reprint requests and correspondence should be sent.

A Guide to Writing for the American Journal of Obstetrics and Gynecology, giving further details of how a manuscript should be prepared, may be obtained from the Publisher on request.

Illustrations. A reasonable number of halftone illustrations will be reproduced free of cost to the author, but special arrangements must be made with the Editors for color plates, elaborate tables, or extra illustrations. Original drawings or graphs should be drawn with black India ink. Typewritten or freehand lettering is not acceptable. All lettering must be done professionally. Do not send original art work, x-ray films, or ECG tracings. Glossy print photographs are preferred, for good black and white contrast is essential.

Announcements. Announcements of meetings must be received by Dr. Brewer at least 2½ months prior to the time of the meeting. Such announcements should concern major meetings and other significant activities. Announcements of symposia or seminars for which fees are charged are not published in the scientific pages of the Journal but may be submitted for paid advertisements, if desired.

Letters to the Editors: A brief Letter to the Editors commenting upon some article which has appeared in the Journal will be considered for publication. The writer of the original article will have an opportunity to reply to unfavorable comments.

A brief case presentation of special interest in the form of a Letter to the Editors will be considered for publication. All such letters should be sent to Dr. Frederick P. Zuspan.

Books. Books received will be listed in the Journal. They should be sent to Dr. Albert B. Gerbie.

Reprints. Reprints of articles must be ordered from the Publishers, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63141, who will send their schedule of prices. Individual reprints of an article must be obtained through the author.

Nearly everybody believed that a very low dose oral contraceptive automatically meant a high incidence of breakthrough bleeding.

11,085 cycles later...

LO/OVRAL®

averaged only 3.9% breakthrough bleeding in total cycles.

Combination oral contraceptive—low estrogen and low progestogen.

Unsurpassed contraceptive effectiveness.

Extremely low incidence of minor side effects.*

Ready acceptance.

Convenient dosage in easy-to-use Pilpak® dispenser.

Low dose oral contraceptive—no other combination is more effective

Despite the fact that LO/OVRAL contains only 0.3 mg. norgestrel and 0.03 mg. ethinyl estradiol, contraceptive effectiveness is comparable to that of higher-dosage combinations. In clinical trials with LO/OVRAL encompassing 1,287 patients for a total of 11,085 cycles, only one pregnancy was reported. By Pearl's formula, this is a pregnancy rate of 0.12 per 100 woman-years' usage.

Minor side effects—even breakthrough bleeding—have been remarkably infrequent

In clinical trials the incidence of breakthrough bleeding in the initial cycle was only nine percent. And even that low incidence decreased to an average of only 3.9 percent as cycles progressed.

Incidence of Breakthrough Bleeding in Premarketing Clinical Trials

Cycle	1	3	6	12	Total Cycles
					11,085
Breakthrough Bleeding	9.0%	3.5%	2.7%	2.6%	3.9%

Acceptance has been excellent

The low incidence of minor side effects has resulted in ready acceptance of LO/OVRAL by the great majority of patients. Patient complaints have been infrequent. Only eight percent of women participating in clinical trials discontinued LO/OVRAL because of common side effects.

Steroidal balance and norgestrel make the difference

Although total steroids in LO/OVRAL are reduced by 40 percent, the time-proved progestogen-estrogen ratio of OVRAL** is retained. This, together with norgestrel's distinctive qualities, is largely responsible for the patient comfort and acceptance experienced to date. Unlike other progestogens in current use, norgestrel is non-estrogenic, is apparently not converted to estrogen *in vivo* and closely resembles natural progesterone in its progestogenic activity.

Simple to take

The dosage regimen with LO/OVRAL is convenient and easy to follow: 3 weeks on, 1 week off. The attractive, uncomplicated Pilpak® dispenser helps patients follow the right dosage schedule.

*Serious as well as minor adverse reactions have been reported following the use of all oral contraceptives. The physician should remain alert to their earliest manifestations and in the event of serious adverse reactions should avoid any oral contraceptives. *Special note, contraindications, warnings, precautions and adverse reactions* in the accompanying IN BRIEF should be carefully considered.

**OVRAL® each tablet contains 0.5 mg. norgestrel with 0.05 mg. ethinyl estradiol, Wyeth.

Important information on next page.

LO/OVRAL®

each tablet contains 0.3 mg. norgestrel with 0.03 mg. ethinyl estradiol, Wyeth

Low dose oral contraceptive.

IN BRIEF:

SPECIAL NOTE: Oral contraceptives have been marketed in the United States since 1960. Reported pregnancy rates vary from product to product. The effectiveness of the sequential products appears to be somewhat lower than that of the combination products. Both types provide almost completely effective contraception.

An increased risk of thrombotic, thromboembolic and cerebral-vascular disease associated with the use of hormonal contraceptives has been shown in studies conducted in both Great Britain and the United States. Other risks, such as those of elevated blood pressure and reduced tolerance to carbohydrates, have been reported, and appropriate tests should be conducted to monitor these during oral-contraceptive therapy. Liver disease has also been reported, and the physician should be alert to its earliest manifestations.

Long-term administration of both natural and synthetic estrogens in subprimate animal species in multiples of the human dose increases the frequency for some animal carcinomas. These data cannot be transposed directly to man. The possible carcinogenicity due to the estrogens can neither be affirmed nor refuted at this time. Close clinical surveillance of all women taking oral contraceptives must be continued.

INDICATIONS: For oral contraception.

CONTRAINDICATIONS: 1. Thrombophlebitis, thromboembolic disorders, cerebral-vascular disease, or a past history of these conditions; 2. Markedly impaired liver function; 3. Known or suspected carcinoma of the breast; 4. Known or suspected estrogen-dependent neoplasia; 5. Undiagnosed abnormal genital bleeding; 6. Known or suspected pregnancy.

WARNINGS: 1. The physician should be alert to the earliest manifestations of thrombotic and thromboembolic disorders, thrombophlebitis, cerebrovascular disorders including hemorrhage, pulmonary embolism and retinal thrombosis. Should any of these occur or be suspected, the drug should be discontinued immediately.

Retrospective studies of morbidity and mortality in Great Britain and studies of morbidity in the United States have shown a statistically significant association between thrombophlebitis, pulmonary embolism and cerebral-vascular disease, occlusive or hemorrhagic, and the use of oral contraceptives. There have been three principal studies in Great Britain[1-3] leading to these conclusions and three[4-7] in this country. The estimate of the relative risk of thromboembolism in the study by Vessey and Doll[3] was about sevenfold, while the United States studies found relative risks of 4.4 to 11, meaning that the users are several times as likely to undergo thromboembolic disease without evident cause as non-users.

In May, 1974, the Royal College of General Practitioners in England[8] issued an interim report of its continuing large-scale prospective study comparing a user group to a non-user group. This study in its interim analysis states: "A statistically significant higher rate of reporting of cerebrovascular accidents in Takers is evident, but the numbers are too small to justify an estimation of the degree of risk." The study also reported a higher incidence of superficial and deep vein thrombosis in users as compared to non-users.

The Sartwell study[4] indicated that the risk did not persist after discontinuation of administration. Both the Sartwell and the Royal College study indicated that the degree of risk was not associated with duration of treatment.

In a collaborative American study[5,6] of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the relative risk of thrombotic stroke was 4.1 to 9.5 times greater in users than in non-users. A comparable estimate for hemorrhagic stroke was 2.0.

None of the American studies was designed to evaluate a difference between products. However, the Sartwell study[4] suggested that there might be an increased risk of thromboembolic disease in users of sequential products.

Other retrospective studies[9,10] have reported an increased risk of post-surgery thromboembolic complications in oral-contraceptive users. It has been recommended that therapy be discontinued at least one month prior to elective surgery.

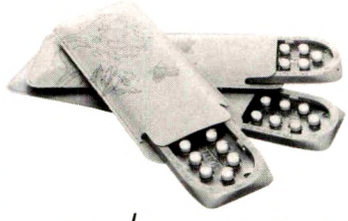
2. Discontinue oral-contraceptive medication if there is: gradual or sudden, partial or complete loss of vision; proptosis or diplopia; onset or aggravation of migraine or development of headache of a new pattern which is recurrent, persistent or severe; papilledema; or any evidence of retinal-vascular lesions. 3. Fetal abnormalities have been reported to occur in the offspring of women who have taken progestogens and/or estrogens during pregnancy.[11,12] The safety of LO/OVRAL® in pregnancy has not been demonstrated. Pregnancy should be ruled out before initiating or continuing the contraceptive regimen. Pregnancy should always be considered if withdrawal bleeding does not occur. 4. A small fraction of the hormonal agent in oral contraceptives has been identified in the milk of mothers receiving these drugs. The long-range effect to the nursing infant cannot be determined at this time. 5. Hepatic lesions (adenomas, hepatomas, hamartomas, regenerating nodules, etc.), occasionally fatal, have been reported in women on oral contraceptives. Such lesions may present as an abdominal mass or with the signs and symptoms of an acute abdomen. These lesions should be considered if the patient has abdominal pain or evidence of intra-abdominal bleeding. Such lesions have been reported in short-term as well as long-term users of oral contraceptives.

PRECAUTIONS: 1. A thorough history and physical examination should be performed before prescribing oral contraceptives and periodically during their administration and should include special reference to breasts and pelvic organs including Papanicolaou smears, since estrogens have been known to produce tumors, some of them malignant, in five species of subprimate animals. 2. Endocrine and possibly liver-function tests may be affected by treatment with LO/OVRAL® Therefore, if such tests are abnormal in a patient taking LO/OVRAL® it is recommended that they be repeated after the drug has been withdrawn for two months. 3. Under the influence of estrogen-progestogen preparations, pre-existing uterine fibromyomata may increase in size. 4. Because these agents may cause some degree of fluid retention, conditions which might be influenced by this factor, such as epilepsy, migraine, asthma, cardiac or renal dysfunction, require careful observation. 5. In breakthrough bleeding, and in all cases of irregular bleeding per vaginam, nonfunctional causes should be borne in mind. In undiagnosed bleeding per vaginam, adequate diagnostic measures are indicated. 6. Patients with a history of psychic depression should be carefully observed and the drug discontinued if the depression recurs to a serious degree. 7. Any possible influence of prolonged LO/OVRAL® therapy on pituitary, ovarian, adrenal, hepatic or uterine function awaits further study. 8. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. The mechanism of this decrease is obscure. For this reason, diabetic patients should be carefully observed while receiving LO/OVRAL® therapy. 9. The age of the patient constitutes no absolute limiting factor, although treatment with LO/OVRAL® may mask the onset of the climacteric. 10. The pathologist should be advised of LO/OVRAL® therapy when relevant specimens are submitted. 11. Susceptible women may experience an increase in blood pressure following administration of contraceptive steroids. 12. Cholestatic jaundice has been reported in users of oral contraceptives. If this occurs, LO/OVRAL® should be discontinued. This condition is more likely to occur in patients who have experienced cholestatic jaundice of pregnancy. Patients with a history of cholestatic jaundice of pregnancy should be carefully observed during LO/OVRAL® therapy.

ADVERSE REACTIONS OBSERVED IN PATIENTS RECEIVING ORAL CONTRACEPTIVES: A statistically significant association has been demonstrated between use of oral contraceptives and the following serious adverse reactions: thrombophlebitis, pulmonary embolism, cerebral thrombosis and hemorrhage, gall bladder disease.

Although available evidence is suggestive of an association, such a relationship has been neither confirmed nor refuted for the following serious adverse reactions: neuro-ocular lesions, e.g., retinal thrombosis, optic neuritis and hepatic lesions with or without intra-abdominal bleeding.

The following adverse reactions are known to occur in patients receiving oral contraceptives: nausea, vomiting, gastrointestinal symptoms (such as abdominal cramps and bloating), breakthrough bleeding, spotting, change in menstrual flow, amenorrhea during and after treatment, edema, chloasma or melasma, which may persist, breast changes: tenderness, enlargement and secretion, change in weight (increase or decrease), changes in cervical erosion and cervical secretions, suppression of lactation when given immediately post-partum, cholestatic jaundice, migraine, rash (allergic), rise in blood pressure in susceptible individuals, mental depression.



Although the following adverse reactions have been reported in users of oral contraceptives, an association has been neither confirmed nor refuted: anovulation post treatment, which tends to occur more frequently in women with a history of menstrual disorders, premenstrual-like syndrome, changes in libido, changes in appetite, cystitis-like syndrome, headache, intolerance to contact lenses, nervousness, dizziness, fatigue, backache, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, itching and vaginitis.

The following laboratory results may be altered by the use of oral contraceptives: hepatic function; increased sulfobromophthalein retention and other tests; coagulation tests; increase in prothrombin, Factors VII, VIII, IX and X; decrease in antithrombin III; increase in platelet aggregability; thyroid function: increase in PBI, and butanol extractable protein-bound iodine and decrease in T^3 uptake values; metyrapone test; and pregnanediol determination.

NOTE: For more specific details on LO/OVRAL, refer to package insert.

With the "double PG impact" (DPGI) technique in 100 sedated first- and second-trimester volunteers, pregnancy was terminated successfully in 99 with a total extraovular $PGF_{2\alpha}$ dose of 19.0 ± 1.5 mg. in 16.9 ± 0.9 hours. Two thirds of the patients received only the initial dose of 11.6 ± 0.5 mg. of PG and aborted in 12.9 ± 0.7 hours without requiring supplemental treatment. Only mild and transient side effects and 14 indicated curettages were recorded. Excepting one gravida (who failed to abort), plasma progesterone in 99 patients decreased at 3 hours after DPGI from 32.5 ± 1.7 to 22.7 ± 1.2 ng. per milliliter ($P < 0.001$). The rate of progesterone withdrawal and IAT showed a close relationship and the first-trimester patients aborted at a lower progesterone level than the second-trimester patients ($P < 0.001$).

This study was supported by the Agency for International Development Contract AID/csd 3160.

Received for publication March, 28, 1975.

Revised June 24, 1975.

Accepted June 26, 1975.

AS LONG AS pregnancy termination is a legal procedure, leading medical centers are medically obliged to develop advanced methods of management in the best interest of the patients. During several decades the accepted procedures were (1) dilatation and sharp curettage (D & C) for interrupting first-trimester and

Reprint requests: Dr. A. I. Csapo, Department of Obstetrics and Gynecology, Washington University School of Medicine, 4911 Barnes Hospital Plaza, St. Louis, Missouri 63110.

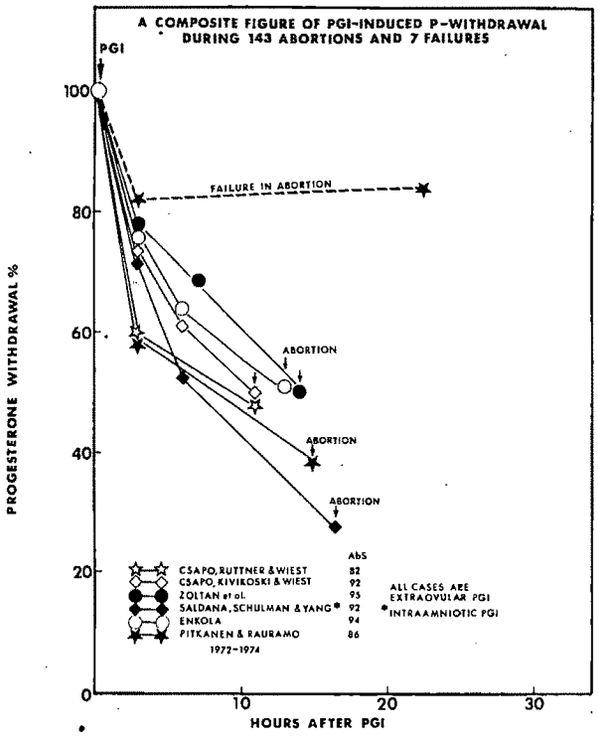

Fig. 1. A summary of the effect of PGI on plasma P levels. For description of this and subsequent figures, see Text.

(2) hysterotomy for terminating second-trimester pregnancies. In most institutions sharp curettage has currently been replaced by suction and hysterotomy by the hypertonic saline method. In the hands of trained specialists, these procedures improved postconceptional therapy.

Statistical evidence showed, however, that in contrast to spontaneous abortions, rapid surgical dilatation affects the structural integrity of the cervix and that "incompetent os" predisposes to premature labor.[1] It also revealed that occasional technical failures in the intra-amniotic administration of hypertonic saline increase the risks of the "salting-out" technique.[2] Therefore, the early reports that prostaglandins (PGs) terminate pregnancy, without harmful consequences, generated considerable interest.[3]

Subsequent trials, however, in which PGs were administered by intravenous or extraovular infusions or by repeated injections, with the intent of stimulating the normal pregnant uterus, have failed to yield clinically acceptable results. The *refractory* uterus did not promptly respond to PGs with cyclic intrauterine pressure (IUP) of that magnitude which was measured several hours after effective PG treatment. The initial response was an unphysiologic and sustained contracture, which changed to cyclic IUP only gradually with the progress of *time*. To increase efficacy of prolonged administration the dose of PGs had to be increased, which resulted in unacceptable side effects. Thus the therapeutic principle "PG-impact" (PGI) had been considered as an alternative approach,[1] with the intent of provoking a *regulatory imbalance,* before attempting myometrial stimulation for the promotion of clinical progress.

The PGI was effective in terminating pregnancy[4] regardless of whether the administration of the drug was intra-amniotic or extraovular. The intra-amniotic method, however, had the disadvantage of transabdominal puncture (in local anesthesia), occasional bloody taps, prolonged instillation-abortion time (IAT, resulting from the initial dilution of the drug by the amniotic fluid), and repeated side effects due to the protracted adsorption of PG. Extraovular PGI had the advantages of transcervical administration, reduced dosage, and short-term side effects (due to rapid elimination of the drug) which could be reduced by sedation. Occasional failures in the effective delivery of PGI limited the broad therapeutic application of this method, however.

To improve the efficacy of PGI, the clinical benefits of the modified technique "double prostaglandin impact" (DPGI) had been considered. The rationale of this modification was based on earlier results (for references and summary, see Fig. 1 and Southern, Csapo, Saldana and their co-workers[4–9], which showed that the single PGI is effective if it provokes a regulatory imbalance, resulting from progesterone withdrawal (Pw), which *converts* the refractory uterus to a reactive organ.[5] Once this conversion had been provoked by Pw, threshold decreased and the uterus readily responded to both endogenous and exogenous stimulation, promoting clinical progress in abortion.[1, 4–9] Therefore, the possibility has been considered that by amplifying the initial effect of PGI, through direct and rapid contact between the drug and the uterus at two points (rather than only one), DPGI (at the same dose level) might increase the efficacy of PGI. In the present study the validity of this premise has been examined.

Study patients and methods

Selection of study patients. After thorough physical and laboratory workup, staff physicians presented their cases to the committee as part of the clinical routine of the department. If the committee approved legal abortion, the alternative techniques were explained to the patients. The obstetrically normal gravidas who formed the study group were those who consented (in writing) both to the use of the "prostaglandin-impact" (PGI) method and to a su-

perimposed academic study of the clinical course of the abortion. The research staff was then requested to recommend a delivery system and a dose which promised the most favorable clinical outcome and to conduct observations of academic interest which promised future therapeutic benefits.

Design of the study. The following considerations were made. While PGE2 was found to be a more effective abortifacient than PGF2α on a per-weight basis, this higher efficacy was not reflected in a reduction of side effects. Synthetic PG analogues were claimed to be more efficacious and acceptable than the natural compounds, but this claim had not been verified.[6] It seemed preferable, therefore, to use the marketed compound PGF2α* and focus interest on improving its delivery to the target organs.

Earlier examinations[1, 4–9] of the efficacy of PGI revealed (Fig. 1) that this technique is effective in terminating pregnancy, regardless of the gestational age of the patients (up to the legal cutoff point of 20 weeks' gestation), provided it provoked rapid and continued Pw. Thus the technique of "double PGI" (DPGI) was conceived and adopted (Protocol No. 5026) with the *intent of provoking effective Pw* more predictably. This method involves the placement, into the left and right sides of the extraovular space, two PG doses which together do not exceed the single dose, previously delivered at one side only. By an extended action with the uterus, at two direct contact points (rather than one), DPGI was expected to provoke Pw more predictably than did PGI.

Procedure. After thorough vaginal preparation and sedation (50 mg. of pethidine, 10 mg. of diazepam, and 0.4 mg. of atropine), a semi-stiff catheter with a flexible tip was introduced transcervically into the left side of the lower pole of the extraovular space under sterile precautions. When in position, the tip of the catheter was moved upward to at least 5 cm. or higher from the internal os. Through this catheter first-trimester patients received an initial dose of 5 mg. of PGF2α and through a second catheter (inserted into the right side of the extraovular space) another 5 mg. After the instillation of each 5 mg. of PGF2α the catheter was withdrawn. Through a similar procedure, second-trimester patients received double doses, 2 × 10 = 20 mg. of PGF2α. Treatment through each catheter lasted for about 5 minutes.

Before, during, and after DPGI, the vital signs of the patients and side effects were recorded. If during PG administration the side effects exceeded the acceptable range, treatment was discontinued.

Patients who aborted, or had advanced cervical dilatation in 8 hours, received no further treatment. If, however, clinical progress was slow, a second dose of PGF2α was administered extraovularly at 8 hours after DPGI. First-trimester pregnant patients received 5 mg. and second-trimester patients received 10 mg. of PGF2α. Occasionally, when this supplemental treatment did not promote distinct clinical progress, an additional dose was given extraovularly or 50 m.U. of oxytocin per minute were administered intravenously. If the fetal membranes (of second-trimester patients) were ruptured accidentally during catheter placement, the initial dose of 20 mg. of PGF2α was delivered nevertheless. The intra-amniotic (rather than extraovular) delivery of the compound was noted, however, to allow retrospective comparison between the efficacy of extraovular and intra-amniotic (transcervical) administration.

Since, in all earlier trials, the effect of PGI on the resting and cyclic intrauterine pressure (RP and IUP) had been monitored throughout the instillation-abortion time (IAT) and the relationship between PGI, RP, IUP, and clinical progress had been established,[1, 4–9] in this study IUP was not recorded. However, blood samples were collected before, at 3 and 10 hours after DPGI, at the time when the fetus was aborted, and 12 hours after the completion of abortion. While it had been demonstrated[4–9] that the therapeutic success of PGI depends on the rate and degree of Pw it provokes (Fig. 1), nevertheless the present quantitation of Pw seemed desirable, since the efficacy and mode of action of a modified procedure (DPGI) had been the subject of study.

After the abortion of the fetus, up to 10 hours was allowed for the spontaneous delivery of the placenta, unless strong bleeding demanded instant evacuation of the uterus by curettage. If the placenta was detached from the uterine wall, it was removed from the cervix or vagina by abortion forceps. Since, in first-trimester gravidas, it is difficult to determine the completeness of abortion, and since the postabortion course was of interest, the patients were divided (post partum) into two groups. One group was subjected to diagnostic curettage (to determine whether or not placental residue was present) and the other group was not. Careful notes were made throughout the study about the patients' temperature, WBC, cervical effacement and dilatation, and the onset and character of the subsequent spontaneous menstrual period.

To assess clinical success, the degree of abortion of each patient was graded by an abortion score (AbS):

*The authors are grateful to Drs. E. M. Southern and G. D. Gutknecht of the Upjohn Company for the generous supply of PGF2α.

Table I. The effect of DPGI in 99 patients*

No. of cases	Age (yr.)	Para No.	Gest. age (wk.)	PGF2α (mg.) Initial	PGF2α (mg.) Total	IAT (hr.)	Abortion score
First-trimester pregnant:							
67	25.2 ±0.8	1.0 ±0.1	9.4 ±0.2	10.0 ±0.0	12.7 ±0.5	17.0 ±1.2	98.2 ±1.0
Second-trimester pregnant:							
32	21.0 ±1.1	0.6 ±0.2	16.3 ±0.4	18.7 ±0.6	33.5 ±3.5	16.7 ±1.3	90.3 ±3.0
Total:							
99	24.4 ±0.7	0.9 ±1.1	11.6 ±0.4	12.7 ±0.5	19.0 ±1.5	16.9 ±0.9	95.6 ±1.3
Extraovular DPGI only†:							
91	24.7 ±0.7	1.0 ±0.1	11.0 ±0.4	12.2 ±0.4	16.4 ±1.1	16.1 ±1.0	96.5 ±1.2

*All values are means ± S.E. in this and all subsequent tables.

†The eight cases of intra-amniotic PGI (due to accidental rupture of fetal membranes) are excluded.

Table II. The effect of DPGI in 67 first trimester pregnant patients

No. of cases	Age (yr.)	Para No.	Gest. age (wk.)	PGF2α (mg.) Initial	PGF2α (mg.) Total	IAT (hr.)	Abortion score
Initial DPGI only:							
44	26.9 ±1.0	1.3 ±0.2	9.0 ±0.2	9.9 ±0.1	9.9 ±0.1	12.8 ±0.7	100.0 ±0.0
Initial and supplementary DPGI:							
23	23.2 ±1.0	0.5 ±0.2	10.0 ±0.3	10.0 ±0.0	18.0 ±0.8	25.1 ±2.6	94.8 ±2.9

100 = complete abortion, 80 = retained placental residue, 60 = complete placental retention, 40 = 2 cm. cervical dilatation. Complications during and after DPGI were recorded and treated. Specific attention was directed toward the pain response of the sedated patients to DPGI and to symptoms of infection before, during, and after abortion, of course, patients with cervicitis had first been treated, or excluded from the study.

In the sequentially collected plasma samples, progesterone (P) and estradiol-17β (E_2) had been determined by radioimmunoassays.[8] All information was placed on computer sheets and subjected to statistical analysis. In examining and tabulating the results, interest was directed specifically toward those parameters which affected the instillation-abortion time (IAT) since, in comparison with the surgical procedures, the major drawback of the pharmacologic methods seemed to be the prolongation of the IAT, demanding lengthy medical supervision and hospitalization.

Results

Table I describes the clinical outcome of 99 pregnancy terminations in patients 6 to 20 weeks pregnant, with the extraovular "double prostaglandin impact" (DPGI) technique. The single case of treatment failure will be described separately. All 67 first-trimester gravidas, who (at the mean ± S.E. gestational age of 9.4 ± 0.2 weeks) received an initial dose of 10.0 ± 0.0 (and a total dose of 12.7 ± 0.5) mg. of PGF2α, aborted in 17.0 ± 1.2 hours with an exceptionally high abortion score (AbS) of 98.2 ± 1.0. All 32 second-trimester gravidas, who (at 16.3 ± 0.4 weeks of gestation) received an initial dose of 18.7 ± 0.6 (and a total dose of 33.5 ± 3.5) mg. of PGF2α, aborted in 16.7 ± 1.3 hours with a high AbS of 90.3 ± 3.0. Thus the 99 study patients, who (at 11.6 ± 0.4 weeks of gestation) received an initial dose of 12.7 ± 0.5 (and a total dose of 19.0 ± 1.5) mg. of PGF2α, aborted in 16.9 ± 0.9 hours with an exceptionally high AbS of 95.6 ± 1.3. Out of 100 gravidas, only one (15 weeks pregnant) multipara failed to abort (in 48 hours), but even this patient progressed to a 2 cm. dilatation after having received a total dose of 50 mg. of PGF2α.

Apparently,[4–9] DPGI yielded better clinical results than PGI (Fig. 1). During catheter placement, the fetal membranes of eight (out of the 32 second-trimester) patients were ruptured accidentally. These accidents represent technical (rather than treatment) failures since, after the membranes were ruptured, PGI was delivered intra-amniotically (rather than extraovularly). In these eight patients abortion was induced without failure. Since the total PG requirement and IAT of these eight gravidas were excessive, however, their removal from the study group improved the outcome of the 91 extraovular cases regarding the (1) total PGF2α dose (16.4 ± 1.1 mg.), (2) IAT (16.1 ± 1.0 hours), and (3) AbS (96.5 ± 1.2), as illustrated by Table I.

Even if the statistical evidence is considered,[1] however suggesting that repeated D & C predisposes to prematurity, surgical rather than pharmacologic pregnancy termination might still be preferred, if the IAT after DPGI is as long as 17.0 ± 1.2 hours (as was the case in the 67 first-trimester pregnant patients listed in Table I). Thus the reasons behind this lengthy IAT were scrutinized, as illustrated by Table II. The results showed that those 44 (out of 67) gravidas who (at 9.0 ± 0.2 weeks of gestation) required only the initial dose of 9.9 ± 0.1 mg. of PGF2α, without supplemental treatment, aborted in 12.8 ± 0.7 hours with a maximal AbS of 100.0 ± 0.0. In contrast, those 23 (out of 67) gravidas who (at 10.0 ± 0.3 weeks of gestation) re-

quired a total dose of 18.0 ± 0.8 mg. of PGF2α, had 25.1 ± 2.6 hours long IAT (with a high AbS of 94.8 ± 2.9, however).

This paradox, that gravidas (34 per cent) who received an average second dose of 8 mg. of PGF2α (supplementing the initial 10 mg.) had an IAT twice as long as that of those patients (66 per cent) who required only the initial (10 mg.) dose, had to be explained. Further scrutiny of the results revealed that while the "fast" aborters were para 1.3 ± 0.2 and the "slow" aborters para 0.5 ± 0.2, parity per se did not explain the difference in the IAT of these two groups of patients. The various retabulations of results indicated that nulliparity only prolongs the IAT in excess of 30 per cent beyond that of the multiparous, because the nulliparous cervix presents an obstacle against the effective transcervical and extraovular delivery of PGI. Proper consideration of this clinical reality is mandatory, since the parity of the patients is outside the control of the attending physician, while the delivery system used by him could be further improved.

If the prolongation of the IAT is only partly due to nulliparity (in both first- and second-trimester patients) and partly to failures in the effective delivery of DPGI, then the decrease in plasma progesterone (P) levels can be expected to be slower in the "slow" than in the "fast" aborters. This premise is based on earlier studies,[4-9] which showed (Fig. 1) a correlation between the rate of P withdrawal (Pw), the length of the IAT, and the therapeutic success in PG-induced abortions.

The changes in P levels induced by extraovular DPGI (or intra-amniotic PGI) are shown in Table III, providing useful information about the control of the IAT. In 91 cases, extraovular DPGI provoked a 32 per cent Pw as early as 3 hours after treatment ($P < 0.001$) and 56 per cent Pw at 16.1 ± 1.0 hours ($P < 0.001$), when patients aborted. In contrast, intra-amniotic PGI in eight gravidas (correcting technical failure with attempted DPGI) provoked a 19 per cent Pw at 3 hours after treatment ($P > 0.05$) and a 48 per cent Pw at 26.3 ± 1.1 hours ($P < 0.05$), when these eight patients aborted. Thus, in spite of the considerably greater total PGF2α dose, in cases of intra-amniotic (59.4 ± 6.8 mg.) rather than extraovular (16.4 ± 1.1 mg.) treatments, the rate of Pw was faster and the IAT shorter in the extraovular group. Furthermore, one patient, whose Pw did not continue after the initial 20 per cent decrease, in spite of her exposure to a total dose of 50 mg. of PGF2α, did not abort in 48 hours. Of additional interest is the finding (Table III), already recognized in earlier studies, that the P value at which the patients aborted is dependent on gestational age.

Fig. 2 describes the relationship between the rate of Pw and the IAT, as well as between the degree of Pw and the success of PG treatment. It illustrates that ~50 per cent Pw precedes successful pregnancy termination with the DPGI technique. Since this relationship between Pw and IAT appears to be the controlling mechanism of the success in this form of pharmacologic pregnancy termination, the results will be further examined.

Table IV illustrates that DPGI provoked in both

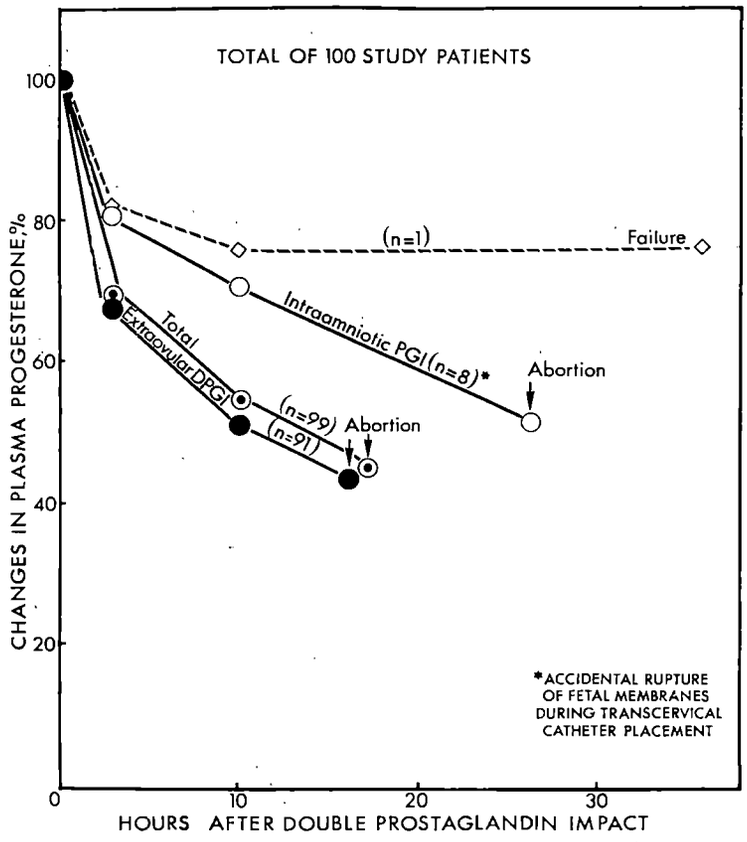

Fig. 2. The rate and degree of Pw provoked by DPGI in 100 patients.

first- and second-trimester pregnant patients significant ($P < 0.001$) Pw as early as 3 hours after treatment (27 and 32 per cent respectively). The degree of Pw at the time of abortion was similar in both groups (56 and 55 per cent respectively). Critical abortion values were reached in 13.5 ± 1.1 hours in the second- and 17.0 ± 1.2 hours in the first-trimester pregnant patients. It is of further interest that while the degree of Pw was similar in the first- and second-trimester patients, the 9.4 ± 0.2 weeks pregnant women aborted at a P level of 10.7 ± 0.7 ng. per milliliter and the 16.0 ± 0.5 weeks pregnant patients at 20.3 ± 1.5 ng. per milliliter ($P < 0.001$). This finding illustrates the critical dependence of the P value at which pregnancy is terminated on gestational age.

Of considerable interest is the additional finding (Table IV) that the group of 58 (first- and second-trimester) gravidas who required only the initial 11.6 ± 0.5 mg. of DPGI for a 58 per cent Pw in 12.9 ± 0.7 hours aborted at this time, whereas those 33 (first- and second-trimester) patients who required supplemental treatment and a total dose of 22.8 ± 1.6 mg. of PGF2α for a 51 per cent Pw in 21.9 ± 2.1 hours aborted at that time. Evidently, the rate of Pw, not the total PGF2α dose, controlled the IAT. This finding is of considerable interest, since it suggests that the clinical success of provoking abortion with a short IAT is determined by the effect of the *initial* PG impact on the P levels.

This conclusion—that fast abortions demand a rapid removal of the P excess (which protects pregnancy)—exposed a new and *quantitative therapeutic endpoint* in the management of pregnancy termination. Detailed examination of the changes in the P levels of 67 first-trimester pregnant patients verified this conclusion. Fig. 3 illustrates that, regardless of how the 67 first-trimester gravidas were grouped (e.g., on the basis of parity or total PGF2α dose), they aborted when 45 to 60 per cent of their P excess had been removed by the effect of DPGI. The absolute P values at which the different groups of patients aborted ranged from 9.5 ± 1.0 to 13.4 ± 1.7 ng. per milliliter. This already narrow range of P was actually narrower, since the patients who aborted at the P level of 9.5 ± 1.0 ng. per milliliter were only 8.7 ± 0.3 weeks pregnant, whereas those who did at 13.4 ± 1.7 ng. per milliliter were 9.5 ± 0.3 weeks pregnant. The effect of gestational age on the P value at which the patients abort having

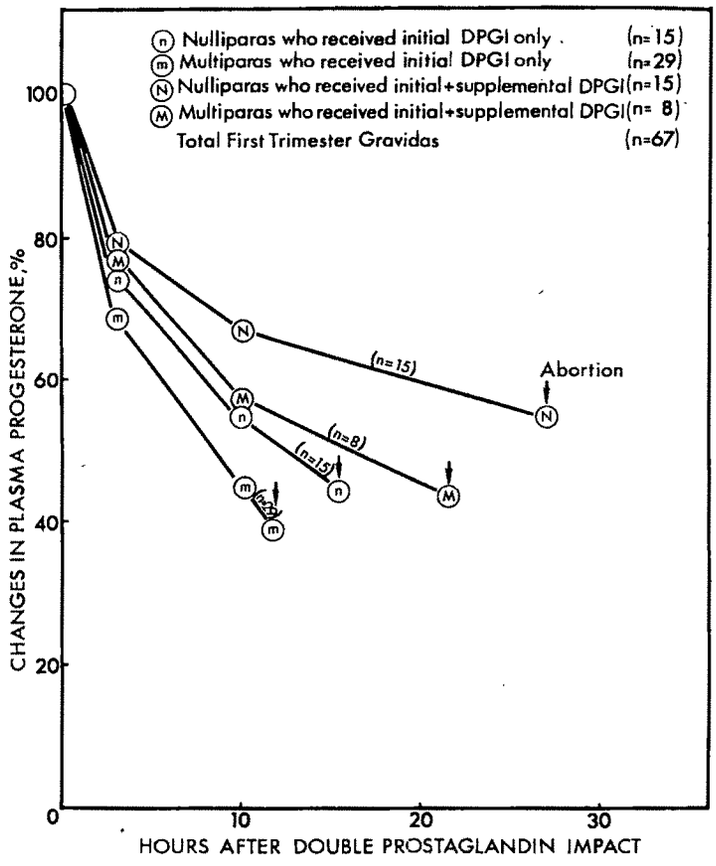

Fig. 3. The rate and degree of Pw in 67 first-trimester patients.

already been demonstrated in Table IV, this finding shows the reality of the "abortion P value" as a quantitative endpoint in PG-induced abortions.

Fig. 3 also illustrates that, while multiparas aborted earlier than nulliparas, and gravidas who required only the initial DPGI aborted earlier than those who required supplemental DPGI, nevertheless the IAT was controlled by the rate of Pw. This important point was re-emphasized by the finding that nulliparas, who required only the initial DPGI for rapid Pw (Group: N) aborted several hours before those multiparas did who required supplemental DPGI to reach abortion P value (Group: M). Apparently, regardless of how the groups were formed (whether on the basis of gestational age, parity, or total PGF2α received), the IAT continued to be controlled by the rate of Pw. Thus future clinical trials with PGs should be so designed that the delivery system of the drug guarantees rapid Pw to the critical abortion value.

The results presented so far demonstrate that (1) Pw to a critical value precedes DPGI-induced abortion, (2) the absolute value to which P has to decrease depends on gestational age, and (3) the rate of Pw controls the IAT.

Fig. 4 describes the clinical characteristics and steroid profiles of the "fast" and "slow" aborters. Disregarding parity (which has been discussed already), the 63 fast aborters were different from the 36 slow aborters in that they (1) received less PGF2α (15.3 ± 1.2 rather than 26.1 ± 3.4 mg.; $P < 0.01$); (2) had a shorter IAT (11.5 ± 0.4 rather than 26.5 ± 1.5 hours; $P < 0.001$); (3) reached their critical P value earlier (in 11.5 ± 0.4 rather than in 26.5 ± 1.5 hours; $P < 0.001$).

These and the additional findings that the fast aborters (1) outnumbered by far the slow aborters (64 per cent), (2) required only the initial DPGI in most instances (71 per cent), and (3) reached critical P value and aborted in 11.5 ± 0.4 hours without supplemental PG stimulation provided evidence that the delivery system DPGI is an effective clinical procedure for the termination of both first- and second-trimester pregnancies.

The additional considerations that: (1) the fast aborters were para 1.2 ± 0.1, whereas the slow aborters were para 0.4 ± 0.1, and (2) 64 per cent of the slow aborters required supplemental PG treatment and, in spite of this supportive therapy, only reached critical P value and aborted in 26.5 ± 1.5 hours, suggest that the

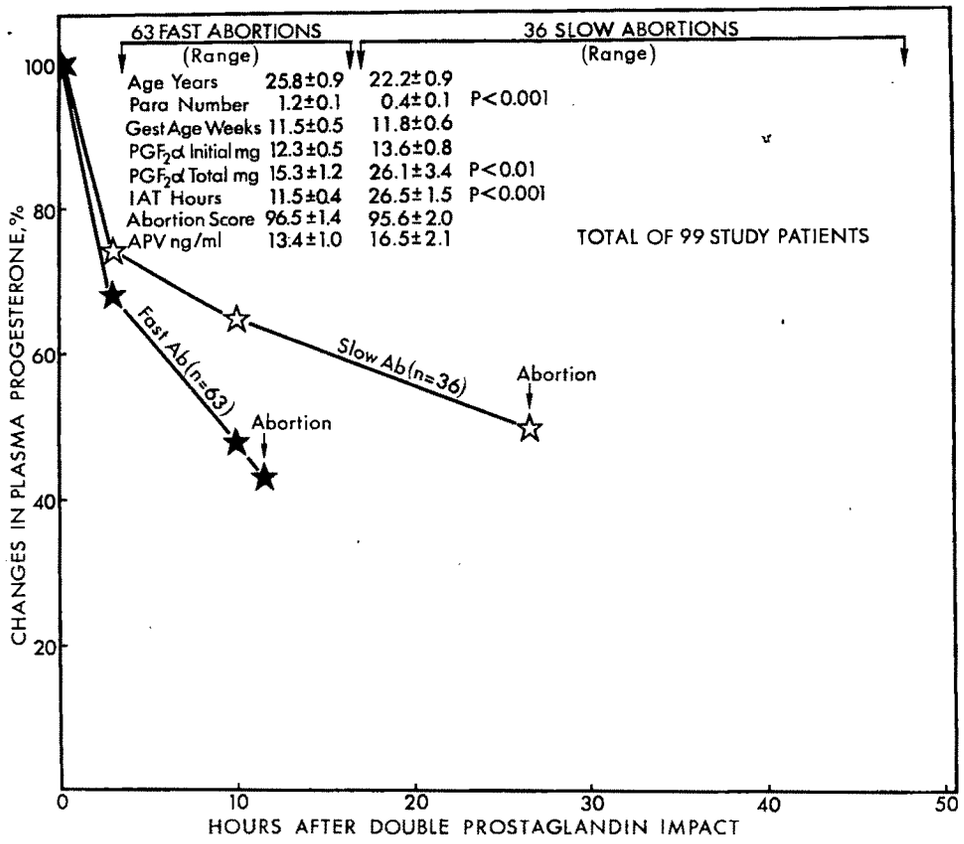

Fig. 4. The rate and degree of Pw in 63 "fast" and 36 "slow" aborters.

effective transcervical delivery of DPGI is occasionally hindered by the nulliparous (or otherwise unfavorable) *cervix.* Since this technical obstacle (being usually recognized after the initial failure in clinical progress) can be corrected only by repeated supplemental treatment, the IAT becomes prolonged.

The elimination of this group (the slow aborters) should be given high priority in future research. The results also showed (Fig. 4) that the slow aborters (who received in 64 per cent of the cases supplemental PG treatment) had slightly less Pw and aborted at a slightly higher P value than the fast aborters. While these differences are not significant statistically, they suggest that (within limits) a lesser degree of Pw is demanded for abortion if the uterus is stimulated continuously by repeated PG treatment or oxytocin infusion.

The results obtained in the 24 second-trimester pregnant patients (who received extraovular DPGI) substantiated the conclusions based on the study of the 67 first-trimester gravidas. Even those eight second-trimester patients who (after accidental rupture of the fetal membranes) received intra-amniotic PGI showed the relationship between Pw, IAT, and abortion. The small total number of second-trimester gravidas did not permit statistical analysis in subgroups.

The rates of cervical effacement and dilatation are informative clinical parameters. Since the transcervical passage of the small uterine contents of first-trimester pregnant patients requires only moderate cervical dilatation (which is difficult to estimate), only the cervical dilatation of the second-trimester gravidas could be correlated with Pw.

Fig. 5 shows that during the initial 3 hours, when PG already reduced plasma P by 26 per cent (yet in previous studies the evolution of IUP was only fractional[1, 9–11]), cervical dilatation was less than 0.5 cm. Apparently DPGI (as PGI) promotes clinical progress only after several hours delay, when the reduced P levels permit *advanced* cyclic IUP, which approximates the ~200 mm. Hg maximum working capacity of the first- and 100 mm. Hg IUP of the second-trimester pregnant uterus ($P = 2\ wT/R$; where P = IUP, wT = wall tension, and R = radius). At 10 hours following DPGI, however, when Pw was ~37 per cent, cervical dilatation advanced to 2 cm. and clinical abortion was in advanced progress in the majority of patients.

Fig. 6 shows that, in contrast to intra-amniotic treatment, extraovular PG rapidly suspends the fetal heart sounds. This finding substantiates the premise

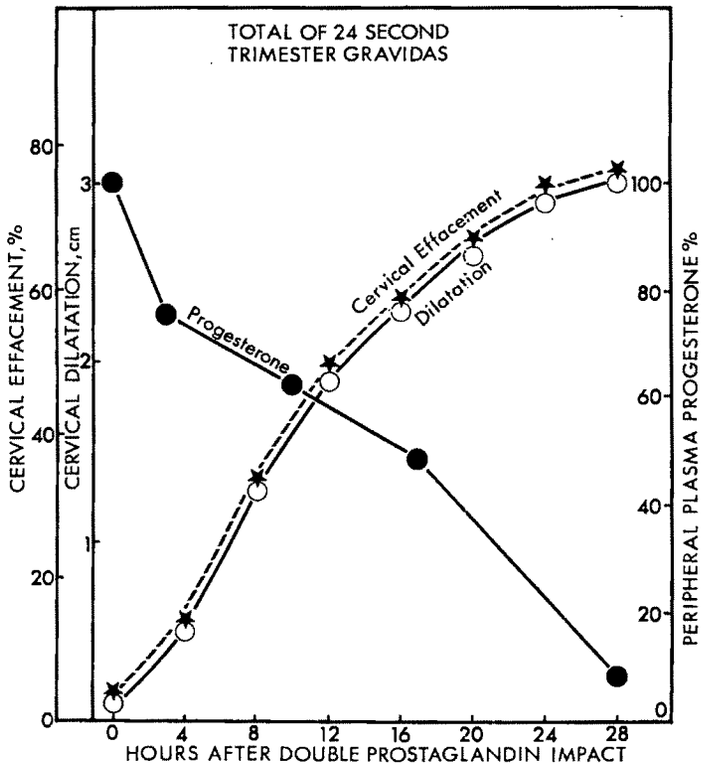

Fig. 5. The rates of Pw and cervical changes in second-trimester patients.

(to be discussed presently) that the effect of extraovular DPGI on the fetoplacental unit is more rapid and extensive than that of any other PG delivery system so far examined. As a result of failure in placental support, none of the fetuses was born alive, although seven patients were 18 to 20 weeks pregnant.

This premise—that DPGI rapidly suppresses fetoplacental function—is further substantiated by an additional observation (already established by earlier work[1, 4–9]) that effective PG treatment provokes rapid and drastic decrease in estradiol-17β (Fig. 6). This withdrawal was 54 per cent in 3 hours ($P < 0.001$), 68 per cent in 10 hours ($P < 0.001$), and 77 per cent at the time of abortion ($P < 0.001$).

Fig. 7 illustrates the cumulative abortion curve of the 100 study patients. Within 24 hours 86 per cent of the patients aborted. Apparently the clinical outcome of DPGI compares favorably with that of intra-amniotic PGI.[4]

The side effects and complications in this study were medically insignificant. Of the 100 sedated patients, 47 had mild, transient, and nonrecurring side effects. They occurred, as a rule, during or shortly after DPGI, in contrast to the early trials[3] when PG was administered through intravenous or extraovular infusions. Only in three gravidas was treatment discontinued because of severe vomiting. These three women aborted nevertheless, in spite of the low dosage received.

There were 31 incidents of nausea or vomiting, 16 hot flashes, 11 transient increases in blood pressure, seven occurrences of dyspnea, four of coughing, and three of diarrhea. Interestingly, in the second-trimester patients the severity and frequency of side effects were similar to those of the first-trimester gravidas, despite having received a double PGF2α dose. This finding suggests that the severity and frequency of (mild and transient) side effects are determined by the "sensitivity" of the patients to PG, or by the rate of initial adsorption, rather than by the total initial dose of PG. Of special interest is the negative finding that while the majority of patients recognized the initial contracture response of the uterus during DPGI, none of the 100 sedated volunteers showed symptoms of excessive pain during this exposure.

A total of 60 patients were curetted; however, in only 14 was curettage indicated by suspected placental residue. In the remaining 46 women, curettage was *diagnostic* and merely established that the uterine cavity was empty. A group of 40 patients were spared from curettage. Their postabortion spotting ceased 9.5 ± 0.5 days after DPGI (a period twice as long as those patients who were curetted). All study patients had spontaneous menstruation 30.6 ± 0.7 days after

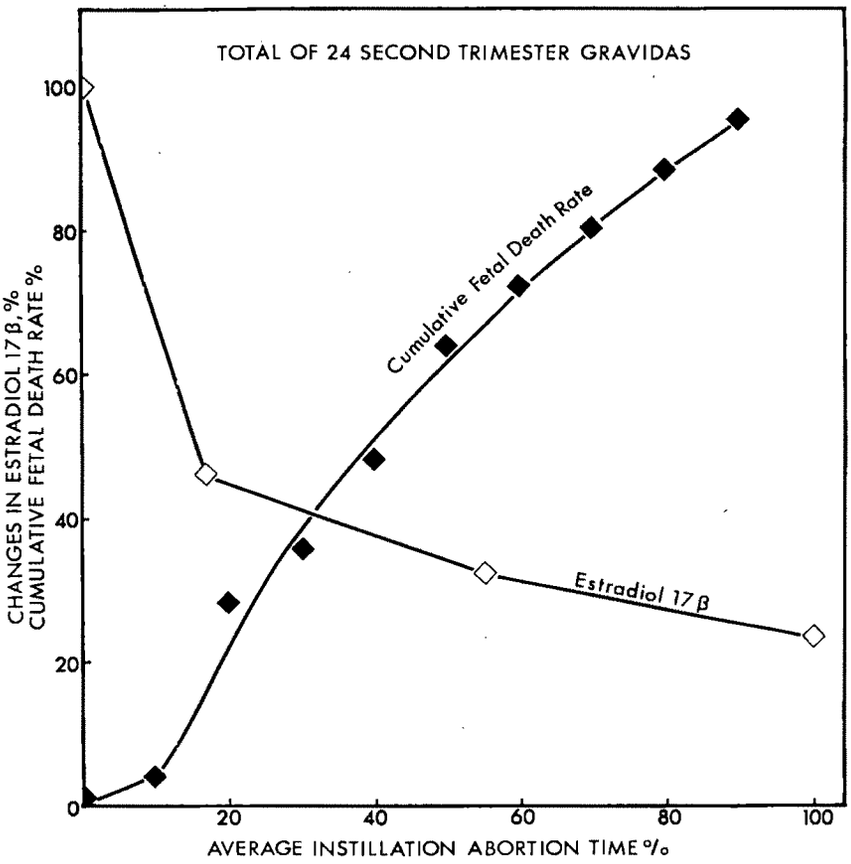

Fig. 6. The rates of E_{2w} and fetal death in second-trimester patients.

DPGI, which was normal in 82 per cent and less or more than normal in 18 per cent.

There were no complications, excepting eight cases of accidental rupture of the fetal membranes during catheter placement. These patients received intra-amniotic PGI and their IAT was prolonged. A total of nine cases of incomplete abortions and five residual postabortions demanded curettage. In spite of omitting curettage in 40 per cent of the study patients, there was only one case of transient elevated temperature. Of course, no gravida with cervicitis was admitted to the study group. The vagina was prepared with extreme care prior to DPGI, catheter placement was performed under strictly aseptic conditions, and after DPGI the treatment catheters were promptly removed. The patients were hospitalized for 1 to 2 days (depending on gestational age) and were repeatedly observed during this period. With the exception of one second-trimester patient, none of the remaining 99 women had elevated WBC or temperature beyond 38° C. during hospitalization, or reported fever after being discharged from the hospital. The one patient who had a peak temperature of 38.2° C. without elevated WBC had normal temperature after 2 days of antibiotic treatment.

Comment

The double prostaglandin impact (DPGI) technique successfully terminated 6 to 20 week pregnancies within 16.9 ± 0.9 hours in 99 out of 100 volunteers. Even the remaining one patient progressed to 2 cm. dilatation during 48 hours. In eight of the 99 gravidas accidental membrane rupture (during catheter placement) resulted in the intra-amniotic delivery of PGI. Of the 91 gravidas who received DPGI extraovularly, two thirds were treated only with the initial dose of 11.6 ± 0.5 mg. of PGF2α and aborted in 12.9 ± 0.7 hours, without requiring supplemental treatment. The remaining one third needed additional treatment, totalling 22.8 ± 1.6 mg. of PGF2α, and despite this increased dosage aborted in only 21.9 ± 2.1 hours.

This finding that at least in two thirds of the patients the theoretically "ideal" treatment has been closely approximated is informative, since there is no agreement among investigators regarding the most efficacious technique for the pharmacologic termination of

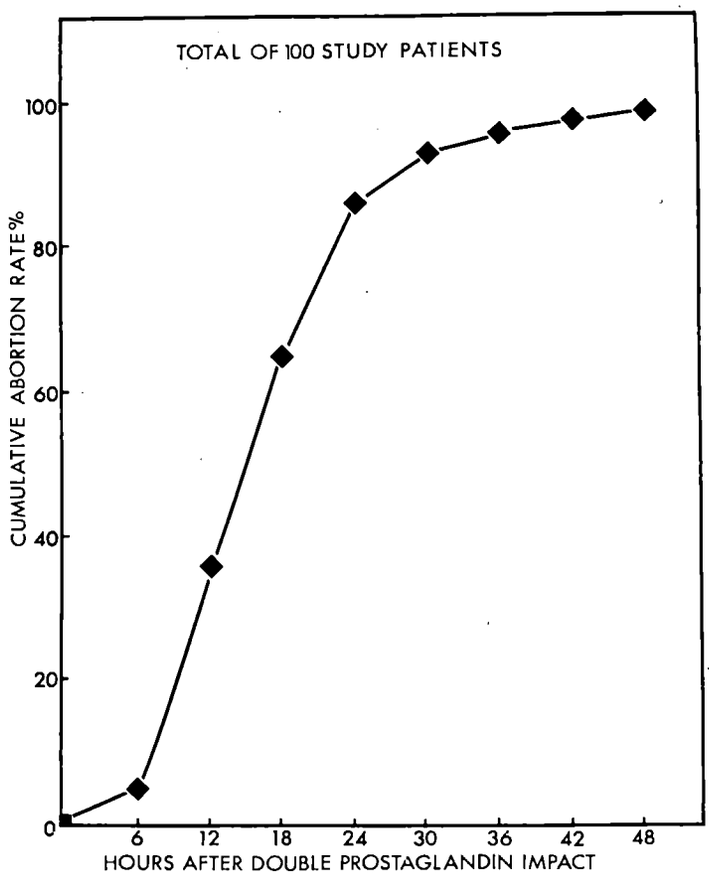

Fig. 7. The cumulative abortion rate of the 100 study patients.

pregnancy. If in the future repeated treatment and prolonged IAT could be avoided, DPGI (or a similar but further improved technique) might be considered for routine clinical use.

Thus the direction of future research is outlined. To promote its success, the question has to be raised: Why did the same DPGI technique provoke fast abortions in two thirds of the patients, without need for supplemental treatment, and slow abortions in one third of the patients despite supplemental treatment? It might be argued that this marked difference between the two groups was due to differences in the patients' "cervical conditions" and "sensitivity" to PG, since individual variations among patients undoubtedly affect the course of clinical progress. A distinct difference in the P levels of cases of treatment failures and successes and of fast and slow aborters has been documented already,[4–9] however, by over 25 reliable studies (Figs. 1 to 5). The sequential radioimmunoassays also established a close correlation between the rate and degree of Pw and the IAT. Regardless of how the patients were grouped (e.g., on the basis of parity, gestational age, initial or initial + supplemental treatment, total PG dose, etc. [see Figs. 1 to 4 and Tables III and IV]), the close correlation between Pw and IAT remained.

The evidence is, therefore, definitive that Pw does occur and that it precedes PG-induced abortion. Opponents of our contention that Pw plays a causal role in PG-induced abortion have to resort, therefore, to the argument that it is not Pw which provokes the evolution of IUP, but IUP provokes Pw. This argument rests on the premise that the *primary* action of the initial PG dose on the pregnant uterus is *oxytocic* and is exerted directly on the myometrial cells, rather than indirectly on their superimposed regulatory mechanism. If so, it can be further argued that it is this oxytocic action which, by generating high-level IUP and a consequent suppression of uteroplacental blood flow, provokes Pw.

The regulatory actions of PG and Pw on IUP being intimately related, the resolution of their temporal relationship (under the present study conditions, when both are changing) is difficult. It can be readily achieved when one of these regulators remains constant, however. Since the resolution of the sequence in which they affect IUP is a basic issue in reproductive

medicine, it is desirable to determine whether PGs induce the evolution of IUP after having provoked Pw or provoke this evolution regardless of P and thus Pw is a consequence of high-level IUP.

If shortly before or during early labor, when the cyclic IUP is only a fraction of the maximum working capacity of the term pregnant human uterus (~70 mm. Hg), a single dose of 25 m.U. of oxytocin or 25 μg of PGF2α is administered to patients in a slow intravenous injection, the myometrium promptly displays ~70 mm. Hg cyclic IUP.[10] This effect (frequently used clinically to determine the "inducability" of patients) is the *classic oxytocic response* of the uterus. The maximum uterine response (at different stages of gestation) is predicted by the Laplace theorem (IUP = 2 wT/R), which states that when uterine wall tension (wT) is constant, IUP is inversely related to the uterine radius (R). Calculation, as well as experimental evidence, show[1, 4–10] that when the reactive uterus is maximally activated, the IUP is controlled by R and thus the second-trimester uterus develops over 100 mm. Hg and the first-trimester uterus about 200 mm. Hg IUP. This demonstration, of course, is possible only if the recording technique of IUP is accurate (e.g., the recording system is not leaky), the fetal membranes are intact and not bulging, there is no partial block in the recording system, and observations continue until the descent of the uterine contents.[10]

Thus, if PGs could exert on the human myometrium a primary oxytocic action during the first half of gestation (the basic premise of the argument opposing our contention) then within 5 minutes PGs should provoke 100 to 200 mm. Hg *cyclic* IUP (depending on R). No one ever observed such a uterine response. Only an unphysiologic *contracture* has been recorded, on which fractional cyclic IUP was superimposed, increasing *gradually* with the progress of *time*.[1, 4–10]

Evidentially, as stated in the "see-saw theory,"[5] PGs cannot *exert* during normal pregnancy a classic oxytocic response on the *refractory* human uterus until it is *converted* into a *reactive* organ by a regulatory imbalance. Thus the premise that PGs provoke high-level IUP through a primary oxytocic action and Pw through that effect on IUP stands unsupported. For, initially PGs do not provoke maximal cyclic IUP; indeed, as late as 3 hours after treatment (when Pw is already highly significant, $P < 0.001$, Table III), the cyclic IUP is still only a fraction of the maximum working capacity of the organ.[1, 4–10]

Since, however, after PG treatment, Pw and the evolution of cyclic IUP follow a similar time course, it is desirable to demonstrate that IUP is controlled by P, rather than the other way around. This demonstration demands a "clean system," in which only P is changing while PG is constant. Accordingly, Pw was provoked in early pregnant women by luteectomy (rather than by PG) and the oxytocic response of the uterus was examined daily to standard intravenous doses of 250 m.U. of oxytocin and 250 μg of PGF2α.[11] It then became apparent that until P decreased to a *critical* value (below 5 ng. per milliliter in cases of early pregnancy), the myometrium *only* responded to constant doses of these powerful oxytocics with transient contractures. High-level cyclic IUP did not appear until P decreased to the critical value. Evidentially, as predicted on the basis of extensive earlier studies,[5] the "sensitivity" of the pregnant human uterus to oxytocics is controlled by P, and thus Pw must *precede* the evolution of IUP. This study also demonstrated that luteectomy provokes abortion by Pw (rather than through an increase in endogenous PGF2α). Even the unphysiologically high dose of exogenous PGF2α (250 μg intravenously) only provoked *contracture*, rather than advanced cyclic IUP, until P decreased to the critical value. As documented by the present (Tables III and IV) and earlier results,[4–11] this critical P value is higher during late first and second trimesters than during early pregnancy.

If Pw precedes the evolution of IUP and oxytocic response, the question is, how do PGs provoke Pw? There is no evidence that in the human subject PGs directly interfere with P genesis, hence the inefficacy of PGs during the luteal phase of the menstrual cycle. In contrast, there is evidence, in both animal "models"[12] and patients,[13] that PGF2α *promptly* provokes *vasoconstriction* in the uteroplacental vessels long before advanced cyclic IUP develops and suppresses uteroplacental blood flow. The prompt and excessive contracture response of the pregnant uterus to PGs is most probably an expression of this circulatory effect of PGs (anoxia).

Jointly, vasoconstriction and contracture can effectively suppress fetoplacental endocrine function and cause continued Pw. Once provoked, Pw reduces the excitability *threshold* of the myometrium[14] and *converts* the refractory uterus to a reactive organ. When converted, the myometrium responds to both endogenous and low-level exogenous PG stimulation.[5] The fact[1, 4–10] that maximal cyclic IUP evolves only several hours after the administration of a single dose of PGF2α (when this exogenous compound is already metabolized), rather than shortly after treatment (when PG concentration is the highest), further supports the contention that PGI is therapeutically effective because it provokes Pw (rather than an oxytocic action). PG stimulation after Pw is therapeuti-

cally desirable, however, since its effect is additive to that of endogenous PGs. Recent measurements of placental P[15] indicate that PG-induced Pw might be more drastic and rapid than is reflected by the circulating plasma P levels. In any case, once effective Pw did provoke the evolution of advanced cyclic IUP, the promotion of activity becomes *autocatalytic,* in that increased IUP further promotes activity through increased reduction of uteroplacental blood flow and fetoplacental endocrine function.

This reconstruction of the mechanism of PGI is, of course, tentative and precise documentation of the sequence of events requires further investigation. From a practical point of view, however, this initial reconstruction has been useful already in explaining why sustained PG infusions and repeated medium doses (given with the intent of direct myometrial stimulation) were clinically ineffective, in spite of excessive and medically unacceptable side effects.[3] Reconstruction also provided a readily measurable endpoint for PG therapy: effective Pw. Rapid radioimmunoassays can inform physicians in a few hours whether PG treatment has been successful. This information could be specifically valuable in cases of "menstrual induction,"[16] when the distinct clinical signs of effective therapy do not evolve as rapidly as they do in cases of more advanced pregnancy.

The authors are grateful to Drs. R. T. Ravenholt, J. J. Speidel, and E. M. Southern for their continued encouragement, regarding the development of advanced delivery systems for PGs, and their useful advice and comments during the conduct and evaluation of this study. The assistance of Elise Csapo, Wynne Stifel, Susan Hayden, and Esther Csapo in statistical analysis, illustration, and the preparation of the manuscript is appreciated.

The Frontier Nursing Service: The primary care nurse in the community hospital

HELEN E. BROWNE, R.N., C.N.M., O.B.E.
GERTRUDE ISAACS, D.N.Sc., C.N.M., M.P.H.
Hyden, Kentucky

On the occasion of the Fiftieth Anniversary of the Frontier Nursing Service, we extend our congratulations for the excellent health care system the Frontier Nursing Service has developed and provided in a medically underserved area, for the progress made, and for the attainment of professional and community cooperation.

The Editors

THE NURSE as a primary care provider was first introduced into rural southeastern Kentucky fifty years ago by the Frontier Nursing Service (FNS). The aim was to establish a viable health care system in medically underserved areas. The nurse-midwife was selected as the most appropriately trained health care provider to meet the problems of the rural areas. She was more easily attainable at less cost than the physician. She could manage the common day-to-day health problems encountered by the family and, most important, take care of the mother throughout the childbearing period and her newborn infant. She was prepared in health teaching and in public health.

The patients with more complex problems requiring medical care were sent to physicians and hospitals in neighboring areas until a hospital could be built and a physician added to the staff. Through this system, the family was never more than one hour's travel time from primary care; now, with improved transportation, it is one half hour. Through established links with State health agencies, University Medical Centers, and other specialty care clinics in the State, the most sophisticated care could be made available to the most isolated family.

In 1970, the nurse-midwifery training program, established in 1939, was broadened to include family nursing, by the addition of diagnosis and management of common health problems. This preparation markedly extends the skills of the nurse. It enables her to perform selected medically delegated tasks in combination with her nursing skills—the caring, teaching, counseling, and management skills. The combination of these skills helps to make her care meaningful to the family, and the close working relationship with the physician and other members of the health team helps to assure the family of quality care. The physician at all times retains ultimate responsibility for medical services and is available around the clock to work with the nurse in management of more complex problems.

The nurse in all areas, hospital, clinic, and home, works with Medical Directives—medical protocol mutually developed by medicine and nursing. These "directives" specify privileges and limitations of practice and provide guidelines for the nurse in the management of common health problems, including prescription of therapeutic measures and drugs and designation of the point at which consultation must be sought or the patient must be referred to the physician. For effective utilization of these directives, the nurse needs to be prepared in history taking, physical examination, common laboratory procedures, diagnosis of disease, health assessment, and the management of common health problems.

Hospital inpatients

The role of the primary care nurse in the FNS hospital may vary substantially. In most situations, the

patient requiring hospitilization is referred by the nurse to the physician who makes the final determination. The nurse may hospitalize the patient in the absence of the physician. This privilege is utilized primarily for situations in which the patient needs nursing observation and care for such considerations as croup or minor injuries, or conditions not considered serious enough to require the immediate attention of the physician but which the family cannot manage at home. In all situations, the physician must be notified within 12 hours after admission. Policies defining the privileges and limitations for hospital admission by the nurse have been established and are filed with the Kentucky Hospital Association.

Primary care nursing functions vary within the hospital, depending on the type of patient served. The family nurse is responsible for all admission physical examinations on the general ward and the pediatric nurse on the pediatric ward. In the process, she is expected to obtain a social and family history, if this has not been done previously. This provides a base for planning care, counseling, health teaching, and discharge. The family is involved as appropriate in the care of the patient. In the process, the family is taught health care of the patient and receives assistance in the management of their own life-style in relation to the needs of the patient. Admission physical examinations are reviewed by the physician, who sees the patient twice daily and as indicated. The nurse continues to follow patient care management, performing nursing and medically delegated functions as indicated. The nurse may write routine admission orders, in accordance with the Medical Directives and hospital policies, but consults with the physician for special orders.

All patient care plans are reviewed daily by the physician-nurse team. Other members of the health team may be included. The amount of teaching and counseling provided by the nurse is dependent on the needs of the patient. Discharge summaries are written by the physician. The family nurse, the pediatric nurse, and the physician consult frequently with each other and the staff nurses (registered nurses and/or licensed practical nurses assigned to the ward) to assure continuity of care and for teaching purposes. Monthly Hospital Utilization Reviews are attended by representatives from the total team, with the aims of improving patient care and establishing appropriate standards.

On the obstetric ward, the nurse-midwife is responsible for the management of all normal obstetric patients that have had prenatal care, and the normal newborn infant. The obstetrician is called when a patient is admitted who has not had prenatal care or when abnormalities which may complicate labor and/or delivery are noted. A pediatrician is called if any abnormalities arise in relation to the fetus or newborn infant. In case of complications, the nurse-midwives and physician work together as a team in the management of patient care. Over 90 per cent of the babies are delivered by the nurse-midwife. Nurse-midwives may perform episiotomies and repairs and use the vacuum extractor. Physicians perform cesarean sections and forceps deliveries when indicated. The nurse-midwife is specially trained for care in the normal situation, so when an abnormal situation occurs, she is quick to recognize it and seek the assistance of the physician. Special attention is paid to the high-risk mother and her infant.

*Rate per 1,000 live births.

†Midpoint year used for state ratios and percentages.

‡Rates per 10,000 live births.

§During the 1969 to 1974 period, increased stillbirths and neonatal death rates were accompanied by a rubella and influenza epidemic in the area served.

Service of the first 10,000 deliveries between 1925 and 1954 indicates 11 maternal deaths (two were not attributed to obstetric causes) as compared with a national maternal mortality rate of 36.3 per 10,000 live births for the midpoint period, 1939 to 1941. Table I illustrates the causes of maternal deaths, national and in the FNS.

The low maternal death rate is particularly significant since 60 per cent of deliveries between 1925 and 1954 were conducted in the home in an extremely poverty-stricken area, where the main mode of transportation was by horseback, modern facilities and medical assistance were difficult to attain, and the percentage of high-risk mothers and infants was great.

The numbers of premature births, stillbirths, and neonatal deaths deliveries performed by the FNS were also lower than the national averages, as indicated in Table II. Comparable figures are available for 1952 to 1954 only.

In all situations where neonatal or maternal deaths occurred, complications were noted during the prenatal period. The study demonstrates that early recognition and management of complications in pregnancy can have a major impact on the mortality rate of high-risk mothers and infants in rural areas.

Since 1952, statistics indicate no maternal deaths in over 8,000 deliveries and a continuing decline in the stillbirth and neonatal mortality rates among 7,264 babies delivered by the FNS between May, 1954, and April, 1974, as noted in Table III. However, the decline is not as rapid as that noted in the Kentucky rates. The birth rate in the area served reached a peak of 41 per 1,000 population in 1965. This subsided rapidly with the introduction of a family planning program which is provided through the nurse-midwifery program with medical support.[2] In 1973, the provisional birth rate for the area served was 17.8 per 1,000 population.

Ambulatory care

The primary care nurse in the ambulatory care clinics at the FNS may be best described as the front line worker. In the fiscal year 1974, approximately 60 per cent of the ambulatory visits were made by primary care nurses located in eight nursing satellite clinics. Forty per cent of these patients were seen in the home, and the remainder were seen in the nursing clinics. Thirty-four per cent of the patients seen were 15 years of age or less; 21 per cent were 60 years of age or over, and 14 per cent were midwifery patients. These form the groups of patients most commonly neglected in our present-day health care system.

Most of the patients seen were in the "no abnormality" category: the prenatal, postpartum, and family planning patients; the newborn, well-child, and school health groups; and patients who desire immunization, a Papanicolaou smear, breast examination, tuberculosis testing, and routine physicals for health care, education, and eating establishment employees.

The most common disorders seen are upper respiratory infections, otitis media, hypertension, arteriosclerotic heart disease, influenza and bronchitis, kidney and urinary tract infection, diabetes mellitus, and chronic obstructive pulmonary disease, in that order. Common infectious disease and minor disorders are managed according to medical protocol. Patients

with chronic disease are identified by the nurse for referral, and follow-up visits are made after a diagnostic work-up by the physician with a plan of care. Medical protocol is specifically developed for these purposes. If the response to treatment is unsatisfactory, medical consultation is sought.

Radio and telephone communications with the physician and other members of the health team are available at all times. The more complex conditions not readily managed with medical protocol are referred to the hospital, physician, or social worker as indicated. A physician visits each district once or twice a month on a regular schedule.

Weekly utilization review meetings are held by the home health care team, including the physician, the district nurse supervisor, the social worker, and the district nurse. Patients on medical care plans are reviewed and other health problems that arise are brought up for discussion. The aims are to assure appropriate health manpower utilization, quality, and high standards of care and to provide a teaching mechanism.

At the hospital clinic, the nurse obtains all initial histories and performs all physical examinations, and she may order specified laboratory procedures or x-rays as indicated. Medical consultation or referral is sought as indicated. Medical Directives provide the basis upon which the nurse initiates care. A physician is on call around the clock and sees all patients requiring the skilled care of a physician. During the day, the physician is available in the hospital; after 4 P.M., he is on call.

A modified problem-oriented record system is used and monitored by the physicians. This helps assure appropriate utilization of family nursing and medical skills and a high standard of health services. It also serves as an excellent teaching tool.

The primary care nurse helps to combine preventive measures with the management of common health problems. Heavy emphasis is placed on helping families to cope with their own health problem. The aim is to lessen the need for costly hospitalization and nursing home care. Only 10 per cent of patients admitted to the hospital are 65 years old and over, which is equivalent to their distribution in the population group. Their average length of stay in the hospital is 7.6 days, which is approximately half of the average length of stay in similar community hospitals. Most chronically ill patients are referred to home health. Only the rare patient is referred to a nursing or personal care home.

The savings for the State and Federal government and the patient created by the primary care system developed by the FNS have not been figured, and a suitable method for measurement of the quality of care has not been found. Research in this area is underway.

Perhaps one of the most important aspects of this type of health care program is the manner in which it helps strengthen or maintain family ties and helps individual members assume greater responsibility for one another. In times of childbirth or illness, there is a natural pulling together of the family. If various members within the family are supported in their efforts to help one another and the necessary guidance is provided, much can be done to alleviate the stress and loneliness of illness and to increase the joy and satisfaction of parenthood. If the health care system is organized in a manner whereby primary care is readily accessible with good specialty care linkages, much can be done to lessen chronic disability and perhaps maintain and revive the community spirit that used to be so vital in the development of this country.

The primary care nurse, whether prepared in family nursing, pediatrics, or midwifery, can do much to broaden the dimensions of health services available and make health care more meaningful to our citizens, particularly in rural and other medically underserved areas. But she cannot do this in isolation or without the whole hearted support of the physician and the other members of the health team.

Intravascular coagulation in obstetrics: Serial dilution protamine sulfate test throughout labor

CARMEN L. AROCHA PIÑANGO
J. LINARES
A. COVA
P. MARTÍNEZ
G. MONTILLA
S. RODRÍGUEZ
Caracas, Venezuela

Serial dilution protamine sulfate tests (SDPS) were performed in 191 women during labor. It was found that 27 per cent of women with uncomplicated pregnancies and 42 per cent with complicated pregnancies had positive SDPS tests, the highest incidence being between three and six hours of labor. These findings support the previous report of a physiologic disseminated intravascular coagulation in pregnancy but make the SDPS test of little value in obstetric cases.

THE EXISTENCE OF a process of physiologic intravascular coagulation during normal labor has been postulated based on the rise of fibrinogen degradation products and on the significant fall in plasma fibrinogen and factor VIII.[1] In 1970, Kleiner and associates[1] suggested that the mechanism involved is qualitatively similar in both normal and pathologic conditions, but it is of higher magnitude in the latter as in cases of abruptio placentae or intrauterine death.

In the present study we have tried to use the induction of the paracoagulation phenomenon with the use of serial dilution protamine sulfate test (SDPS) described by Niewiaroski, Gurewich, and Hutchinson[2, 3] as a means of identifying disseminated intravascular coagulation (DIC) in women undergoing labor.

Material and methods

Patients studied. Blood specimens were tested from 191 women chosen at random in the delivery room.

†$p > 0.70$ for the difference between primigravida and multiparous patients.

Labor starting time and associated pathology were recorded. Single blood samples were drawn from 171 women, and in 60 serial samples were obtained at two-hour intervals during labor. Seventy-one patients experienced some sort of complication during the process (pre-eclampsia, intrauterine death, cephalopelvic desproportion, premature rupture of membranes, etc). All women were followed for 24 hours after delivery.

Citrated plasma. Blood, 4.5 ml., was drawn in disposable plastic syringes and mixed in polystyrene tubes with 0.5 ml. of sodium citrate (3.2 per cent) which contained either ten per cent epsilon amino caproic acid (EACA) or 2000 U. of aprotinin. The blood was centrifuged immediately at 3,000 r.p.m. for ten minutes. Plasma was separated with the use of plastic

pipettes and was tested the same day or kept frozen at −20° C. until used.

Protamine sulfate (Roche), one ampule, was opened daily and dilutions of 1/5, 1/10, 1/20, 1/40, and 1/80 were made in tris-saline buffer, 0.05M, pH 6.5; 0.2 ml. of each dilution was added to 0.2 ml. of plasma, mixed, and left for 30 minutes at room temperature. Reading was done with the naked eye with the use of a fluorescent lamp against a black background. The results were expressed as coarse precipitate, fibrin strands, and gel. All samples which showed either fibrin strands or gel in one or several dilutions were considered positive.

Results

There were no differences between samples taken either with EACA or aprotinin or between the samples tested fresh or frozen.

In normal labor the incidence of positive SDPS in primigravid and secundigravid women was 32 and 40 per cent, respectively, compared with 11 per cent in multiparous patients ($p < 0.01$). In complicated labor the incidence was 34 per cent for primigravid women, 64 per cent for secundigravid women and ($p < 0.01$) 32 per cent for multiparous women ($p < 0.70$) (Table I). Of these patients only ten with normal pregnancies and two with complicated pregnancies had previous histories of miscarriage, and only one of each group had positive SDPS test.

In the group from whom serial samples were taken every two hours, it was found that in seven of the women with normal pregnancies (eight per cent) and nine of those with complicated pregnancies (22 per cent) in whom the tests were negative at the beginning of labor, the tests became positive with the following samples.

Table II shows the incidence of positive SDPS tests according to the diagnosis. Although the number of subjects tested is rather small in each pathology, the percentage of positive cases is higher than that in normal subjects ($p < 0.001$).

Table III shows the results of SDPS tests in uncomplicated and complicated pregnancies during labor. Samples were grouped in periods of three hours according to the onset of labor. The positive tests were expressed as percentage of samples in each period. In normal labor an increase of positivity during the first six hours is shown, declining thereafter during the subsequent periods. In abnormal labor the highest percentage of positive tests was also observed during the first six hours, but the number of positive cases was about 50 per cent higher than that in women with normal labor. No hemorrhagic complications were observed in any of the SDPS-positive patients.

Comment

Pregnancy seems to be accompanied by DIC which is greater in those patients who tend to become complicated with pre-eclampsia and other factors which increase the prenatal morbidity and mortality rate.[4–8]

Hyde and co-workers,[9] with the use of the SDPS test to detect the presence of thrombin-induced fibrinogen derivatives in plasma of women during pregnancy and puerperium, have found a significantly increased incidence of positive SDPS tests in uncomplicated primigravid pregnancies compared with secundigravid and multiparous pregnancies and an influence on the positivity of a history of previous miscarriages. Our findings in normal and complicated labor are similar,

but the highest positivity occurred in secundiparous patients and is not affected by the history of miscarriage (Table I).

Hyde and associates[9] also found an incidence as high as 47.5 and 43.6 per cent of positive SDPS tests in the second and third trimesters of patients who had normal pregnancies and 68.5 per cent in pre-eclamptic patients. Therefore, we could expect a similar incidence during labor; but surprisingly the highest percentage of positivity we found was 27 per cent for normal and 38 per cent for complicated labor during the first six hours, with a total incidence of 27 per cent and 42 per cent, respectively (Tables II and III). These values are much lower than those of the above-mentioned authors.

The work performed by the myometrium during labor increases from a starting pressure of 25 mm. Hg up to a pressure of 100 mm. Hg during fetal expulsion.[9] It might be assumed that as labor progresses the increase of uterine activity could result in a progressive release of thromboplastin from the placental tissue,[10] the activation of the hemostatic mechanism becoming greater with a higher incidence of SDPS. Nevertheless, our results do not confirm this hypothesis, since in both the normal and abnormal series the highest incidence was found in the first six hours of labor with a significant decrease after seven hours (Table III). At the moment we do not have an explanation in each case. Further studies are underway in order to elucidate this problem.

In conclusion the lack of correlation between the positive results and the absence of hemorrhagic complications makes the SDPS test of limited value to detect DIC in obstetric patients.

We would like to thank Dr. V. Gurewich (Boston), who kindly checked the protamine sulfate (Roche) used in this research, Professor G. I. C. Ingram (London), Dr. O. Aguero, and Dr. M. Layrisse (Caracas) for their advice and criticism.

Amount and distribution pattern of soluble fibrin monomer complexes during the early puerperium

H. GRAEFF, M.D.
A. WIEDEMANN, M.D.
R. VON HUGO, M.D.
R. HAFTER, PH.D.
Munich, Germany

Soluble fibrin monomer complexes (SFMC) were determined in 12 patients following delivery, 2, 4, 6 days and 3 months post partum. Quantitative gel filtration (4 per cent agarose) of the β-alanine–precipitated plasma samples yielded the relative (per cent of the total fibrinogen content) and absolute (milligrams per 100 ml. of plasma) amount of SFMC. During the early puerperium the amount of SFMC remained essentially constant, with average postpartum values of 6.3 ± 1.2 per cent and 27.6 ± 9.1 mg. per 100 ml. (mean and standard deviation). Three months after delivery the level of SFMC was significantly ($p < 0.001$) decreased (3.3 ± 1.3 per cent and 8.4 ± 3.4 mg. per 100 ml.). The quantitative estimation of SFMC in the early puerperium as presented in this study indicates that a state of hypercoagulability can be evaluated by measuring the thrombin-mediated catabolic products of fibrinogen.

THE OCCURRENCE of soluble fibrin monomer complexes (SFMC) during delivery is a rather frequent phenomenon which might be related to the so-called state of hypercoagulability during gestation. Recently a fibrinogen derivative with a higher molecular weight than that of the parent molecule was observed in plasma samples from normal pregnant patients.[1, 2] The physicochemical and immunologic properties of this component are in agreement with the assumption of a dimeric structure which may occur either as a fibrinogen fibrin monomer complex or as a covalently linked dimer.[2] It is eluted during gel filtration on 4 per cent agarose gel in a shoulder prior to the fibrinogen peak.

The frequency of venous thrombosis and pulmonary embolism is significantly increased during the puerperium. Observations during this period may give further information concerning the occurrence of SFMC and their relation to hypercoagulability and thromboembolism. Quantitative gel filtration was therefore applied in the present study to determine the amount and distribution pattern of SFMC during the early puerperium.

Material and methods

Collection of blood specimens. Twelve healthy primiparas and multiparas, 23 to 39 years of age, were examined. Pregnancy, delivery, and postpartum course were in all cases uneventful. All newborn infants had an Apgar score of 8 to 10.

Blood was obtained within the first 12 hours of the immediate postpartum period, on day 2, 4, and 6 of the puerperium, as well as 3 months after delivery. The blood samples were drawn from the cubital vein under constant mixing with the anticoagulant (1:10) (trisodium citrate 3.8 Gm., TES 1.38 Gm., 10 ml. of Trasylol, Bayer, Leverkusen, Germany, to 100 ml. at pH 7.5). Platelet-poor plasma was prepared by centrifugation in a refrigerated centrifuge. When it was necessary to store samples, they were held at −25° C. up to 4 weeks.

The fibrinogen content of plasma was assayed by measuring the optical density (280 to 325 nm.) of the clottable protein[3] from 0.5 ml. of plasma (dissolved in 10 ml. of 40 per cent urea, 0.2N NaOH, and 1 ml.

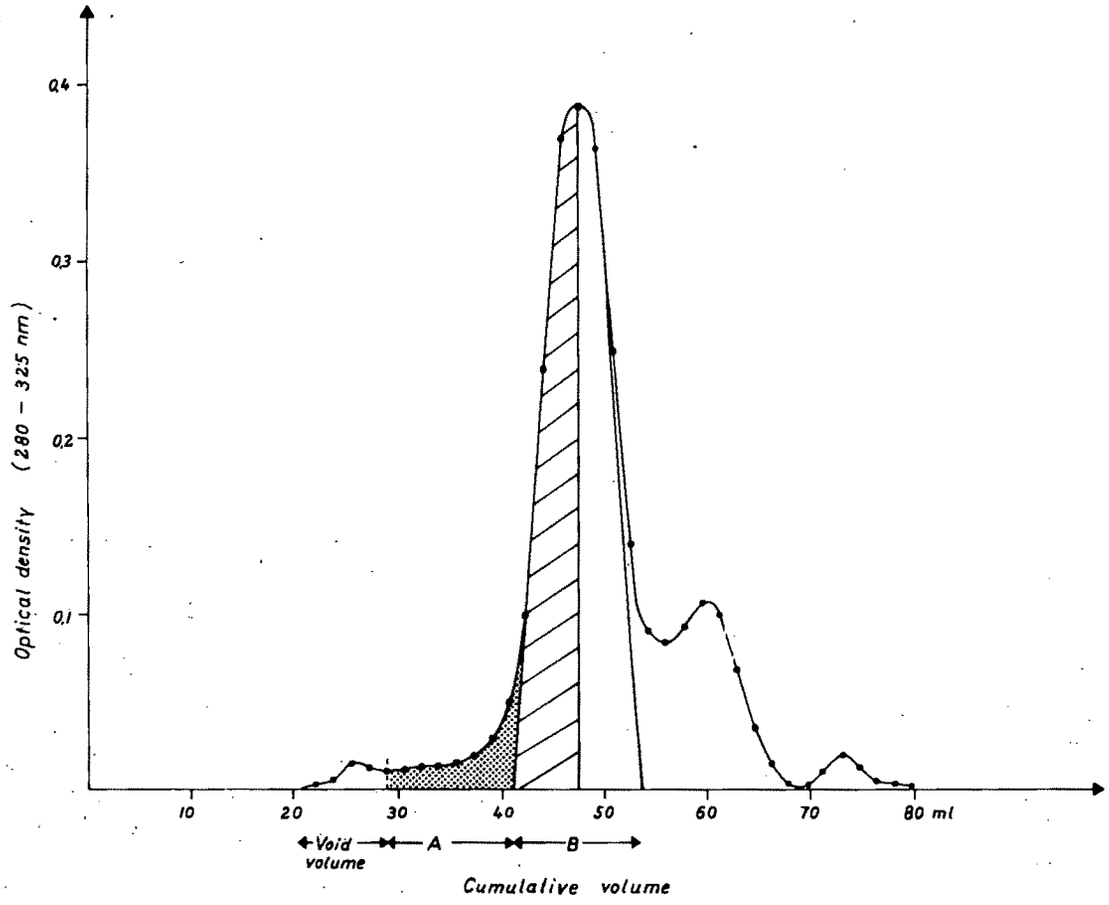

Fig. 1. Elution pattern following agarose gel filtration (Biogel A-15 m) of a β-alanine precipitated plasma sample during the early puerperium. Optical density (280-325 nm.) shown by the dotted curve. The cut of the eluate between the elution position of the void volume and the ascending part of the fibrinogen peak *(A)* is compared with the one of the fibrinogen peak *(B)*. The percentage of SFMC (in relation to the total fibrinogen content) is determined according to the formula: SFMC per cent = A × 100/A + B.

0.3M NaCl) using an extinction coefficient of fibrin in alkali as 15.87 ($E^{1\%}_{1cm}$).[4] The measurements were performed in duplicate and the evaluation of the precision of the assay method yielded a coefficient of variation attributable to the method of 2.8 per cent.

Purification procedure. Fibrinogen and its derivatives were precipitated from plasma with β-alanine. Crystalline β-alanine was added at 0° C. to the plasma specimen (2.5 ml.) up to a final concentration of 2.5M and the precipitate was redissolved in Tris-Cl-citrate buffer (pH 7.6) containing 100 KIU Trasylol per milliliter.[5]

Quantitative agarose gel filtration. A 4 per cent agarose gel filtration was performed with Biogel A-15 m spherical agarose, 100 to 200 mesh (Bio-Rad Laboratories, Munich, Germany). A 1 ml. sample containing 5 to 8 mg of protein was applied to a 1 by 90 cm. column and eluted with Tris-Cl-buffer, pH 7.6. The flow rate was 10 ml. per hour (1.6 ml. per fraction). Double determinations were performed by using two columns in parallel. The optical density of the fractions was measured at 280 and 325 nm. with a Hitachi 181 spectrophotometer. The elution position of the void volume of each column was determined by use of Dextran Blue and that of the fibrinogen peak by use of commercially available human fibrinogen (FFBH, Deutsche Kabi GmbH, Munich, Germany).

In earlier studies it was demonstrated that the presence of SFMC in plasma is evidenced by the elution of fibrinogen-related antigen (FR-antigen) material in a shoulder prior to the fibrinogen peak and that the material eluted in this range between the elution position of the void volume and the ascending part of the fibrinogen peak consists mainly of a component with the relative electrophoretic mobility of 0.28×10^{-5} cm.²/V × sec. in polyacrylamide gel.[2, 6] This cut of the eluate was planimetrically evaluated and compared with the one of the fibrinogen peak

Table I. Amount of soluble fibrin monomer complexes (SFMC) and of fibrinogen in plasma during the early puerperium and 3 months after delivery (mean ± standard deviation)

	Postpartum				*t test*	
	<12 hr. after delivery I	*2 days II*	*4 days III*	*6 days IV*	*a: I vs. V b: I-IV vs. V c: III vs. IV*	*3 mo. after delivery V*
SFMC (per cent of total fibrinogen content)	6.1 ± 1.5	6.2 ± 1.8	7.0 ± 2.0	6.0 ± 1.9	a: $p < 0.001$ b: $p < 0.001$ c: $p > 0.05$	3.3 ± 1.3
SFMC (mg. per 100 ml.)	27.4 ± 10.5	28.1 ± 12.0	29.1 ± 11.6	21.8 ± 9.8	a: $p < 0.001$ b: $p < 0.001$ c: $p < 0.05$	8.4 ± 3.4

(weight of the respective paper cut areas) (see Fig. 1). The percentage of SFMC in relation to the total fibrinogen content was determined according to the formula SFMC per cent = A × 100/A + B, where A is the area of the shoulder and B the one of the fibrinogen peak. The presence of FR-antigen material in the eluted fractions of the shoulder and of the peak was confirmed in certain cases by use of the staphylococcal clumping test (RKW 10, Behringwerke A. G., Marburg, Germany). The precision of the assay method was evaluated by double determinations. The coefficient of variation attributable to the method was 8.7 per cent. The absolute amount of SFMC in milligrams per 100 ml. of plasma was calculated by relating the relative amount of SFMC to the fibrinogen concentration in the respective plasma sample.

Statistical evaluation. Distribution of the data was evaluated by use of a probit type plot. Mean values and standard deviations were calculated and Student's t test for paired observations was utilized to compare the data from the early puerperium with those from 3 months after delivery. The Wilcoxon test for paired observations was additionally applied.

Results

The results of the determinations of SFMC and fibrinogen are summarized in Table I. During the immediate postpartum period and until day 6 of the puerperium the relative (per cent of total fibrinogen content) as well as the absolute (milligrams per 100 ml.) amount of SFMC remained essentially constant. The mean values of the relative amounts of SFMC varied between 6.0 and 7.0 per cent, the ones of the absolute amounts between 21 and 29 mg. per 100 ml. (mean and standard deviation of the average postpartum values collected from all patients, 6.3 ± 1.2 per cent; 27.6 ± 9.1 mg. per 100 ml.).

No statistically significant differences were observed until day 4. Between days 4 and 6 a statistically significant decline was observed for the absolute amount of SFMC (milligrams per 100 ml.) ($p < 0.05$) only.

The level of SFMC was considerably lower 3 months after delivery than in the early puerperium and was estimated at 3.3 ± 1.3 per cent of total fibrinogen content and at 8.4 ± 3.4 mg. per 100 ml. (mean ± S.D.). The differences between the values from the immediate postpartum period and those from 3 months after delivery (a) as well as the differences between the average postpartum values of each patient (b) and those from 3 months after delivery were statistically significant on a 0.001 level.

The fibrinogen content of plasma during the immediate postpartum period until day 6 of the puerperium remained at levels between 369 ± 97 and 445 ± 139 mg. per 100 ml. (mean ± S.D.). No statistically significant differences were observed in this collection period. Yet the values 3 months after delivery were considerably lower (269 ± 99 mg. per 100 ml., mean ± S.D.), and the difference between the immediate postpartum period and 3 months after delivery was statistically significant at the 0.001 level of probability (average of all postpartum values vs. values at 3 months after delivery: $p < 0.005$).

Though the optical impression of the probit type plot from the data of the first collection period indicated a normal distribution pattern, a nonparametric test was additionally applied. The Wilcoxon test for paired observations confirmed the results described above.

Comment

The data presented indicate that increased levels of SFMC are observed during the early puerperium as compared to 3 months post partum. Further identification of the material which was eluted in the shoulder

prior to the fibrinogen peak was not possible in this study because of the small amounts of protein eluted. Yet the similarity of the elution pattern after 4 per cent agarose gel filtration of the β-alanine–precipitated plasma samples with the one in earlier studies[2, 6] strongly suggests that the fractions from the shoulder contain predominantly a component with a dimeric structure which may occur either as a fibrinogen fibrin monomer complex or as a covalently linked dimer, and which has a relative electrophoretic mobility in 5 per cent polyacrylamide gel of 0.28×10^{-5} cm.^{2}/V × sec. ("0.28 derivative"). A fibrinogen derivative with the elution behaviour and the electrophoretic mobility of the 0.28 derivative was also observed after in vitro addition of small amounts of thrombin to plasma.[6, 7] The striking similarity between the in vitro findings and the observations in plasma samples from patients suggests that the 0.28 derivative is also in vivo induced by the effect of thrombin or of a thrombinlike enzyme on fibrinogen.

The "hypercoagulable" state of the puerperium with its increased incidence of thromboembolic episodes is thus well reflected by an elevated level of SFMC in vivo. It might be assumed that the SFMC described in this study is related to the cryoprofibrin characterized by Shainoff and Page.[8] Sherman[9] recently reported a considerably shorter half-life time for ^{125}I-cryoprofibrin in rabbits (13 hours) than for fibrinogen. If similar biological t ½ values in human subjects are assumed, the unaltered increased level of these products till day 4 of the puerperium would indicate that an increased formation of soluble fibrin is maintained over this period. This increased fibrinogen catabolism is additionally reflected by the elevated fibrinogen level in plasma. The slight, though statistically significant, decline of the absolute amount of SFMC (milligrams per 100 ml.) from day 4 to day 6 may signal the return of the increased fibrinogen catabolism to normal.

The planimetric evaluation of the gel filtration pattern tends, according to the procedure involved, to result in probably too high estimations, if the shoulder prior to the fibrinogen peak is very small. Therefore, the indicated level of approximately 3 per cent of the total fibrinogen content for a normal female 3 months after delivery could well be overestimated. Yet in this regard, it seems of interest to note that Hörmann and Ströder[10] already demonstrated oligomers of fibrin in a cold insoluble fraction from normal human plasma. An over-all coefficient of variation applicable to the method of 8.7 per cent seems to warrant a sufficient precision of the assay.

The presence of SFMC in plasma samples of pregnant or postpartum patients was also demonstrated by other techniques such as cryoprecipitation,[11, 12] serial dilution protamine precipitation,[11] or by ethanol gelation,[2, 13, 14] but a more direct and quantitative approach will probably lead to more definite conclusions.

The quantitative estimation of SFMC in the early puerperium as presented in this study indicates that a state of hypercoagulability can be evaluated by measuring the in vivo occurring, thrombin-mediated catabolic products of fibrinogen. This may be of help for the early diagnosis of venous thromboembolic disease. In addition, this evaluation of hypercoagulability may be of diagnostic value in cases of intrauterine growth retardation, as suggested by Frigoletto and his colleagues,[14] or of pre-eclampsia.[11] Together with the qualitative identification of high molecular weight derivatives of fibrinogen in plasma[15] it may also lead to a more detailed description of the degree of disseminated intravascular coagulation in a given case.

Indomethacin induces rat uterine contractions in vitro and alters reactivity to calcium and acetylcholine

J. L. HARGROVE
D. NESBITT
M. J. GASPAR
L. C. ELLIS
Logan, Utah

The initial contractions of uteri in vitro from castrated, estrogen-treated rats, were markedly diminished following replacement with fresh bathing medium. Indomethacin and aspirin (10^{-5} to 10^{-4}M) strongly stimulated such quiescent preparations and reduced their subsequent responsiveness to Ca^{++}. Reintroducing the initial bathing medium (which contained prostaglandin-like material), or adding prostaglandin $F_{2\alpha}$ to the fresh medium, initiated uterine contractions and restored responsiveness to calcium ion. Injections of indomethacin into castrated, estrogen-treated rats reduced initial in vitro uterine motility, abolished production of prostaglandin-like compounds, and prevented either indomethacin, aspirin, or Ca^{++} from stimulating uterine contractions. Uterine responsiveness to acetylcholine in vitro was significantly reduced in rats pretreated with indomethacin.

PROSTAGLANDINS are now thought to be major intrinsic regulators of uterine contractility.[1] Prostaglandin production may increase following activation of the uterus by estradiol,[2] and prostaglandin $F_{2\alpha}$ levels are dependent on the stage of the menstrual cycle in the human Fallopian tube.[3] Two established inhibitors of prostaglandin synthesis, aspirin and indomethacin,[4] have been reported to abolish uterine contractions in vitro.[5, 6] They also prolong parturition in the rat[7] and the monkey,[8] presumably by blocking endometrial prostaglandin synthesis. Salicylates, however, elicit an apparently contradictory result—premature parturition in mice.[9] Informal reports suggest that aspirin also may precipitate abortion in women during early pregnancy.[10]

Prostaglandin production often contributes to spontaneous contractions that smooth muscles develop in vitro. Adding fresh bathing medium may remove these prostaglandins, abolish or reduce initial motility, and alter the response of a smooth muscle preparation to calcium ion and other stimulatory agents.[11] Indomethacin affects not only prostaglandin synthesis but also calcium balance.[12] We, therefore, investigated the effect of changing the Tyrode's solution prior to administering indomethacin, aspirin, Ca^{++}, or prostaglandin $F_{2\alpha}$ to rat uterine preparations in vitro. We also studied the effects of indomethacin injections prior to sacrifice on rat uterine contractility, prostaglandin production, and responsiveness to acetylcholine.

Materials and methods

Two groups of six ovariectomized female rats received 10 μg per kilogram of estradiol benzoate in 0.2 c.c. of corn oil daily for 5 days. One of the groups also received 10 mg. per kilogram of indomethacin in corn oil intraperitoneally during the final 2 days and 1 hour prior to sacrifice. The uteri were excised and suspended in all-glass, water-jacketed muscle warmers containing 20 ml. of oxygenated Tyrode's solution (37° C.) immediately after the rats had been killed by decapitation. Contractions were recorded isometrically against a tension that was equivalent to less than 0.5 g. The uteri were incubated for 30 minutes to allow recovery from thermal or operative shock, and fresh

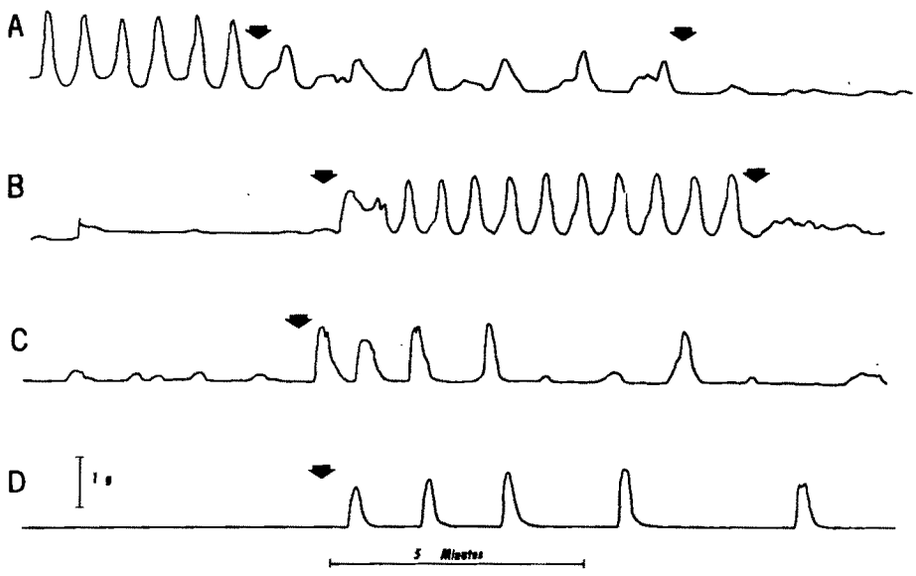

Fig. 1. *A*, Reduction of rat uterine contractility in vitro following two changes of the bathing medium (indicated by arrows). *B*, Restoration of contractility after initial medium from an active preparation was added back to quiescent preparation (first arrow), with reduction in activity after one rinse (second arrow). *C*, Contractions induced by addition (at arrow) of 28 μM indomethacin, followed by tachyphylaxis. *D*, Contractions in response to 0.10 mM. aspirin (arrow) followed by tachyphylaxis. medium was added prior to treatment of inactive preparations with pharmacologic agents. Indomethacin, aspirin, and $PGF_{2\alpha}$ were dissolved in ethyl alcohol and added to the bathing media in aliquots of 5 to 100 μl. $CaCl_2$ (5 mM.) was dissolved in 20 ml. of Tyrode's solution and put directly into the muscle warmer.

Two additional groups of four rats were similarly ovariectomized and treated with estradiol (10 μg per day for 5 days); one such group received indomethacin (10 mg. per kilogram) on the final 2 days and 1 hour before sacrifice. Uteri from these animals were suspended in Tyrode's solution as stated above and used to generate log dose-response curves in response to acetylcholine (Sigma).

Prostaglandin extraction and chromatography

Initial bathing media (20 ml. volumes) were collected following the 30 minute incubation period and stored at −20° C. Media from four preparations of each treatment group (estradiol alone, or indomethacin plus estradiol) were pooled, acidified to pH 3.0 with HCl, and partitioned three times against equal volumes of distilled ethyl acetate. The organic solvent was collected and dried at 40° C. in rotary evaporators. Residues were taken up with three 5 ml. volumes of ethyl acetate, transferred to 15 ml. capacity test tubes, and evaporated under nitrogen gas. Lipidic material was dissolved in 50 μl of ethanol and spotted on chromatographic plates coated with a slurry (0.25 mm. thick) of 30 Gm. of silica gel H (Merck) and 6 Gm. of silver nitrate. Plates containing authentic prostaglandin were developed with phosphomolybdic acid for confirmation of the R_f values reported by Green and Samuelsson.[13] The silica gel coat was scraped from the plates on which the extracts had been spotted in zones corresponding to these R_f values, transferred to centrifuge tubes, and eluted three times with 5 ml. aliquots of methanol to recover any prostaglandin-like material. This solvent was then evaporated under nitrogen gas at 40° C. To remove salts from the residue, the material was redissolved in 5 ml. portions of phosphate buffer (pH 3.0) and partitioned three times against equal volumes of ethyl acetate. After evaporating the organic solvent, the residues were taken up in Tyrode's solution for bioassay on the rabbit testicular capsule as reported.[14] To estimate the per cent recovery of prostaglandins, 0.5 μg of PGE_1 and 1.0 μg of $PGF_{2\alpha}$ were added to Tyrode's solution; this fluid was extracted and chromatographed in the same manner as the uterine bath fluid prior to bioassay.

Results

Uteri from estrogen-treated rats contracted autorhythmically in vitro at a greater amplitude than those treated with estrogen and indomethacin (Table I). The contractions were markedly diminished or

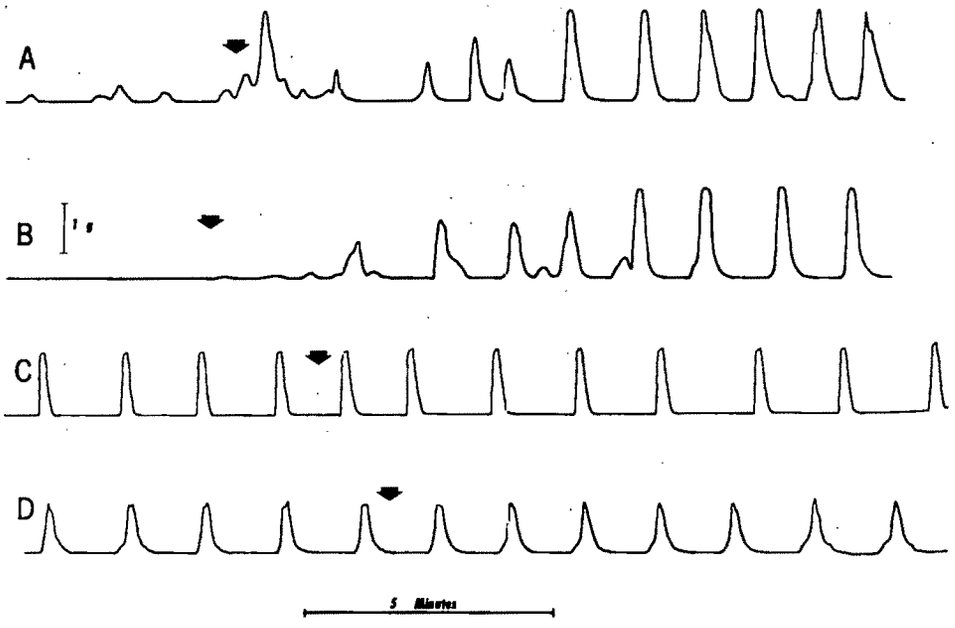

Fig. 2. *A*, Stimulation of inactive rat uterus by 0.14 mM. indomethacin (added at arrow). *B*, Stimulation of inactive rat uterus by 0.28 mM. aspirin (added at arrow). *C*, Lack of inhibition of rat uterine contractility following addition (at arrow) of 0.035 mM. indomethacin. *D*, Lack of inhibition of actively contracting rat uterus after addition (at arrow) of 0.056 mM. aspirin.

totally abolished by a change of the bathing medium, but were restored if the original medium was reintroduced (Fig. 1, *A* and *B*). Extraction of the original media for acidic lipids followed by chromatography and bioassay demonstrated that media from estrogen-treated preparations contained prostaglandin-like material in zones corresponding to authentic prostaglandins $F_{2\alpha}$, $F_{1\alpha}$, and E_1, but not E_2. However, indomethacin-pretreated preparations were less motile than untreated units, and produced no detectable stimulatory material (Table I).

The contractile responses of quiescent preparations to aspirin or indomethacin proved to be dose-dependent, with a brief stimulation followed by tachyphylaxis seen at 10^{-5} to 10^{-4}M final concentrations (Fig. 1, *C* and *D*). At concentrations greater than 10^{-4}M, both aspirin and indomethacin initiated contractions in previously inactive preparations (Fig. 2, *A* and *B*); this motility persisted for at least 30 minutes in vitro. Replacing the media with fresh Tyrode's solution abolished this contractility (data not shown). However, when actively contracting uteri were treated with doses of these compounds from 3.5×10^{-5} to 1.4×10^{-4}M, neither marked stimulation nor inhibition was observed (Fig. 2, *C* and *D*). Inactive preparations from indomethacin-pretreated animals responded to neither aspirin nor indomethacin with contractions (Table II).

Uteri from estradiol-pretreated rats responded to Ca^{++} with increased contractility; this phenomenon was particularly evident in quiescent, rinsed preparations (Fig. 3, *A*). Uteri from indomethacin-pretreated rats, however, reacted little to the addition of Ca^{++} to the medium (Fig. 3, *B*; Table II). In every case 7×10^{-7}M $PGF_{2\alpha}$ completely restored uterine responsiveness to Ca^{++} (Fig. 3, *C*). Ethanol (10 to 100 μl) did not markedly affect either spontaneously active or inactive, rinsed preparations (Fig. 3, *D* and *E*).

Table I. Initial amplitude of contraction and prostaglandin-like material recovered from the bathing media of uteri from estradiol-treated (10 μg per day) and estradiol plus indomethacin-treated (10 mg. per kilogram) rats.

	Estradiol ($n = 6$)	*Estradiol and indomethacin* ($n = 6$)	*P*

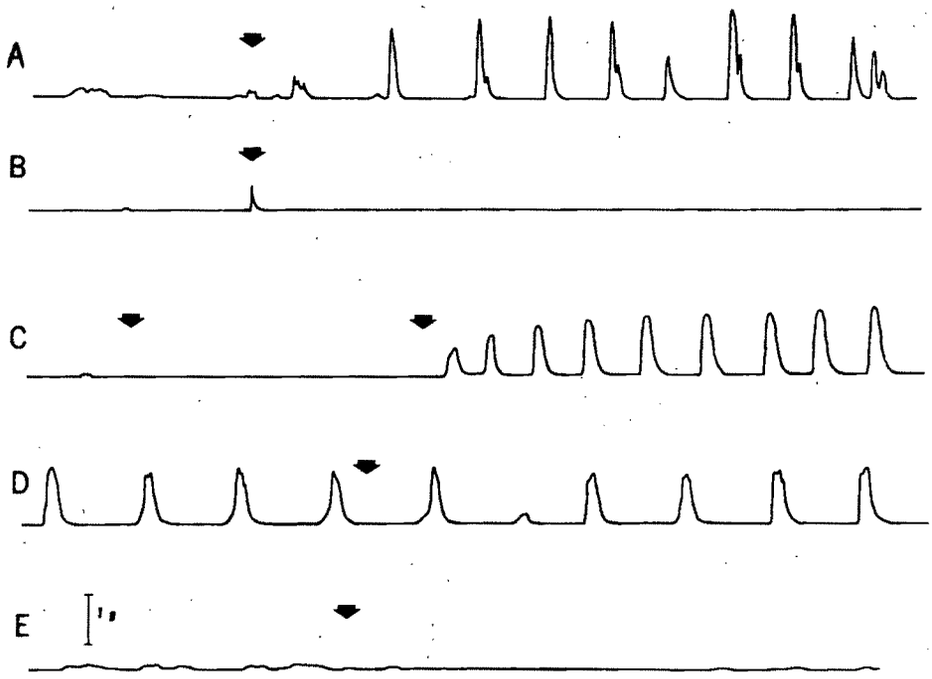

Fig. 3. *A*, Stimulation of rat uterine contractility by 7 mM. $CaCl_2$ (added at arrow). *B*, Lack of effect of 7 mM. $CaCl_2$ (arrow) on quiescent uterus from indomethacin-pretreated rat. *C*, Lack of effect of 7 mM. $CaCl_2$ (first arrow) followed by contractions induced by addition of 71 nM. prostaglandin $F_{2\alpha}$ (second arrow). *D*, Slight inhibition of actively contracting rat uterus caused by addition of 50 λ of ethanol (42 mM. final concentration) at arrow. *E*, Lack of stimulation of quiescent rat uterus by 50 λ of ethanol added at arrow.

Pretreatment of spayed female rats with indomethacin (108 mg. per kilogram) prior to sacrifice significantly reduced the responsiveness of uterine preparations to acetylcholine ($p < 0.05$; Fig. 4, *A* and *C*) when compared to the response of uteri from control animals. Addition of prostaglandin $F_{2\alpha}$ to the media at threshold levels (7×10^{-9}M) failed to increase sigficantly the response to acetylcholine of uteri from animals pretreated with indomethacin ($p > 0.20$; Fig. 4, *B*).

Comment

Nonsteroidal, anti-inflammatory drugs may inhibit smooth muscle contractility. Northover[12] has attributed this effect to an alteration by indomethacin of Ca^{++} binding by subcellular membranes. Other workers have found prostaglandin output to decrease following indomethacin or aspirin treatment of rat uterine and other preparations.[5, 6] In addition, cyclic AMP production increases in rat gastric mucosa in the presence of aspirin.[15] We here report an additional, stimulatory effect of these drugs on smooth muscle contractility, in consonance with aspirin's ability to bring about premature parturition in mice.[9] One plausible cause of increased motility would be a displacement of Ca^{++} from subcellular membranes, leading to temporarily high levels of unbound, intracellular Ca^{++}. Reduced motility would be expected following an efflux of this ion from smooth muscle cells. Our observations that uteri from indomethacin-pretreated rats are initially quiescent in vitro, and that these uteri respond to either acetylcholine or Ca^{++} at a low level, accord with such a train of events.

In a previous report, Vane and Williams[6] did not find any change in uterine sensitivity to acetylcholine after indomethacin treatment in vitro. These workers, however, added the indomethacin directly to the uterine bathing medium for brief periods (30 to 90 seconds), whereas we injected rats with this compound intraperitoneally for 2 days prior to the experiment. In addition, their failure to observe increased contractility could be due to their use of preparations that were already motile as a consequence of prostaglandins present in the bathing medium. By first rinsing the uteri with fresh Tyrode's solution, we reduced contractility, thereby increasing the sensitivity of the preparation to aspirin or indomethacin. Our present results support the conclusion drawn from previous studies[5, 6] concerning the contribution of prostaglandins to smooth muscle motility in vitro, since uteri from rats

Table II. Contraction frequency (10 minute interval) of uteri from estradiol-treated (10 μg per day) rats vs. those from estradiol plus indomethacin-treated (10 mg. per kilogram) rats in response to stimulation by indomethacin, aspirin, and $CaCl_2$

pretreated with indomethacin produced no prostaglandin-like material and were inactive. In addition, prostaglandin $F_{2\alpha}$ always restored uterine contractions and responsiveness to Ca^{++}. As did Vane and Williams,[6] we failed to detect any prostaglandin E_2 in the media from actively contracting preparations, although other PG's were present. We found no direct inhibition of active uteri by either aspirin or indomethacin, however. We conclude, therefore, that reports of immediately reduced motility may be attributable to rinsing the preparations, thereby removing any prostaglandins that may already have been present. Alternatively, indomethacin or aspirin may directly inhibit uterine contractions, regardless of the presence of prostaglandins, at the lower concentrations used by other researchers.[5, 6]

The evidence presented here suggests that, in addition to exerting inhibitory effects on prostaglandin synthesis, indomethacin and aspirin directly affect smooth muscle. Observed activation of uterine musculature by high doses of anti-inflammatory compounds may explain the premature induction of labor by indomethacin or aspirin,[9, 10] whereas their reported delay of parturition[7, 8] may be due to their effects on prostaglandins, cyclic AMP, or Ca^{++} balance. It now seems apparent that the actions of indomethacin and aspirin may not be totally explained by their inhibiting prostaglandin synthesis.

We thank Dr. John E. Pike of the Upjohn Co., Kalamazoo, Michigan, for the prostaglandins, and Dr. Horace Brown of Merck, Sharp and Dohme, Rahway, New Jersey, for the indomethacin used in these studies.

Prognostic value of antenatal screening

JAMES WALKER, M.D.

Dundee, Scotland

Rates of stillbirths and first-week deaths have fallen steadily in Scotland in the last 30 years. Seventy-five per cent of all such deaths in the City of Dundee now follow the clinical condition of "antepartum hemorrhage," "premature labor," "poor fetal growth," and "lethal deformity," all of which are conditions associated with poorer environmental conditions which are worse in larger industrial cities. Therefore, we are concerned with these clinical situations and with fetal death and subsequent morbidity of children born in those situations. This paper describes in summary a planned study of antenatal screening with assessment of fetal placental hormones, fetal biparietal diameter, and other determinants of fetal well-being, the growth of the child and weight at birth, the quality of the labor, the neonatal state, and the ultimate quality of the child.

CERTAINLY, SINCE 1940, there has been in Scotland a steady and continuous fall in the perinatal mortality rate (stillbirths after 28 weeks plus first-week deaths).

The reasons for this fall are a steady improvement in the health of the community (although nearly 25 per cent of women of reproductive age are still less than 5 feet, 1 inch in height) some change in the age and parity distribution, and, of course, greatly improved obstetric and early neonatal care.

Value of antenatal screening

In the City of Dundee, there was a high birth rate in 1960 to 1963 because more women were having third, fourth, or fifth babies. The birth rate has now fallen to 12.3 per 1,000 in 1973, because of fewer women having more than two children. There is a fall in the number of first pregnancies possibly because of some postponement of child-bearing, but 35 per cent of all births are now to primigravidas and 30 per cent are second pregnancies — only 7 per cent are fifth or later pregnancies. Forty-five per cent of our mothers are under 25 years of age, and only 4.7 per cent are over 35.

However, it is possible to evalute the *clinical* situation in which improvement has occurred only when each individual death is classified by the clinical cause responsible for the death.[1]

Years	*DEF*	*APH*	*PU*	*MD*	*TOX*	*TR*	*MU*	*O*
1956-1959	8.8	5.7	5.3	2.8	2.5	3.0	3.6	1.1
1960-1963	9.3	4.7	5.3	1.7	1.4	1.7	3.1	1.9
1964-1968	6.1	3.4	3.8	1.6	0.7	1.1	2.4	1.3
1969-1973	5.1	2.5	3.0	1.0	0.2	1.2	1.5	1.3
		10.6			5.0			
1974	8.2	0.9	5.0	0.45	0.9	0.9	1.4	1.8
		72%						

DEF = Lethal deformity; APH = antepartum hemorrhage; PU = premature unknown; MD = maternal disease; TOX = toxemia; TR = trauma; MU = mature unknown; O = other.

Such a classification has been applied to national death on a limited scale, but intensive analysis of perinatal deaths in the cities of Aberdeen, Dundee, and, more recently, Glasgow has been undertaken by the technique. In Dundee, it will be seen that, since 1956, there has been a steady fall in death rates in all clinical cause groups (Table I). Provisional figures for 1974 show that 72 per cent of all perinatal deaths are in the clinical cause group of "lethal deformity," "antepartum hemorrhage," and "premature unknown" and that 25 per cent of all deaths are in fetuses weighing less than 1,000 grams.

Comparison of clinical death causes and rates in infants of unselected Glasgow women with those of "selected" Dundee married women having a single pregnancy (Table II) show that the major difference between the two is in the same groups, i.e., the

"environmental" group plus the "mature unknown" group which is often associated with late pregnancy failure. Causes easily amenable to obstetric care are roughly equal in the two cities.

Perinatal death of the mature infant is no longer a serious clinical problem, and we are now concerned almost entirely with the environmental problems of lethal deformity, premature labor, and retarded intrauterine growth and with death resulting from these causes or with the "quality" of the child surviving these situations. Therefore, we must study all these events of pregnancy and labor which might influence physical and mental growth and development of the fetus or which may physically damage its mechanisms or its normal state.

Labor and the events of labor as producers of risk are covered by intensive monitoring systems. However, perinatal death associated with labor and the immediate postnatal period has a rate (corrected for deformity) of some 3 per 1,000, and it is clear that intensive monitoring of labor will save the lives of very few babies indeed. However, it may minimize morbidity. The intelligent concern of the obstetrician is, as we have said, now centered more on the "quality of the child produced" and on those events of pregnancy and labor which may influence that quality. There is much evidence that the fetus in a poor growth situation is, of course, particularly at risk of long-term handicap from added labor risk.

It has become customary to talk of the "at-risk pregnancy" selected on clinical grounds for special antenatal and labor care. Multiple antenatal and labor monitoring systems are in the process of evolution and evaluation largely at random in the somewhat frantic search for guidelines to the well-being of the individual fetus and as a measure of the stress to which he has been subjected. In view of this, it was decided, in 1974, by the Departments of Obstetrics and Gynaecology, Clinical Chemistry, and Paediatrics, of the University of Dundee, that a systematic study should be developed of the clinical value of the various biochemical, physical, and physiologic tests available to us.

Three groups of patients were selected: (1) those with a bad obstetric history, especially of pregnancy failure; (2) a mixed group of primigravidas which were divided into a group likely to provide normal pregnancy (tall, well-nourished, and 20 to 30 years of age) and a group in which poor fetal growth and prematurity were likely (low social class, small, and under 25 or over 35 years of age).

The screening study

Antenatal assessments. Urine samples (24 hours) were analyzed for "total" estrogen content at 30, 34, and 38 weeks as a check against other findings. Blood samples taken after 16 weeks regularly throughout pregnancy and during labor for estimations (mostly by radioimmunoassay techniques) of human chorionic gonadotropin, human placental lactogen, estriol, estradiol, progesterone, and alpha fetoprotein (others in special cases). The biparietal diameter of the fetal head was determined by ultrasound at similar stages in all pregnancies.

During labor. Maternal blood samples, electronic monitoring of the fetal heart rate, and intrauterine pressure were recorded, and the scalp blood pH was measured if necessary. Maternal uterine vein samples were taken where the abdomen was open.

At birth. Umbilical vessel samples were taken for hemoglobin and haematocrit, blood gas, and blood hormone estimations as in the mother. Babies were then automatically specially followed up by the neonatal pediatric service. A long-term follow-up is being undertaken by the pediatric assessment organization already mounted within the city.

To date, we have screened approximately 150 mothers. Their babies have also had unbilical vein samples and are now in pediatric follow-up. About a further 100 will be delivered in the next six months. We propose to cease the screening by late summer of 1975, and extensive analyses will be made.

Results

Sample preliminary results of three analyses are presented.

Alpha fetoprotein. Alpha fetoprotein was demonstrated in serum from the human fetus in 1956,[2] and, in 1967, its source was noted to be the fetal liver in the human subject.[8] (The possibility of some production by the human yolk sac was not fully investigated; in the rat, the yolk sac is a common source.)

It was shown[4] that in anencephalic pregnancy the

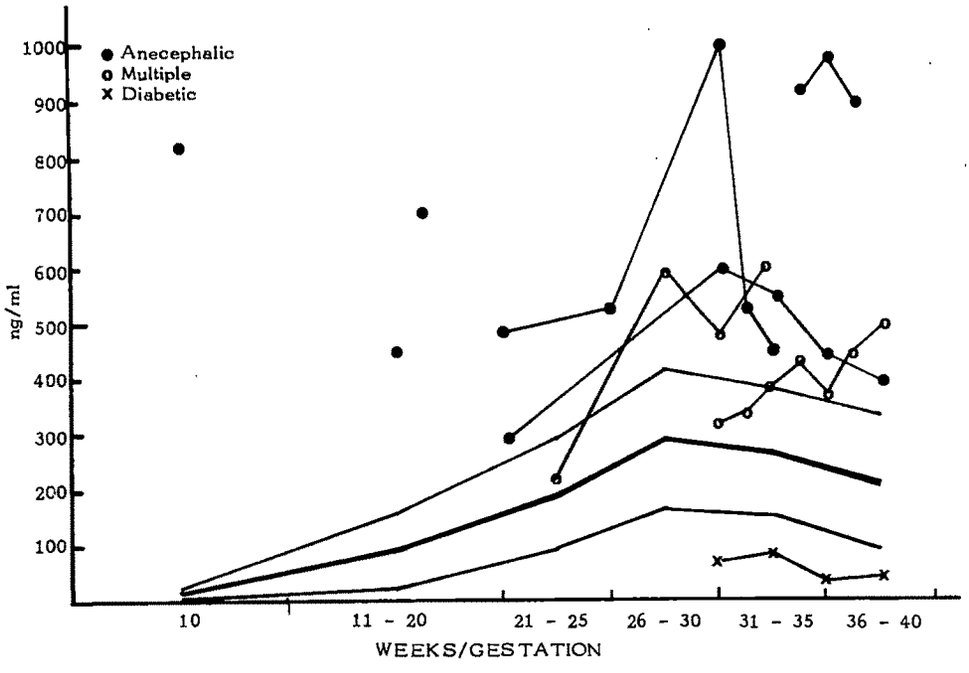

Fig. 2. Alpha fetoprotein in maternal serum—normal pregnancy (mean ± one standard deviation), pregnancy with anencephaly, and multiple pregnancy.

alpha-fetoprotein concentration in the amniotic fluid was well above the normal range before 25 weeks of gestation but that the difference from the normal range was not quite so clearly defined after that time. Brock and Sutcliffe[4] were the first to suggest that alpha fetoprotein could act as a *marker molecule* to select pregnancies where termination would prevent the birth of an anencephalic child or a child severly affected by spina bifida.

Subsequent evidence suggests that high readings in the amniotic fluid are seen only in the serious degrees of spina bifida and not in minor degrees, especially in closed spina bifida (15 per cent of the total) which will respond to postdelivery therapy. High readings in

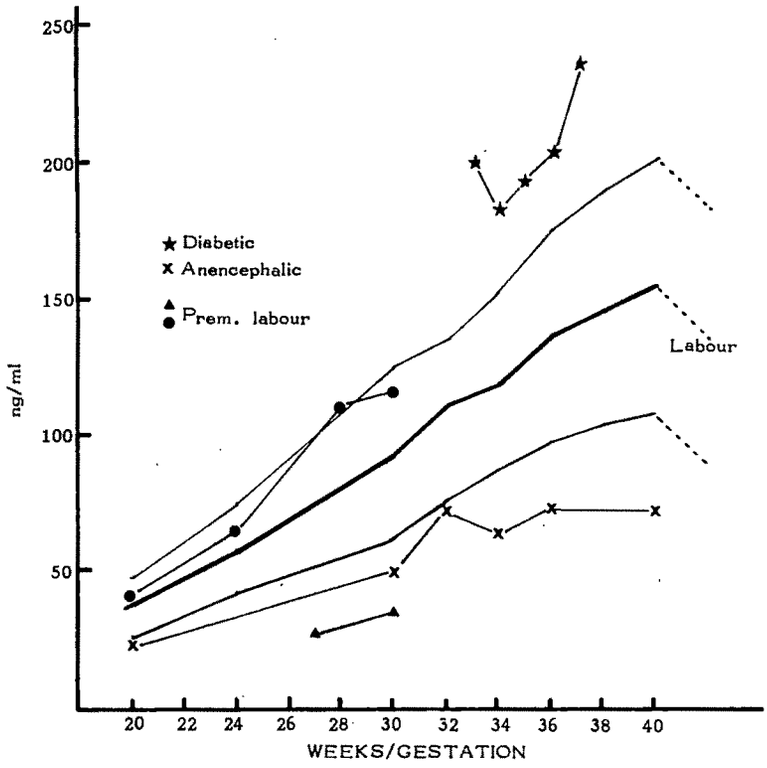

Fig. 3. Progesterone in maternal plasma (mean ± one standard deviation) in normal pregnancy and in some abnormal conditions.

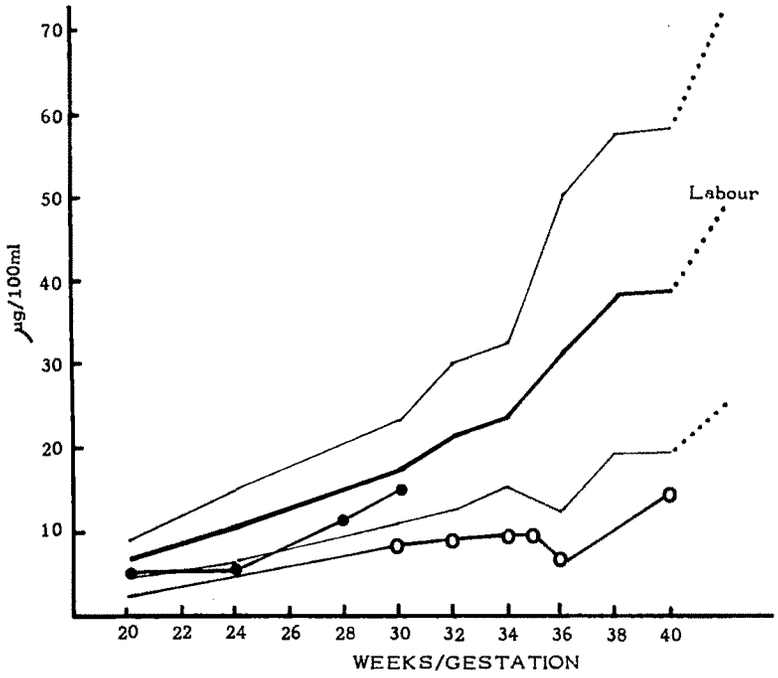

Fig. 5. Estriol levels in maternal plasma in pregnancy with anencephaly.

amniotic fluid are seen in congenital nephrosis[11] and in other central nervous system anomalies.

We have previously shown that there are two varieties of clinical anencephaly,[16] that occurring in first or second pregnancies (often associated with previous abortion), which tends to repeat several times, and that occurring sporadically in later pregnancies. Those who have had a damaged child before are at high risk and amniocentesis is justified, but the very large majority of women with an anencephalic or spina bifida–affected child have not had a previous child with the same condition. Therefore, screening by a blood test is essential. We have begun this screening and now take serum at all first clinic visits (10 to 20 weeks). High readings are expected in some 2 per cent of pregnancies, and in those amniocentesis is justifiable; however, anencephaly should be checked if possible by estriol excretion or by ultrasound and multiple pregnancy should be excluded.

In our own city, the rate of open spina bifida or anencephaly is likely to be about 7 per 1,000. Amniocentesis would be justifiable in cases with a high alpha fetoprotein level, since nearly one third of these are likely to have a child sufficiently abnormal to justify termination.

Preparation for screening test. Purified alpha fetoprotein was prepared by Mr. John Young in our laboratories from human fetal serum at 14 to 18 weeks' gestation.

Anti–alpha fetoprotein prepared in rabbits was obtained from Behringwerke. The radioimmunoassay was performed with the double-antibody method; the second antibody (a donkey anti-rabbit globulin) was obtained from Wellcome Laboratories.

Fig. 1 is a diagrammatic figure of the likely findings: (1) amniotic fluid, peak level at 14 weeks and by term may be barely detectable; (2) fetal serum, peak level also about 14 weeks of pregnancy and the fall is similar in time and degree to that in amniotic fluid; (3) maternal serum, levels are low at 14 weeks and rise to peak at 30 weeks, then decline.

Our own results in normal pregnancies (Fig. 2) show the expected pattern. It is important to see that in anencephaly (closed circles) very high readings before 20 weeks are clearly distinguishable from the normal. Levels change little in the presence of anencephaly so that by 30 weeks serum levels are very close to the upper range of normal.

Open circles show a twin pregnancy which at 30 weeks or so is indistinguishable from anencephaly. In diabetic pregnancy, readings are very low. Readings at 16 weeks should screen out anencephaly/spina bifida.

Progesterone. Progesterone produced by the placenta is essential to the fetus as a building block for the adrenal corticoids, and much profit might be gained from a study of fetal response to stress in association with the available levels of placental progesterone. High levels of corticosteroid of fetal origin are

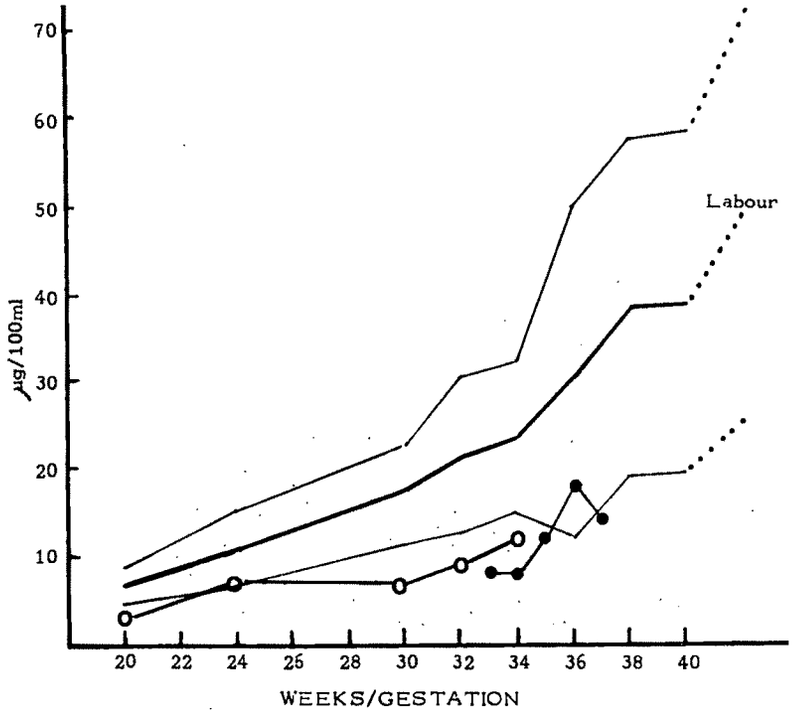

Fig. 6. Estriol levels in maternal plasma in a patient with diabetes.

associated with labor at term, and there must be an association with progesterone. Therefore, we are concerned with progesterone but still doubtful of its real role.

Our laboratory[9] demonstrated plasma levels running from 70 ng. at 20 weeks to a mean at 38 weeks of some 140 ng. although the scatter was wide (50 to 250 ng.). There was no rise or fall in the mean after 36 weeks.

Others[14] have shown mean levels rising from 50 to 150 ng. per milliliter from 20 to 34 weeks and then a clear fall to a mean of 100 ng. in the next few weeks until labor, but this fall was not found by all workers.[12]

Our most recent results are seen in Fig. 3. The mean level rises from 37 ng. per milliliter at 20 weeks steadily and *without a fall* to 154 ng. at 40 weeks (114 to 194 ng. ± one standard deviation).

A *diabetic* subject had very high readings in the blood, confirming the findings of others,[3] and some of the patients with *anencephalic* fetuses have low levels. Patients with *premature labor* had mixed readings.

The mean level of the maternal peripheral blood in the first stage of labor is a little lower than the term reading, but this is not uniform in the individual case as I[15] have shown previously.

Determination of the full significance of progesterone levels and those of its associated metabolites and of the ratio of estrogens (estradiol-17β and estriol) requires further study.

Estriol. The value of estimation of maternal urinary estriol in the antenatal care of women with hypertension syndromes in pregnancy,[7] in poor growth situations, and as an occasional monitor for anencephaly, congenital hepatitis, and the adrenal deficiency syndrome is undoubted.[6]

Estriol itself has no assignable function. It arises primarily - from maternal acetate by steps well known to us, from progesterone, and from maternal placental estradiol or estrone.

It is noted in studies from our biochemical medicine laboratory (Fig. 4) that levels of plasma estriol rise rapidly in late pregnancy. A rise has been shown by us previously with the use of gas-liquid chromatography (GLC) instead of radioimmunoassay.[5]

The clinical biochemists for this study used the technique originally described by Wilson[17] which is a modification of the technique of Gurpide and associates.[10] The antiserum itself is nonspecific, but adequate partitioning should remove estradiol, estrone, and other interfering estrogens. The assay as shown by GLC should then be specific for estriol and measure total conjugated, nonconjugated, protein-bound, and non–protein-bound hormones. The results shown here are roughly double those quoted by Wilson, and we are not entirely happy that our results are, in fact, totally specific but they are of practical clinical value.

Plasma estriol in this study rises rapidly for a mean of 6.4 μg per 100 ml. at 20 weeks to nearly 40 μg by term. In early labor, the level is even higher. Note the special

levels seen in those mothers with premature labor, poor growth of the fetus,[13] anencephaly (Fig. 5), and diabetes (Fig. 6). This promises to be a very useful tool.

It is interesting to note that alpha fetoprotein is likely to bind estrogen strongly and that the period of fall of alpha fetoprotein levels is close to that at which estrogen increases in concentration, again over a period of maximum blood volume.

Comment

This is a very sketchy outline of a preliminary report of an extensive study.

When we have complete studies, we should be able to correlate fetal well-being with the whole battery of tests as well as labor onset and the pattern of labor with the ranges and ratios of various hormones. Fetal levels at delivery will be available as will fetal blood gas information. Testosterone in the infant at birth will be followed into three-month testosterone levels and related to the stress situation. The infants will be followed up by Dr. Cecil Drillien and her research team. Perhaps in a year or so we may weave a series of stories from our material.

Discussion

DR. JOHN B. MONTGOMERY. Philadelphia, Pennsylvania. I was impressed by Professor Walker's statistics which showed that perinatal deaths in Scotland have declined from 68 to 25 in each 1,000 births over a period of 30 years. This amazing decline is attributed to improvement in the health of the community, some decrease in parity, and improved obstetric care. This is in striking contrast to the rate in my own city of Philadelphia where the perinatal mortality rate has increased from 42 to 61 deaths per thousand births during the past 20 years. This dismal figure is, of course, associated with our shifting population, the increasing percentage of non-whites, an illegitimacy rate of 26 per cent, and other factors relating to population and geography.

By identifying the clinical cause of each perinatal death, Professor Walker has revealed that 72 per cent of the perinatal deaths in Dundee and in Glasgow are due to fetal deformity, antenatal hemorrhage, prematurity, and factors causing intrauterine fetal death. These losses cannot be prevented by obstetric care or intensive monitoring of labor.

Incidentally, the high rate of lethal fetal deformity (8.2 per 1,000 births) is apparently peculiar to Dundee and to Scotland. It contrasts sharply with the rate of 3 per 1,000 reported in Philadelphia in 1973.

Professor Walker accepts the use of intensive monitoring during labor but believes that this will save the lives of very few babies in Scotland. I suspect that its usefulness will prove to be far greater in our country, especially in those areas where we continue to em-

phasize childbirth without pain, elective induction of labor with oxytocin, heavy analgesia during labor, and operative delivery.

The real importance of Professor Walker's paper relates to his carefully planned cooperative study of the value of a variety of tests now available to us in studying the growth and development of the fetus. This area of study obviously could produce vitally important information regarding uncontrollable perinatal deaths which are of great concern to Professor Walker and to all obstetricians. The plan of study that he has presented appears to be logical and practical. The careful monitoring of these parameters of fetal growth and development throughout pregnancy in a sizable series of patients is a major effort involving many people and a great deal of work. The preliminary data that Professor Walker has presented from three important areas verify and expand some current concepts and indicate that much more extensive information will be available following completion of the current physiologic monitoring program. Correlation of those data with the quality of the baby produced and with the subsequent growth and development of the child should produce much new, valuable, and possibly startling information.

DR. E. STEWART TAYLOR, Denver, Colorado. Professor Walker has given the elements of modern prenatal care which comprise the new clinical science of perinatology. The elements that are most useful, I think, and in fact are almost indispensible to the operation of a modern obstetric unit are as follows: (1) serum estriol determinations, (2) amniotic fluid/creatinine levels, (3) lecithin/sphingomyclin ratios, (4) ultrasonic evaluation of the fetus for growth and development and for detection of congenital abnormalities in indicated situations, (5) the availability of genetic amniocentesis for study and detection of karyotype or chemical abnormalities, (6) availability of electronic and chemical fetal monitoring during labor, and (7) an intensive care nursery. Approximately 11 per cent of prenatal patients of an average service will require biochemical, ultrasonic, or genetic study during the prenatal course. These tests have to be done in specialized laboratories. Approximately 20 per cent of patients need to have electronic or biochemical monitoring during labor. We have found that 4 per cent of newborn infants in the State of Colorado require the availability of, or transfer to, an intensive care nursery. The staff must be composed of specially trained people.

The simple listing of these seven added essentials to modern obstetric care is not enough. In order to provide these services, a hospital must have at least one full-time consultant present who can interpret the data that come from the specialized laboratories and must have a team in the labor and delivery area that can evaluate and apply the information gained from the fetal monitoring. Most important of all, I think, is a well-equipped and well-staffed intensive care nursery facility where early diagnosis and treatment of diseases of the newborn infant can be carried out by nurses and pediatricians who are also neonatologists.

I enjoyed Professor Walker's review of the experience in Scotland very much. According to his statistics, only 25 per cent of the problem of perinatal loss is solvable by the acts of obstetricians; 75 per cent of the problem is social or genetic and beyond the scope of our instrumentations, laboratories, techniques, and decisions.

DR. KAMRAN S. MOGHISSI, Detroit, Michigan. I think that perhaps Dr. Taylor raised a very important point. We know that socioeconomic problems are having a great impact on perinatal deaths. Is Professor Walker able to tell us whether he can break down the socioeconomic subgroups contributing to each one of his reported factors in perinatal death? And, if so, how will he go about correcting such factors?

DR. A. BRIAN LITTLE, Cleveland, Ohio. I have an innate admiration for the British in that they have regionalized obstetric care. There are also attempts being made to regionalize obstetric care in this country. Although we are far behind, Professor Walker's presentation will add stimulus.

I would like to emphasize some points that he made. The first is cost. It has been simple in Britain and in Canada as health care costs gradually reached the gross national product and some decisions had to be made. For example, one of our colleagues recently referred to the large number of blood estriol determinations for prenatal diagnosis as "the billion dollar boondoggle." Therefore, we have to approach all newer tests with some reasonable type of evaluation to determine what is of value and what is not.

Also, most of us are not aware of the costs of obstetric care once proper care has been instituted for the patients that have high-risk problems, because they are concentrated in certain parts of the country and in certain parts of the cities. We have recently done a cost survey on 10 maternal and infant care projects across the country. The initial visit for a patient to one of these units will cost anywhere from $90 to $250. In addition, there has been an additional $40 to $50 for laboratory determinations that are being made on these patients. This appears to be a very high cost. When we also realize that the Robert Wood Johnson Foundation is now putting some ten or eleven million dollars into five centers to try to determine if regionalization if efficient, economic, and reasonable, I think we then can realize the importance of the work that has been presented to us today. We must solve some of these problems or we are going to price ourselves out of business.

DR. EDWARD J. QUILLIGAN, Los Angeles, California. I would like to make a couple of obvious comments. One is that the 23 per cent figure that has been alluded to is a very important figure. It tells us that one is going to

need to have tremendous numbers of patients before these techniques can actually be evaluated. This evaluation does need to be done, I think, desperately. Many of the techniques, including fetal heart rate monitoring and scalp sampling, have been almost accepted without complete evaluation which leads me to a question for Dr. Walker.

Are his patients going to be randomly assigned to these diagnostic modalities so that at an "x" period of time I can tell how patients have fared who have been monitored by one technique or another as opposed to those who have not?

DR. JAMES WALKER (Closing). I was expecting more criticism of some of our biochemistry.

In response to Dr. Montgomery's comments concerning the problems of perinatal death, we are fortunate that we have regionalization so that we can, in fact, examine deaths from a compact area. We are in our area about half a million people all together, and it is easy to keep an eye on what is happening and assess the clinical cause in each case of perinatal death. Interestingly, lethal deformity has gone up in the last few years.

Another new phenomenon also has occurred. Dr. Herrmann (and Dr. Moghissi) was talking the other day about the urban/rural story. We find in our rural districts that we now have a much higher perinatal death rate than in our urban districts. This is because of an increase in deformity rates and high prematurity rates in the rural population. This is quite new. The rise was bad enough to worry the local people there about obstetric standards until we showed them the causes. And, of course, it makes one feel a little helpless. Whether or not this has something to do with some new problem of the rural poor, I do not quite know. This method of using clinical assessment and clinical evaluation of death does help to pinpoint at least the obstetric clinical situations in which the problems are arising.

Dr. Taylor, I can assure you we have special nursery care which is of very high quality because our neonatal pediatrician was trained in Denver, as you know. He is a Scotsman who stayed for a long period in Denver and then came back, and we are delighted to have him. That is where we get our quality.

In this screening group of selected women that we are studying, we do not use invasive techniques. In other words, we are not using creatinine or lecithin/sphingomyelin ratios as part of the screening because we did not think this would be acceptable in otherwise perfectly normal patients. We do, of course, use such tests where they are clinically required.

The socioeconomic problems, of course, are terribly real. They show up, and this is re-emphasized as Dr. Little mentioned.

What are the problems now? How do we get better babies? Only something like 3 per cent of our perinatal risk is the *labor risk.* Labor is, of course, very highly and carefully monitored. But it is a tiny numerical group, 3 per cent of the total risk situation. The very, very high risk is in the babies who do not grow, the babies who are born too soon, and the babies who are abnormal. I do not know whether one should continue to be too worried about these; is it nature? We may well be coming down to an irreducible low, but, nevertheless, we should keep trying.

Before we consider the idea of feeding fetuses, we must get some measure of the problem. As you now know, amino acid studies suggest it is not always the mother who is at fault. The mother's levels are often high, but the baby's are not. So there are all sorts of problems.

Cost is part of the reason that brought this up. A Scot is canny, as you know. Half of this research was done by our own departmental (Obstetrics/Gynaecology) laboratories, and half was done by the routine hospital clinical chemists. They were worried that a whole range of tests would be asked for—without our junior staff knowing what the investigations meant and using them randomly. We were putting up costs as several thousand patients have routine tests done without any knowledge of the value of each test. This is why we did this study. It costs us something of the order of $2 for each estriol test.

Pure alpha fetoprotein is a very expensive material to obtain, and we have many vials which we made ourselves. This is one of the strange things. We have a very good young laboratory graduate technician who didn't know it was difficult to extract pure alpha fetoprotein so he just did so!

In this study, as currently designed, Dr. Quilligan, every woman has all tests done as a method of assessing value. Once this stage has been reached and we begin to assess value, we must get some answers with a "two-tailed" test or any other kind of statistical technique; we will do our best.

Varices of Pregnancy

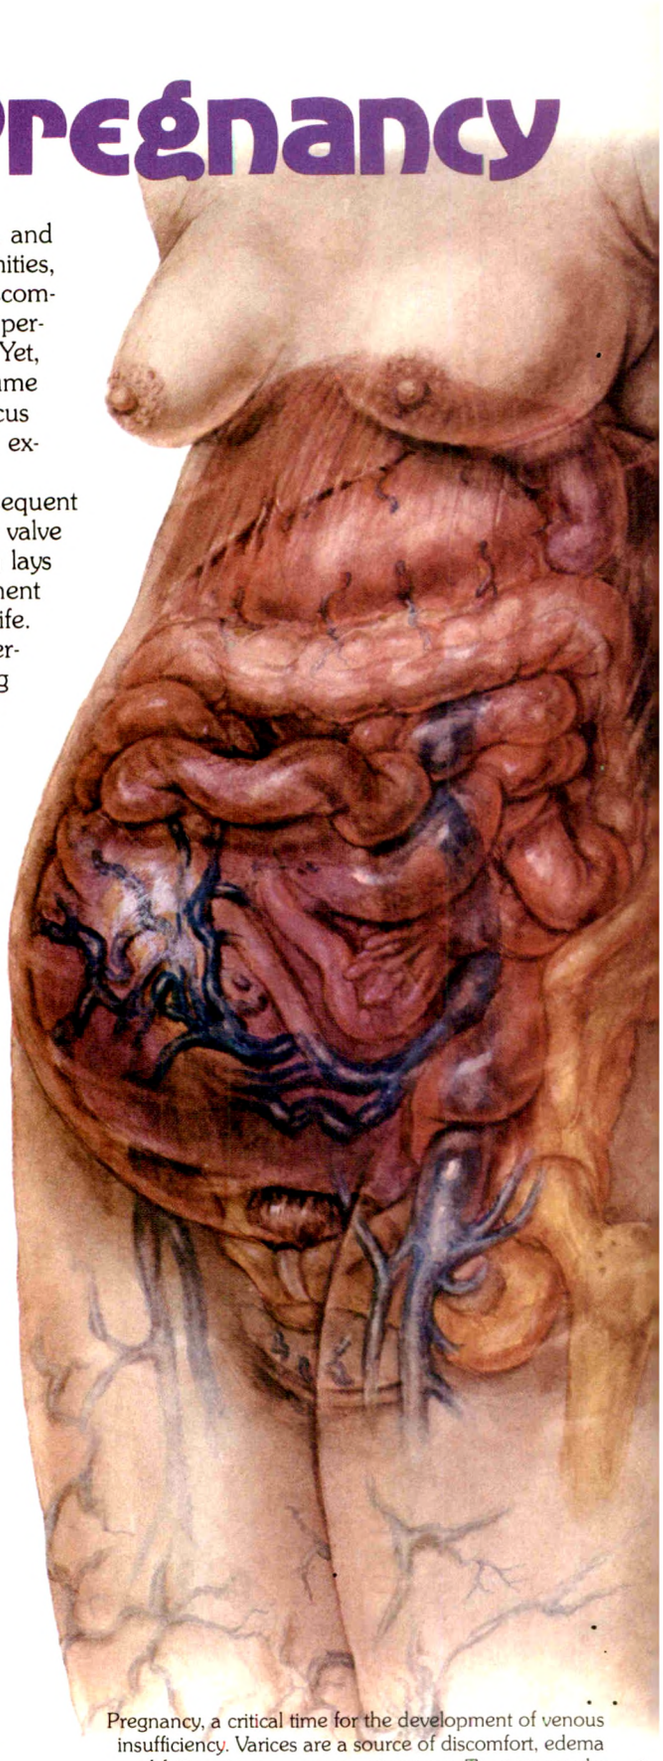
Impending motherhood is a time for great expectation, and time for increased risk of varices in the lower extremities, especially with a second or subsequent pregnancy. The discomfort and disfigurement of varices are an unwelcome and perhaps unnecessary intrusion upon these special moments. Yet, increased intra-abdominal pressure, expanded blood volume and decreased physical activity may come to sharp focus during pregnancy predisposing to varices of the lower extremities.

Naturally, varicose veins become more severe in subsequent pregnancies and may reach the critical stage. Temporary valve incompetence associated with chronic venous distention lays the groundwork for vascular impairment of a very permanent nature, perhaps varicosities of the lower extremities for life.

A Jobst Pregnancy support applies external counter-pressures that oppose excessive venous pressures during pregnancy. Fatigue and discomfort are relieved. Edema is alleviated.[1] A Jobst support worn during the critical months of gestation, may prevent permanent damage to distended veins.[2]

Thompson reports, "We have preferred the Jobst stocking in our clinic. An elastic leotard produced by this company is particularly useful for varicose veins during pregnancy. Most patients are pleasantly surprised by the comforting support this garment gives."[3]

Write for the Jobst Program of Treatment for Varicosities Attendant to Pregnancy. You will receive a collection of clinical reprints on the subject and a full color, twelve-page monograph and bibliography describing the physiological fluid dynamics of external elastic compression. You might also like a twenty-eight-page patient education booklet, edited by a prominent obstetrician, entitled: Answering Your Questions About Varicose Veins During Pregnancy.



Varices of Pregnancy?
Jobst can help.

Pregnancy, a critical time for the development of venous insufficiency. Varices are a source of discomfort, edema and fatigue to many pregnant women. Temporary valve incompetence associated with chronic venous distention lays the groundwork for vascular impairment of a very permanent nature. Perhaps, disfigurement for life.

When a mixed infection causes a vaginal problem...two agents may be better than one.

"...the patient may have concurrent infection with *Candida*... as well as *Trichomonas vaginalis*."[1]

Burning, erythema, itching and discharge are common symptoms of a variety of vaginal infections. It is therefore important to realize that vaginal infection can be mixed. The coexistence of *Candida* and *Trichomonas vaginalis*, for example, is not uncommon.

A topical fungicide will usually control the yeast infection of candidiasis.

Flagyl® (metronidazole) is the recognized treatment of choice for trichomonal vaginitis, which is often characterized by a bubbly, thin, yellow to light green or grey discharge. In addition, secondary symptoms of pruritus vulvae, soreness, irritation, burning, dyspareunia, offensive odor and, occasionally, urinary frequency may occur. The systemic action of Flagyl may usually be relied upon to eliminate trichomonads from the vagina, the paraurethral and Bartholin's glands, and the bladder as well.

Therapy of choice for women: One 250-mg. Flagyl tablet orally three times daily for ten days in conjunction with treatment of her male partner, when he has been shown to harbor the organism.

The only choice for infected men: One 250-mg. Flagyl tablet orally two times daily for ten days concurrent with treatment of his infected female partner. Topical medications are useless in men. Only the systemic action of Flagyl can eliminate trichomonads entrenched in the male genitourinary tract.

1. Cibley, L. J. and Kasdon, S. C.: A New Look at Vulvovaginitis, ed. 2, Chicago, Searle & Co., 1972, p. 11.

Flagyl®

brand of

metronidazole

Make sure trichomoniasis isn't left behind.

Flagyl®
(metronidazole)

Indications: For the treatment of trichomoniasis in both male and female patients and in the sexual partners of patients with a recurrence of the infection provided trichomonads have been confirmed by appropriate laboratory procedures (wet smear or culture). The oral tablets are indicated also for acute intestinal amebiasis (amebic dysentery) and amebic liver abscess.

Contraindications: Evidence or history of blood dyscrasia, active organic disease of the CNS, the first trimester of pregnancy and a history of hypersensitivity to metronidazole.

Warnings: Flagyl should not be used in the first trimester of pregnancy (see *Contraindications).* Use with discretion during the second and third trimesters of pregnancy and restrict to those pregnant patients not cured by topical measures. Flagyl (metronidazole) is secreted in the breast milk of nursing mothers. It is not known whether this can be injurious to the newborn.

Note: Tumorigenicity Studies in Rodents. Metronidazole has shown evidence of tumorigenic activity in a number of studies involving chronic, oral administration in mice and rats.

Most prominent among the effects in the mouse was the promotion of pulmonary tumorigenesis. This has been observed in all five reported studies in that species, including one study in which the animals were dosed on an intermittent schedule (administration during every fourth week only). The published results of one of the mouse studies indicate increases in the incidence of malignant lymphomas as well as pulmonary neoplasms associated with lifetime feeding of the drug. All these effects are statistically significant.

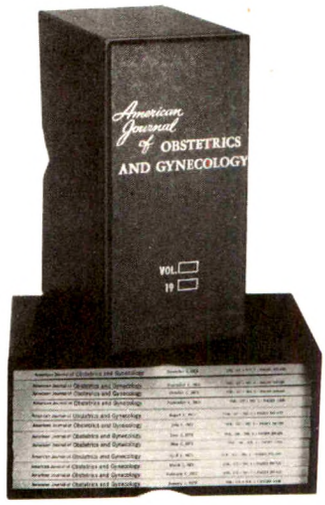
Two long-term toxicity studies in the rat have been completed. There was a statistically significant increase in the incidence of various neoplasms, particularly mammary tumors, among female rats administered metronidazole over that noted in the concurrent female control groups.

Unpublished results of a lifetime tumorigenicity study in hamsters have been reported to be negative.

Precautions: Mild leukopenia has been reported during Flagyl use; total and differential leukocyte counts are recommended before and after treatment with the drug, especially if a second course is necessary. Avoid alcoholic beverages during Flagyl therapy because abdominal cramps, vomiting and flushing may occur. Discontinue Flagyl promptly if abnormal neurologic signs occur. Exacerbation of moniliasis may occur. In amebic liver abscess, aspirate pus during metronidazole therapy.

Adverse Reactions: Nausea, headache, anorexia, vomiting, diarrhea, epigastric distress, abdominal cramping, constipation, a metallic, sharp and unpleasant taste, furry tongue, glossitis and stomatitis possibly associated with a sudden overgrowth of *Monilia,* exacerbation of vaginal moniliasis, an occasional reversible moderate leukopenia, dizziness, vertigo, incoordination and ataxia, numbness or paresthesia of an extremity, fleeting joint pains, confusion, irritability, depression, insomnia, mild erythematous eruptions, "weakness," urticaria, flushing, dryness of the mouth, vagina or vulva, pruritus, dysuria, cystitis, a sense of pelvic pressure, dyspareunia, fever, polyuria, incontinence, decrease of libido, nasal congestion, proctitis, pyuria and darkened urine have occurred in patients receiving the drug. Patients receiving Flagyl may experience abdominal distress, nausea, vomiting or headache if alcoholic beverages are consumed. The taste of alcoholic beverages may also be modified. Flattening of the T wave may be seen in ECG tracings.

Dosage and Administration: For Trichomoniasis. *In the female:* One 250-mg. tablet orally three times daily for ten days. Courses may be repeated if required in especially stubborn cases; in such patients an interval of four to six weeks between courses and total and differential leukocyte counts before, during, and after treatment are recommended. Vaginal inserts of 500 mg. are available for use, particularly in stubborn cases. *When the vaginal inserts are used,* one 500-mg. insert is placed high in the vaginal vault each day for ten days and the oral dosage is reduced to two 250-mg. tablets daily during the ten-day course of treatment. Do not use the vaginal inserts as the sole form of therapy. *In the male:* Prescribe Flagyl only when trichomonads are demonstrated in the urogenital tract, one 250-mg. tablet two times daily for ten days. Flagyl should be taken by both partners over the same ten-day period when it is prescribed for the male in conjunction with the treatment of his female partner.



For Amebiasis. *Adults:* For acute intestinal amebiasis, 750 mg. orally three times daily for 5 to 10 days. For amebic liver abscess, 500 to 750 mg. orally three times daily for 5 to 10 days. *Children:* 35 to 50 mg./kg. of body weight/24 hours, divided into three doses, orally for ten days.

Dosage Forms: Oral tablets, 250 mg. Vaginal inserts, 500 mg.; inactive ingredients are lactose, potato starch, polyvinyl alcohol and hydrogenated castor oil.

PERSONALIZED LIBRARY CASES

Keep your personal copies of AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY in these specially designed library file cases. Two files hold an entire year's issues. Designed to keep your journal copies near at hand in your office, library, or home.

Your case is heavy bookbinder's board in a rich red Kivar cover. Files are scuff-resistant and washable.

Lettering is stamped in gold leaf and the cases make a fit companion for the most costly binding.

Files are reasonably priced—only $4.25 each, postpaid (3 for $12., 6 for $22.). Add $1.00 postage per case for orders outside U. S. Satisfaction unconditionally guaranteed or your money back! Use the coupon for prompt shipment.

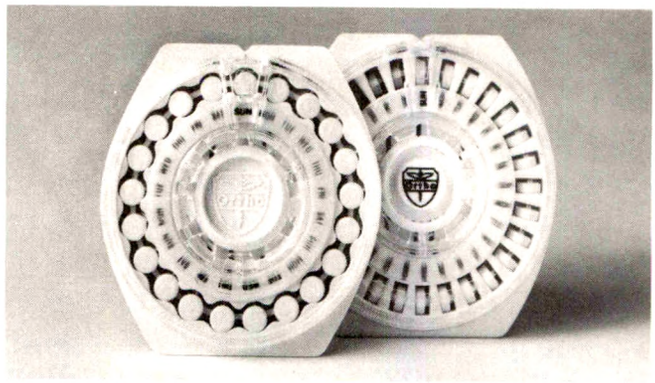
An effective low-dose oral contraceptive

Ortho-Novum 1/50 □ 21

TRADEMARK

Each tablet contains 1 mg norethindrone and 0.05 mg mestranol.

A sensible way to start a woman on oral contraceptives is with an effective, low-dose combination like Ortho-Novum 1/50 □ 21. This combination offers a low dose of estrogen, 50 mcg of mestranol, and a low dose of progestin, 1 mg norethindrone, which can fulfill your contraceptive requirements and her contraceptive needs.



Ortho-Novum 1/50 □ 21 is usually a well-tolerated† combination; thus, in clinical studies, there is a low drug-related drop-out rate.

Add to this the simplicity of the dosage regimen — three weeks on and one week off — and the unique Dialpak* Tablet Dispenser, which helps reduce the chance of error or missed doses, and you have an effective combination that fits very nicely into their life-style...and their worl

†Serious as well as minor conditions have been reported following the use of oral contraceptives. These conditio include thromboembolic disease. The physician should alert to the earliest manifestations of any symptoms of serious disease and discontinue oral contraceptive there when appropriate. The physician should be fully aware of the complete Prescribing Information for this produc

TRADEMARK

See prescribing information on following page.

an effective low-dose oral contraceptive

Ortho-Novum 1/50□21 and 28

TRADEMARK

Ortho-Novum 1/50□21 and Ortho-Novum 1/50□28

Description: Each ORTHO-NOVUM 1/50□21 Tablet contains 1 mg of the progestational substance, norethindrone, together with 0.05 mg of the estrogenic compound, mestranol.

Each yellow ORTHO-NOVUM 1/50□28 Tablet contains 1 mg of the potent progestational substance, norethindrone, together with 0.05 mg of the estrogenic compound, mestranol. Each green tablet contains inert ingredients.

Actions: ORTHO-NOVUM 1/50□21 and ORTHO-NOVUM 1/50□28 act through the mechanism of gonadotrophin suppression, i.e., through the estrogenic and progestational actions of the ingredients. Alterations in cervical mucus and in the endometrium may also contribute to the efficacy of ORTHO-NOVUM 1/50□21 and ORTHO-NOVUM 1/50□28.

Special note: Oral contraceptives have been marketed in the United States since 1960. Reported pregnancy rates vary from product to product. The effectiveness of the sequential products appears to be somewhat lower than that of the combination products. Both types provide almost completely effective contraception.

An increased risk of thromboembolic disease associated with the use of hormonal contraceptives has now been shown in studies conducted in both Great Britain and the United States. Other risks, such as those of elevated blood pressure and reduced tolerance to carbohydrates, have been reported and appropriate tests should be conducted to monitor these during oral contraceptive therapy. Liver disease has also been reported, and the physician should be alert to its earliest manifestations.

Long-term administration of both natural and synthetic estrogens in subprimate animal species in multiples of the human dose increases the frequency for some animal carcinomas. These data cannot be transposed directly to man. The possible carcinogenicity due to the estrogens can neither be affirmed nor refuted at this time. Close clinical surveillance of all women taking oral contraceptives must be continued.

Indication: Contraception.

Contraindications: 1. Thrombophlebitis, thromboembolic disorders, cerebral vascular disease, or a past history of these conditions. 2. Markedly impaired liver function. 3. Known or suspected carcinoma of the breast. 4. Known or suspected estrogen-dependent neoplasia. 5. Undiagnosed abnormal genital bleeding. 6. Known or suspected pregnancy.

Warnings: 1. The physician should be alert to the earliest manifestations of thrombotic and thromboembolic disorders. thrombophlebitis, cerebrovascular disorders including hemorrhage, pulmonary embolism and retinal thrombosis. Should any of these occur or be suspected, the drug should be discontinued immediately.

Retrospective studies of morbidity and mortality in Great Britain and studies of morbidity in the United States have shown a statistically significant association between thrombophlebitis, pulmonary embolism and cerebral vascular disease, occlusive or hemorrhagic, and the use of oral contraceptives. There have been three principal studies in Great Britain[1-3] leading to these conclusions and three in this country.[4-7] The estimate of the relative risk of thromboembolism in the study by Vessey and Doll[3] was about sevenfold, while the United States studies found relative risks of 4.4 to 11, meaning that the users are several times as likely to undergo thromboembolic disease without evident cause as non-users.

In May, 1974, the Royal College of General Practitioners in England[8] issued an interim report of its continuing large-scale prospective study comparing a user group to a non-user group. This study in its interim analysis states, "A statistically significant higher rate of reporting of cerebrovascular accidents in Takers is evident, but the numbers are too small to justify an estimation of the degree of risk." The study also reported a higher incidence of superficial and deep vein thrombosis in users as compared to non-users. The risk of superficial and deep vein thrombosis was reported to be lower in women using 50 mcg estrogen preparations.

The Sartwell study[4] indicated that the risk did not persist after discontinuation of administration. Both the Sartwell and the Royal College studies indicated that the degree of risk was not associated with duration of treatment.

In a collaborative American study[5,6] of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the relative risk of thrombotic stroke was 4.1 to 9.5 times greater in users than in non-users. A comparable estimate for hemorrhagic stroke was 2.0.

None of the American studies was designed to evaluate a difference between products. However, the Sartwell study[4] suggested that there might be an increased risk of thromboembolic disease in users of sequential products.

Other retrospective studies[9,10] have reported an increased risk of post-surgery thromboembolic complications in oral contraceptive users. It has been recommended that therapy be discontinued at least one month prior to elective surgery.

2. Discontinue oral contraceptive medication if there is: gradual or sudden partial or complete loss of vision; proptosis or diplopia; onset or aggravation of migraine or development of headache of a new pattern which is recurrent, persistent or severe; papilledema; or any evidence of retinal vascular lesions.

3. Fetal abnormalities have been reported to occur in the offspring of women who have taken progestogens and/or estrogens during pregnancy.[11,12] The safety of ORTHO-NOVUM 1/50□21 or ORTHO-NOVUM 1/50□28 in pregnancy has not been demonstrated. Pregnancy should be ruled out before initiating or continuing the contraceptive regimen. Pregnancy should always be considered if withdrawal bleeding does not occur.

4. A small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The long-range effect to the nursing infant cannot be determined at this time.

5. Hepatic lesions (adenomas, hepatomas, hamartomas, regenerating nodules, etc.), occasionally fatal, have been reported in women on oral contraceptives. Such lesions may present as an abdominal mass or with the signs and symptoms of an acute abdomen. These lesions should be considered if the patient has abdominal pain or evidence of intra-abdominal bleeding. This has been reported in short-term as well as long-term users of oral contraceptives.

Precautions: 1. A thorough history and physical examination should be performed before prescribing oral contraceptives and periodically during their administration and should include special reference to breasts and pelvic organs, including Papanicolaou smear since estrogens have been known to produce tumors, some of them malignant, in five species of subprimate animals. 2. Endocrine and possibly liver function tests may be affected by treatment with ORTHO-NOVUM 1/50□21 or ORTHO-NOVUM 1/50□28. Therefore, if such tests are abnormal in a patient taking ORTHO-NOVUM 1/50□21 or ORTHO-NOVUM 1/50□28, it is recommended that they be repeated after the drug has been withdrawn for two months. 3. Under the influence of estrogen-progestogen preparations, pre-existing uterine fibromyomata may increase in size. 4. Because these agents may cause some degree of fluid retention, conditions which might be influenced by this factor, such as epilepsy, migraine, asthma, cardiac or renal dysfunction, require careful observation. 5. In breakthrough bleeding, and in all cases of irregular bleeding per vaginam, nonfunctional causes should be borne in mind. In undiagnosed bleeding per vaginam, adequate diagnostic measures are indicated. 6. Patients with a history of psychic depression should be carefully observed and the drug discontinued if the depression recurs to a serious degree. 7. Any possible influence of prolonged ORTHO-NOVUM 1/50□21 or ORTHO-NOVUM 1/50□28 therapy on pituitary, ovarian, adrenal, hepatic or uterine function awaits further study. 8. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. The mechanism of this decrease is obscure. For this reason, diabetic patients should be carefully observed while receiving ORTHO-NOVUM 1/50□21 or ORTHO-NOVUM 1/50□28 therapy. 9. The age of the patient constitutes no absolute limiting factor, although treatment with ORTHO-NOVUM 1/50□21 or ORTHO-NOVUM 1/50□28 may mask the onset of the climacteric. 10. The pathologist should be advised of ORTHO-NOVUM 1/50□21 or ORTHO-NOVUM 1/50□28 therapy when relevant specimens are submitted. 11. Susceptible women may experience an increase in blood pressure following administration of contraceptive steroids. 12. Cholestatic jaundice has been reported in users of oral contraceptives. If this occurs, ORTHO-NOVUM 1/50□21 or ORTHO-NOVUM 1/50□28 should be discontinued. This condition is more likely to occur in patients who have experienced cholestatic jaundice of pregnancy. Patients with a history of cholestatic jaundice of pregnancy should be carefully observed during ORTHO-NOVUM 1/50□21 or ORTHO-NOVUM 1/50□28 therapy.

Adverse reactions observed in patients receiving oral contraceptives: A statistically significant association has been demonstrated between use of oral contraceptives and the following serious adverse reactions: thrombophlebitis, pulmonary embolism, cerebral thrombosis and hemorrhage, gallbladder disease.

Although available evidence is suggestive of an association, such a relationship has been neither confirmed nor refuted for the following serious adverse reactions: neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis, hepatic lesions with or without intra-abdominal bleeding.

The following adverse reactions are known to occur in patients receiving oral contraceptives: nausea, vomiting, gastrointestinal symptoms (such as abdominal cramps and bloating), breakthrough bleeding, spotting, change in menstrual flow, amenorrhea during and after treatment, edema, chloasma or melasma, which may persist, cholestatic jaundice, migraine, rash (allergic), mental depression, change in weight (increase or decrease), breast changes (tenderness, enlargement and secretion), changes in cervical erosion and cervical secretions, suppression of lactation when given immediately post-partum, rise in blood pressure in susceptible individuals.

Although the following adverse reactions have been reported in users of oral contraceptives, an association has been neither confirmed nor refuted: anovulation post-treatment, which tends to occur more frequently in women with a history of menstrual disorders, premenstrual-like syndrome, changes in libido, changes in appetite, cystitis-like syndrome, headache, intolerance to contact lenses, nervousness, dizziness, fatigue, backache, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruptions, itching, vaginitis.

The following laboratory results may be altered by the use of oral contraceptives: hepatic function—increased sulfobromophthalein retention and other tests; coagulation tests—increase in prothrombin, Factors VII, VIII, IX and X; decrease in anti-thrombin III; increase in platelet aggregability; thyroid function—increase in PBI, and butanol-extractable protein-bound iodine and decrease in T^3 uptake values; metyrapone test; pregnanediol determination.

FETUS, PLACENTA, AND NEWBORN

Management of isoimmune neonatal thrombocytopenia

ANNELIESE L. SITARZ, M.D.
JOHN M. DRISCOLL, JR., M.D.
JAMES A. WOLFF, M.D.
New York, New York

Two infants, who presented at birth with isoimmune thrombocytopenic purpura, are the basis for this report. The problems confronting the physician in treating an affected infant, as well as in the management of subsequent pregnancies after an infant with isoimmunization has been delivered, are discussed. In view of the small but serious risk of intracranial hemorrhage during the birth process in these infants, delivery by cesarean section is advocated for all pregnancies known to be at risk i.e., after a previous infant has been shown to be affected.

WHEN THROMBOCYTOPENIA is noted at birth in an infant whose mother has a normal platelet count and no known platelet defect, an isoimmune etiology may be hypothesized. Although there have been many reports of this phenomenon,[1-3] the incidence is relatively low, approximately 1 or 2 per 10,000 births.[3-4] Pearson and associates[1] estimated that 20 per cent of all cases of neonatal thrombocytopenia fall into this category. In these infants the disease process is suspected of being analogous to that seen with red cell antigens in erythroblastosis fetalis. First-born infants are likely to be affected; in fact, Shulman and associates[3] reported that in a group of 51 suspected cases of neonatal isoimmune thrombocytopenic purpura, 49 per cent were in the first-born child.

Although the incidence of serious hemorrhage in infants with thrombocytopenia is low,[5] the greatest risk of intracranial bleeding would appear to be during the birth process and perinatal management may be critical. Two siblings will be presented who were found to have purpura at birth. Both infants have neurologic sequelae. The probability that this damage was secondary to intracranial hemorrhage during the birth process has prompted a re-evaluation of pre- and postnatal management of infants in whom isoimmune thrombocytopenia is a possibility.

Case reports

Case 1. A male infant, birth weight 3,610 grams, was delivered on May 18, 1971, to a gravida 1, 25-year-old mother, who had a negative serology and whose blood type was B-Rh positive. She had been in good health and had never received blood transfusions. Primary dysfunctional labor was augmented by pitocin infusion and led to a vertex delivery. The infant had Apgar scores of 8, 9, and 10 at 1, 2, and 5 minutes. A purpuric.

rash present at birth over the shoulders and in the inguinal area was noted to increase in the first few moments of life. The infant appeared vigorous and had no hepatosplenomegaly. Laboratory evaluation revealed the following: blood type, B-Rh positive; direct Coombs test, negative; hemoglobin, 17 Gm.; platelets, 22,000; WBC, 25,000; polymorphonuclear leukocytes (poly.), 66 (0-2-64); lymphocytes (lymph.), 30; monocytes (mono.), 2; eosinophils (eos.), 2; reticulocyte (retic.) count, 11.3 per cent (Table I). Screening tests for coagulation abnormalities were normal for age of patient. Bone marrow aspiration showed a normal number of megakaryocytes. Urinalysis was normal. Neonatal infection was suspected but could not be bacteriologically proven. Blood culture, serology, toxoplasmosis titer, and rubella titer were all negative. Skeletal survey and skull x-rays were normal. Urinary amino acid screening was normal and serum IgM titer was normal (12 mg. per 100 ml.).

At 60 hours of age slight jaundice was noted and a peak total bilirubin level of 11.4 mg. per 100 ml. was observed on the fourth day. A repeat hemogram on the third day showed the following: hemoglobin, 16.9 Gm.; WBC, 10,500; retic., 7.7 per cent; platelets, 26,000. No medication was given. By the fifth day the petechiae had cleared; when the baby was discharged on the sixth day, his physical and neurologic examinations were normal. The hemogram at discharge was as follows: hemoglobin, 15.8 Gm.; WBC, 10,300; poly., 34 (0-2-32); lymph., 57; mono., 6; myelo., 3; platelets, 90,000.

Blood was drawn from the mother and the infant on the third day following delivery for performance of platelet Factor III antibody test.[6] An elevated antibody titer of 1:24 was found in the mother's blood and 1:80 in that of the infant (normal $< 1:4$). Simultaneous platelet counts in the mother and infant were 260,000 and 20,000, respectively. At age 4 months, the infant had a hemoglobin of 11.3 Gm. and a platelet count of 220,000.

At 8 months of age he was readmitted to the hospital due to infantile spasms and a possible mild right hemiparesis. The platelet count was normal at this time. The child has been followed by a pediatric neurologist and found to have psychomotor retardation and poor language development at age 3 years.

Case 2. A second male child, birth weight 3,540 grams, was delivered to the same mother on October 17, 1972, at term, after an uneventful pregnancy. No platelet antibodies had been detected in the maternal blood when tested 4 weeks prior to delivery. This fact led to the decision to allow vaginal delivery rather than to perform a cesarian section. Labor lasted 8 hours and the membranes ruptured 3 hours before delivery. The infant was biochemically monitored during labor with serial scalp blood samples. A sustained bradycardia was noted, and for this reason delivery was assisted by the application of midforceps. The infant had Apgar scores of 8, 8, and 9 at 1, 2, and 5 minutes. There was acrocyanosis and petechiae were noted over the trunk and groin. Molding and a large caput succedaneum were also noted. The anterior fontanelle measured 2 by 3 cm. and was flat. No heart murmur was heard. The liver and spleen were not enlarged. The petechiae were noted to increase and the infant was transferred to the newborn intensive-care unit. Laboratory evaluation showed the following: blood type, AB-Rh positive; direct Coombs test, negative; hemoglobin, 15.4 Gm.; hematocrit, 43.5 per cent; WBC, 14,100; RBC, 4.09 million; poly., 49 (1-7-41); eos., 4; lymph., 37; mono., 9; myelo., 1; platelets, 15,000 (Table I).

Despite the fact that platelet antibodies had not been demonstrated in the maternal blood 4 weeks prior to this infant's delivery, a presumptive diagnosis of platelet isoimmunization was made on the basis of findings in the previous pregnancy. This diagnosis was later supported by the finding of platelet Factor III antibody in a titer of 1:20 in the infant's blood at birth. Oral prednisone was started in a dose of 10 mg. per day.

Since the first-born infant had exhibited evidence of CNS injury, probably secondary to perinatal intracranial bleeding, it was deemed advisable to do an exchange transfusion on the second infant in an attempt to correct the thrombocytopenia. This was performed at 5 hours of age. Since platelet-matched blood was not readily obtainable, it was elected to perform the exchange transfusion, using 500 c.c. of blood obtained from the mother. The procedure was carried out without difficulty and without ill effects to either the mother or the infant. In this case no problems were presented by the red cell antigens, the mother being B-Rh positive and the baby AB-Rh positive.

Platelet counts and other peripheral blood findings in the infant during the first 10 days of life are shown in Table I.

At 24 hours of life there were no new petechiae and no bleeding. There was, however, intermittent bradycardia. Neurologic evaluation was inconclusive in the light of equivocal head control and questionable hypotonia, but the neurologic consultants felt that no further studies were indicated. The child improved over the next 4 days and was discharged to his home at 7 days of age. Prednisone was gradually tapered and discontinued 16 days after discharge. The platelet count remained normal.

The infant has been followed as an out-patient by a pediatric neurologist and at two years of age has significantly delayed motor milestones and no speech development.

Comment

Two main problems confront the physician who is faced with a patient in whom isoimmune neonatal purpura is suspected: one concerns the treatment of

Table I. Hematologic findings in the neonatal period

Date	Hgb.	WBC	Differential					Platelets	Retic. (%)
			Poly.	Lymph.	Eos.	Mono.	Myelo.		
Case no. 1—1971:

*Eight nucleated RBC per 100 WBC.

the affected infant and the other concerns the management of subsequent pregnancies in a mother who has delivered one affected infant.

The course of isoimmune thrombocytopenia in the infant is variable, ranging from benign resolution in 2 to 3 weeks to a 12 to 14 per cent mortality rate, secondary to intracranial hemorrhage.[1–5] In addition, there can be neurologic sequelae in those infants in whom clinically inapparent or seemingly minor bleeding may have occurred. This would seem to have been the case in the two infants reported here. Various modalities of treatment have been used. Steroids have been given prenatally to the mother or at birth to the infant.[1–3]

Exchange transfusion with RBC-compatible blood does aid in the removal of circulating antibody, but, unless the blood is also platelet-type specific, it will not appreciably increase the level of circulating platelets. Platelet typing is not yet readily available and for this reason the use of maternal platelets which would not be affected by the platelet antibody has been advocated.[2, 4] In the second infant described, the platelet count rose immediately after the exchange transfusion to 116,600 per cubic millimeter. This rise was due to platelets received from the mother and persisted until the fourth day. The dip in platelet counts on the fourth and fifth days probably reflected disappearance of maternal platelets. Exchange transfusion with maternal whole blood is feasible where mother and infant have compatible RBC antigens and avoids the technical problem of separating off the platelets.

Various types of platelet antibodies have been detected in isoimmune neonatal thrombocytopenia. Some of these are unique to platelets and others are shared by platelets and leukocytes. PL^{A1} antigen, which is unique to platelets, has been implicated most frequently.[1–4] Since 97 to 98 per cent of people are positive for PL^{A1}, the chances of obtaining a compatible PL^{A1}-negative donor on a routine basis are slight. In addition, platelet typing is cumbersome and not readily available at present. Those antigens which platelets share with leukocytes, the HLA types, can be identified more easily, but they are not frequently implicated and appear to be found in the milder cases of immunization.[7]

With the methods of detecting platelet antibodies that are currently available, one can usually establish retrospectively that platelet isoimmunization may have occurred in an affected infant. Since, however, the greatest risk of intracranial hemorrhage occurs during the birth process, a major problem remains of prediction of the outcome of a given pregnancy. This difficulty is increased by virtue of the fact that platelet isoimmunization occurs most often in first pregnancies. Once a woman has delivered an affected infant, the physician can be alerted to the possibility of subsequent children being at risk. Serial antibody titers in the mother during pregnancy may be helpful, but it has

been shown that the level of maternal antibodies does not correlate with the severity of the disease in the infant.[3, 8] Furthermore, when antibodies are found in the mother at the time of delivery of an affected child, they can usually be detected for only about 2 weeks postpartum and, as in our second patient, may not be found to be elevated antepartum even when the infant is affected. The analogy to Rh sensitization may be used in interpreting these antibody titer findings. It has been found[7] in Rh sensitization that if a titer has been rising during pregnancy and then dips 4 to 6 weeks before delivery, the infant is likely to be affected and its red cells in effect have "soaked up" the antibodies. Similarly, if titers were elevated from a previous pregnancy and remained so during a subsequent pregnancy, the infant is likely to be "D" negative and unaffected.

It is possible that the lack of platelet antibodies in maternal blood 4 weeks prior to the delivery of the second child reported here may have been an indication of the fact that the infant was affected. Since this was the only titer obtained during this pregnancy, we do not know if there might have been an earlier elevation.

While the incidence of severely affected infants is low, when neurologic damage occurs, it is devastating. In the absence of reliable indicators for identifying platelet isoimmunization prior to delivery not much can be done to protect a first affected infant. When a previous pregnancy has resulted in a baby who had isoimmune thrombocytopenic purpura, however, it would seem prudent to consider all subsequent pregnancies at risk. In such a situation, serial testing for platelet antibody in maternal serum may be helpful, but delivery by cesarian section would appear to be the only way of protecting the potentially affected infant from the trauma of vaginal delivery.

Cortisol in amniotic fluid and cord blood in relation to prenatal betamethasone load and delivery

GERHARD GENNSER
STEN OHRLANDER
PETER ENEROTH
Malmö and Stockholm, Sweden

The influence of maternal corticosteroid administration on the cortisol concentration in fetal blood and amniotic fluid (AF) was studied in women receiving betamethasone for prevention of IRDS. Thirty-four pregnant women in danger of spontaneous or induced preterm delivery were treated with 12 mg. of betamethasone daily for 3 days. AF was obtained by amniocentesis on the day before and the day following the betamethasone treatment and by amniotomy at delivery; cord arterial and venous blood was taken at delivery. Corresponding samples were obtained from 17 pregnant control subjects. All samples were analyzed in duplicate for cortisol by radioimmunoassay. The basal AF cortisol level rose with gestational age. The AF cortisol concentration fell from the basal value of 24.5 ± 1.8 to 5.4 ± 0.4 ng. per milliliter 3 days after the start of treatment, and it remained low at delivery if the treatment-delivery time was less than 1 week. An almost significant positive correlation (r = 0.543) was found between the cortisol concentration in cord arterial blood and AF. The cortisol concentration in cord blood in the controls was 108.2 ± 14.3 ng. per milliliter in the arteries and 106.4 ± 18.6 ng. per milliliter in the vein. Also, the cord blood cortisol level was depressed if betamethasone had been given within one week before delivery. The multifactorial influence on cord blood cortisol level prevents interpretation of the results as support for the concept that the human fetal adrenal is involved in labor initiation. The duration of gestation was not altered by the betamethasone treatment. The analysis of cortisol in the easily accessible amniotic fluid is suggested for estimating the function of the fetal adrenal cortex.

CORTICOSTEROIDS seem to play an important role for induction of several biologic mechanisms during fetal life. Glucocorticoids are believed to participate in the initiation of parturition in certain domestic animals such as sheep[1–5] and goats.[6] The lung maturation in utero seems to be influenced by fetal glucocorticoid production,[7] and prenatal administration of glucocorticoids might reduce the incidence of the respiratory distress syndrome in premature infants.[8] Recently, cortisol in cord blood was found to be lower in infants who subsequently developed respiratory distress than in infants without this complication.[9]

In the present investigation, betamethasone was given to pregnant women to prevent respiratory distress of the newborn where there was a risk of induced or spontaneous premature labour. To study any effect on the hormone levels in the fetoplacental unit exerted by the betamethasone treatment, the cortisol concentrations in the amniotic fluid and in the cord blood were monitored in these cases and in a control group. An attempt was also made to evaluate factors influencing the fetal cortisol levels around the time of parturition.

prevention of the respiratory distress syndrome. Seventeen other gravidas in similar risk pregnancies served as controls; they were not given corticosteroid treatment, but apart from that were subjected to the same investigations and treatment as the study group. Seven of the women in the study group had premature rupture of the membranes at the start of the observation period; in all the control subjects, the membranes were intact until the beginning of delivery. All women were hospitalized and were in the last trimester of pregnancy. No cases of polyhydramnios were included in the material. No perinatal deaths occurred and all infants appeared normal at routine clinical examinations. Tables IA and IB give the clinical data of the two groups.

Amniocentesis was usually performed twice on all patients with 3 days' interval, during which the women in the study group were given, as a daily intramuscular injection, 6 mg. of fast-acting betamethasone disodium phosphate and 6 mg. of slow-acting betamethasone acetate (Celestone Chronodose, Schering Corp.). No amniotic taps were performed in the women with ruptured membranes at admittance. At delivery, amniotic fluid was obtained before or after the start of labor by elective amniotomy where there were intact membranes.

As presented in Results, the depressant effect exerted by the betamethasone administration on the cortisol levels at delivery, both in the amniotic fluid and in the cord blood, had completely disappeared 3 weeks after the treatment started. Therefore, the cortisol values where the treatment-delivery interval exceeded 3 weeks were added to the controls in order to enlarge this group for some of the statistical evaluations.

Noncentrifuged amniotic fluid was frozen and stored at −20° C. until analyzed. The umbilical cord was immediately clamped at delivery, and blood in the vein and in the arteries was collected separately in EDTA-containing tubes. Plasma was frozen and stored at −20° C. Cortisol was determined by radioimmunoassay with a commercial kit* according to the manufacturer's recommendations. ^{3}H-labeled cortisol (5,000 c.p.m.) was added to 20 μl of plasma or 100 μl of amniotic fluid to monitor and correct for procedural losses. Each sample was analyzed in duplicate. The coefficient of variation of duplicate determinations in the assay was 3.9 per cent (intraassay) and 8.9 per cent (interassay). The results obtained with this method represent total nonconjugated cortisol. Betamethasone disodium phosphate tested in amounts corresponding to as much as 1,600 ng. per milliliter of plasma did not interfere with the cortisol determination.

Conventional statistical methods were employed. The critical level for rejection of significance was $p = 0.05$.

Results

Amniotic fluid. The cortisol concentration in the amniotic fluid (AF) obtained at the first amniocentesis was of similar over-all magnitude in the betamethasone group (24.5 ± 1.8 ng. per milliliter, n = 18) and the control group (28.2 ± 2.9 ng. per milliliter, n = 17). The short-term variability of the cortisol concentration was low: the intraindividual difference between cortisol concentrations in two amniotic fluid specimens obtained with 3 days' interval in the control group was 3.2 ± 2.0 ng. per milliliter. No sex difference was found in the cortisol concentration in the amniotic fluid; the level was 27.3 ± 2.2 (n = 17) in cases with a female fetus and 25.4 ± 2.6 (n = 18) in cases with a male fetus.

The administration of betamethasone markedly decreased the AF cortisol concentration from 24.5 ± 1.8 ng. per milliliter (n = 18) to 5.4 ± 0.4 ng. per milliliter (n = 19) 3 days after the start of the treatment. At delivery, the AF cortisol concentration remained low if delivery occurred within 1 week after the start of treatment. At longer treatment-delivery intervals, the AF cortisol concentration did not differ from that of the control group (Table II).

As is evident in Table II, in the controls and in the betamethasone group with the treatment-delivery time exceeding 21 days the AF cortisol concentration was significantly higher ($p < 0.05$) at delivery than at the first amniocentesis. When the influence of the gestational age on the AF cortisol concentration was further evaluated in gravidas before labor, the cortisol value after the thirty-sixth week was found to be significantly higher than before this age ($p < 0.01$; Table III). Controls: (29.7 ± 4.3) n = 17	33.4 ± 0.5	37.5 ± 0.5	8 ± 0	6/11	12/5	6.1 ± 1.0	2639 ± 163

weak but significant correlation appeared between the AF cortisol concentration and the gestational age between the thirtieth and fortieth week ($r = 0.378$; $p < 0.01$; Fig. 1).

When the relation between the AF cortisol values at delivery and the mode of initiation of labor was analyzed, two groups of parturients were compared. There was no statistically significant difference of AF cortisol levels between the women with spontaneous onset of labor (n = 10) and those with no labor (five elective sections and six vaginal amniotomies) (Table IV). It is important to note that, in the former group, the amniotic fluid was obtained after an average of 4 hours' labor, whereas in the second group, the samples were taken before the onset of labor. This, if anything, would tend to increase any cortisol difference between the groups (Table IV). The gestational age in the two groups was identical.

Umbilical blood. The cortisol concentration in the umbilical blood at delivery had a somewhat higher value in the arteries than in the vein, both in the betamethasone group (84.4 ± 10.9 and 79.2 ± 10.1 ng. per milliliter, respectively) and in the control group (108.2 ± 14.3 and 106.4 ± 18.6 ng. per milliliter, respectively). The arteriovenous difference, however, was not significant in these groups or in the subgroups discussed further on; therefore only the arterial cortisol levels in the umbilical blood are considered in the following.

The umbilical cortisol level in the group receiving betamethasone treatment was significantly lower than that of the controls when delivery occurred within 7 days after the start of the treatment ($t = 5.633$; $p < 0.001$). There was no significant difference between the treated women and the controls at posttreatment intervals exceeding 7 days (Table V).

Apart from the betamethasone treatment, also the following factors were considered for a possible influence on the cortisol concentration in the cord blood at delivery: (1) the gestational age, (2) the spontaneous onset of labor, and (3) the duration of labor. The amalgamated groups of the controls and the women with betamethasone treatment more than 3 weeks before delivery were used for these evaluations. The cortisol level in umbilical arterial blood rose with the gestational age, as it did in the amniotic fluid (Table VI). The difference between the youngest and the oldest group was significant ($p < 0.05$) but the groups were not homogeneous with respect to the other factors (2), (3). A study of the relation between the duration of labor and the cord arterial cortisol level (Fig. 2) showed that both the group with spontaneous labor and that with induced onset of labor tended to have a reduced cortisol level when the duration of labor diminished. Analysis of the interrelation between the cortisol level, the gestational age, and the duration of labor in groups of different delivery modes showed no statistically significant correlations (Table VII). This is undoubtedly ascribable to the heterogeneity of the clinical material.

The cord blood cortisol in the controls and in the betamethasone group with posttreatment interval exceeding 3 weeks was not significantly correlated to either the the birth weight of the infant or the placental weight ($r = 0.28$ and $r = -0.08$, respectively). Only one woman in the betamethasone group and one in the control group were delivered of a child with Apgar-score at 1 minute below 7. The umbilical cortisol level

*Cortisol in amniotic fluid before (first amniocentesis) and after (second amniocentesis) administration of 12 mg. of betamethasone to the woman daily for 3 days, and at delivery. Values of control subjects not receiving betamethasone are given for corresponding times. Significance of difference in table refers to value at first amniocentesis for each group. At delivery the difference between A and the control group was highly significant. The differences between B and the control group and between C and the control group were not significant (means ± S.E.M.). Figures in parentheses denote number of cases.

in both these cases was low, i.e., 50.8 and 69.9 ng. per milliliter, respectively.

The time from the first amniocentesis until *spontaneous* delivery was compared between the controls (n = 11) and the gravida receiving betamethasone (n = 12). Here, all patients with premature rupture of the membranes were excluded because of the obvious risk of coming into premature labor. No significant difference in the postamniocentesis interval was encountered between the two groups (Table VIII). It is important to note that the gestational age at delivery was identical in both groups.

Comment

The study of the pituitary-adrenal axis in the human fetus is attractive for several reasons: (1) the elucidation of basal physiologic mechanisms, i.e., the function of the fetal adrenals in relation to the gestational age, the transfer of adrenal steroids into intrauterine compartments like the amniotic fluid, and the dependence of the fetal adrenals on the fetal pituitary; (2) the search for evidence that the human fetal adrenal is functionally involved in the initiation of labor, as suggested for some other species; (3) evaluation of the role of the adrenal steroids for induction of the synthesis of surface-active phospholipids in the fetal lung.

*Amniotic fluid obtained at cesarean section or amniotomy in both groups (mean ± S.E.M.).

Our knowledge of the hormonal state of the human fetus is largely based on measurements of hormonal concentrations in umbilical blood after delivery; extrapolations from these values backward to the time before birth seem to be less valid. For technical reasons, it has not been feasible to obtain blood safely from the fetus in utero. Amniotic fluid, on the other hand, is readily available from diagnostic amniocenteses. In the present work, advantage was taken of the amnion taps made for measuring the effect on the fetal surfactants of an inductive treatment with betamethasone.[10] Thus, we followed the influence of a large betamethasone dose admistered to the pregnant woman on the cortisol concentration in the amniotic fluid and in the umbilical blood at various times after the administration. The betamethasone effect on the phospholipids in the amniotic fluid is excluded from the present report; it will be published elsewhere.[10]

The *cortisol concentration* in human *amniotic fluid* at delivery found in the present study agrees with corresponding values obtained by fluorometric determination[11] and by a competitive protein binding

method.[12] The rise of the amniotic fluid cortisol concentration with advancing gestational age is paralleled by the observation of an amnion cortisol level at premature delivery lower than at term.[12] The origin of the cortisol in amniotic fluid is not definitely determined. There is strong evidence that, during the last trimester, the fetal urine is a major contributor to the amniotic fluid.[13, 14] It has been shown that in human beings most of the maternal cortisol passing the placenta is converted to cortisone,[15] and it was calculated that the fetus near term produces about 75 per cent of its cortisol.[16] It therefore seems reasonable to infer that the cortisol which reaches the amniotic fluid by the fetal urine is predominantly of fetal origin. If the metabolic clearance rate of amniotic cortisol remains constant and the passage of maternal cortisol through the amniotic membranes is negligible, the cortisol concentration in amniotic fluid can be considered to reflect the integral level of cortisol in fetal plasma for a certain time. This possibility is strengthened by the fact that, in the present investigation,

betamethasone administration occasioned a quantitatively identical reduction of cortisol in the umbilical artery blood (to 22.8 per cent of controls) and in the amniotic fluid (to 22.0 per cent of original level) 3 days after the start of the treatment. It was earlier demonstrated that this treatment decreased the maternal plasma cortisol level to 10 per cent of basal value at the same time (3 days after the start of treatment.[17] The changes of the cortisol levels in the amniotic fluid thus correspond more to the fetal than to the maternal blood level changes.

The cortisol concentration in the arterial cord blood compared with that in the amniotic fluid in *simultaneously* obtained samples showed an almost significant positive correlation (r = 0.543). The ratio between the cortisol concentrations in the two compartments was approximately 2:1. This concentration gradient might be explained by different levels of cortisol-binding globulin and albumin in the amniotic fluid and in the cord blood. In fact, the concentration of total protein in the amniotic fluid is 27 times lower than in fetal serum;[18] albumin occupies 60 to 69 per cent of this in amniotic fluid at term[19, 20] vs. 56 per cent in fetal serum.[18] The cortisol binding capacity is lower in fetal than in maternal human plasma,[21] but no reports are available about whether cortisol-binding globulin is present in amniotic fluid.

The static and dynamic relation between the fetal and the amniotic cortisol suggests that a fairly rapid exchange of this steroid occurs between the two compartments. These results point to the possibility of using cortisol analysis in the easily accessible amniotic fluid for estimating the secretion of the fetal adrenals.

Earlier reports on the *cortisol concentration in cord blood* vary considerably, partly owing to different methods of determination, which in some cases might include steroids other than cortisol.[12, 29, 30–32, 34, 35, 41] The wide range of basal cortisol values given might also be ascribed to the fact that cortisol in man is known to be released episodically rather than continuously,[22] and to circadian variations of plasma cortisol concentration which are present in pregnant women[23] and which might influence the cord blood levels too. The present results, however, agree with other reported levels when only the competitive protein-binding method used at cesarean section is considered.

The concept that the fetal pituitary-adrenal axis plays an important role in the initiation of labor is based on observations and experiments mainly on sheep.[1, 2, 4, 24, 25] The influence of the human fetal adrenal function on the onset of parturition has been more difficult to study and has been suggested by the alleged prolongation of pregnancy in some cases of anencephaly.[26] On the other hand, in several other

forms of congenital adrenal hypoplasia in man, the gestational period has been of normal duration.[27, 28] It has been repeatedly observed that the concentration of corticosteroids in cord blood is higher at vaginal deliveries than at cesarean sections.[29–32] The cortisol levels in cord blood have been determined in several recent studies and related to various modes of delivery, giving inconsistent results. A lower level of cord blood cortisol was found at elective cesarean sections compared with indicated sections[33] and vaginal deliveries[34]; equal cortisol levels in these groups have also been reported.[35] This inconsistency seems to be partly ascribable to the fact that these studies have not conclusively distinguished between the alleged influence on plasma cortisol by factors such as the spontaneous or induced initiation of parturition, the labor stress, and the gestational age. As is suggested by the present investigation, some of these factors, such as the duration of labor and the stage of gestation, seem to determine the cord blood cortisol concentration at delivery. The influence on the fetal cortisol level exerted by the stress in utero[36, 12] and by the gestational age[23] has, in fact, been shown recently. Therefore, due to the multifactorial regulation of cord blood cortisol level, the present results cannot answer the question whether in the human fetus a rise in plasma cortisol precedes the initiation of spontaneous labor.

Hitherto, there has thus been little definite support for the concept that, in man and in the nonhuman primates, the fetal adrenals are involved in the labor initiation, in contrast to what has been found in sheep. This discrepancy seems logical in view of the fact that the human placenta is not impermeable to cortisol,[16, 37] which means that the fetal plasma cortisol level is to some extent influenced by the maternal level.[38] The present study clearly shows that large doses of betamethasone to the mother did not reduce the gestational period. This suggests that betamethasone cannot replace cortisol in any alleged role for labor initiation. A similar conclusion regarding dexamethasone has recently been reached in both man[39] and rhesus monkey.[40] On the other hand, the induced decrease of the blood cortisol concentration in the fetus did not postpone the parturition. Whether this lack of effect on the duration of gestation is due to the transient nature of the fetal cortisol depression in the present study remains to be elucidated.

In a preliminary investigation using a fluorometric assay, a significant reduction of the cortisol concentration in the amniotic fluid was observed after treatment of pregnant women with betamethasone.[17] This finding was substantiated in the present work by means of a radioimmunoassay. The effect of betamethasone on the amniotic fluid cortisol paralleled that of cord blood in time course and magnitude, and is consistent with a presumed passage of betamethasone into the fetoplacental unit where it exerts a negative feedback function on the fetal pituitary. This presumption is validated by a recent study where maternally administered cortisol was found to pass the placenta and cause a 57 per cent diminution of ACTH in umbilical artery plasma.[41] There is now substantial evidence that the human fetus contributes to its own plasma cortisol level.[33, 34] The present investigation clearly shows that, with pharmacologic doses of betamethasone, it is possible to lower the level of endogenous cortisol in fetal plasma. Further study is necessary to determine whether such treatment would turn off a prematurely activated mechanisms for labor induction.

Mrs. Marita Johansson's expert technical assistance is gratefully acknowledged.

Serum levels of a placental protein during gestation in the baboon

VERNON C. STEVENS
HANS BOHN
JOHN E. POWELL
Columbus, Ohio, and Marburg, West Germany

A placental specific protein (Sp-1) isolated from human placentas was used to establish a radioimmunoassay for measurement of a baboon protein in the sera of pregnant baboons. No reaction was observed with any known pituitary or placental hormone in this assay system. Levels of Sp-1 were detected at 17 to 18 days of gestation and reached high levels by the end of the first trimester of pregnancy. A slow increase in serum levels continued thereafter until parturition. Disappearance of Sp-1 post partum was very slow and required 26 to 34 days to become undetectable in the serum. No function or role of Sp-1 in pregnancy has been suggested, but possible use of its measurement for detecting abnormal placental function deserves investigation.

SEVERAL proteins have been isolated from placental tissue and have been shown to be present in the serum of pregnant women. Among these are hormones, including human chorionic gonadotropin (HCG), human chorionic somatomammotropin (HCS), and human chorionic thyrotropin (HTS). Recently, one of us (H. B.) has demonstrated the existence of placental proteins other than those listed above that are believed to be produced solely from placental tissue.[1] One of these proteins, herein referred to as Sp-1, is also present in the maternal serum in large amounts during pregnancy.

Preliminary biochemical characterization of Sp-1 has been performed,[2, 3] although no known hormonal or other biologic function of this substance has been identified. Antisera to Sp-1 have been prepared and a specific radioimmunoassay for it has been established. Extracts from baboon placentas and serum from pregnant baboons react very strongly in this assay system for human Sp-1. This report deals with the measurement of a baboon Sp-1–like protein in the serum of six pregnant baboons throughout gestation as a preliminary study to the role and function of this substance in pregnancy.

Materials and methods

Animals. Female baboons *(Papio cynocephalus)* were housed and maintained as previously described.[4] Pregnancy was established by housing females with a male of proved fertility for 3 days at midcycle, beginning 2 days prior to expected ovulation. Pregnancy determinations and the course of gestation were monitored by hormone determinations in serial serum samples collected at frequent intervals after mating. Blood samples were collected more frequently at the beginning and end of gestation and during the postpartum period. Serum samples were stored frozen (−20° C.) until assayed for hormone and Sp-1 content.

Assays. Measurements of baboon chorionic gonadotropic (CG) levels were performed by the method reported earlier.[4] Similar procedures were used to assay serum levels of baboon chorionic somatomammotropin (CS). A highly purified preparation of baboon CS[5] was used to prepare antisera in rabbits, to prepare ^{125}I-labeled tracer, and for use as a standard in the baboon CS radioimmunoassay. Antisera did not react with other baboon or human pituitary or placenta hormones excepting human CS. Likewise, ^{125}I-labeled baboon CS did not bind to antisera raised to human and baboon hormones other than anti-HCS. The sensitivity of the assay was 10 ng. per milliliter and

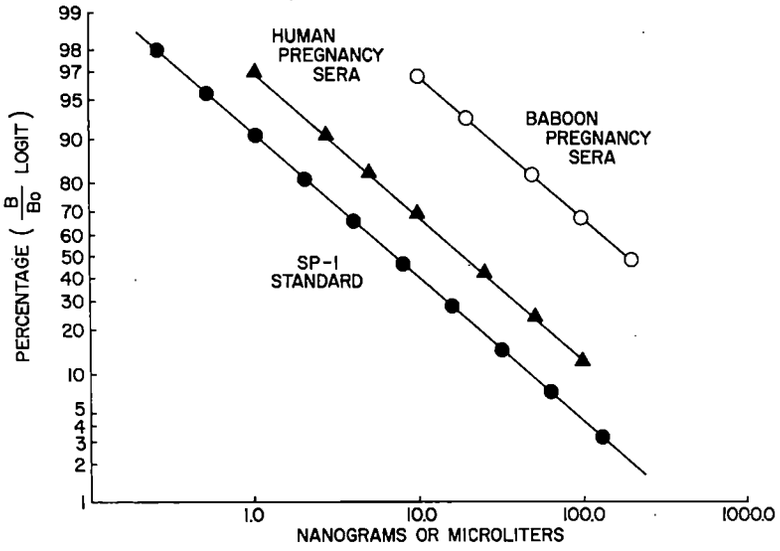

Fig. 1. Dose response lines to standard and pregnancy serum in the Sp-1 radioimmunoassay.

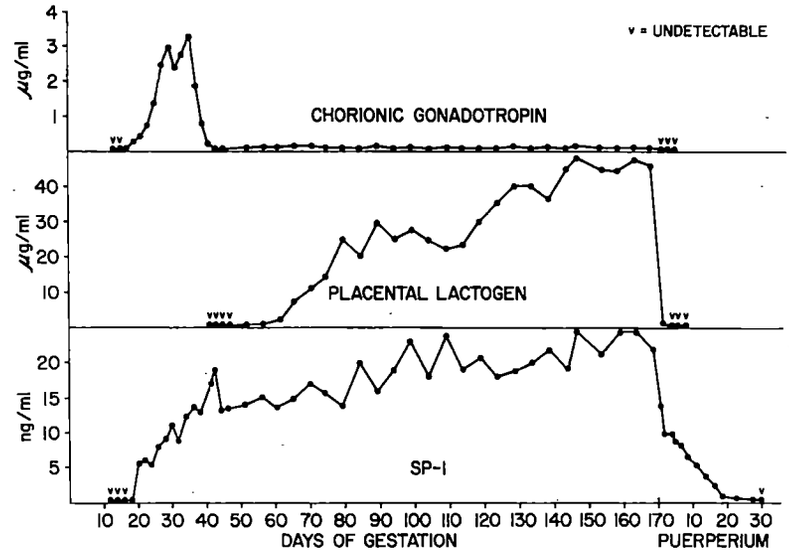

Fig. 2. Patterns of serum Sp-1, baboon chorionic gonadotropin, and baboon placental lactogen during a normal baboon pregnancy. Parturition in this animal was at 170 days of gestation.

the over-all precision of this system permitted reproducibility of serum values within ±12 per cent.

A radioimmunoassay for Sp-1 was developed with essentially identical procedures used for other protein hormones. Highly purified Sp-1 was radiolabeled with ^{125}I according to a modified procedure of Greenwood, Hunter, and Glover.[6] Iodinated Sp-1 (250 pg.) with a specific activity of 95 to 125 μc per microgram was reacted with 200 μl of rabbit antisera to Sp-1 in a final dilution of 1:160,000. This serum dilution bound approximately 112 pg. of the labeled antigen and was used for most assays reported here. Sheep antirabbit gamma globulin (200 μl) was employed in this double-antibody radioimmunoassay system.

No binding of anti-Sp-1 serum in dilutions from 1:1,000 to 1:100,000 was observed to radiolabeled human HCG, HCS, FSH, LH, TSH, HGH, beta subunit of HCG, or baboon CG, LH, and CS. Likewise, no binding of 250 pg. of ^{125}I Sp-1 was observed with high-teter antisera to human FSH, LH, HCG, HCS, HGH, TSH, beta subunit of HCG, or baboon CG, LH, and CS. Thus, no evidence was found to indicate nonspecific reactions of this assay to any known substances in pregnant baboon sera.

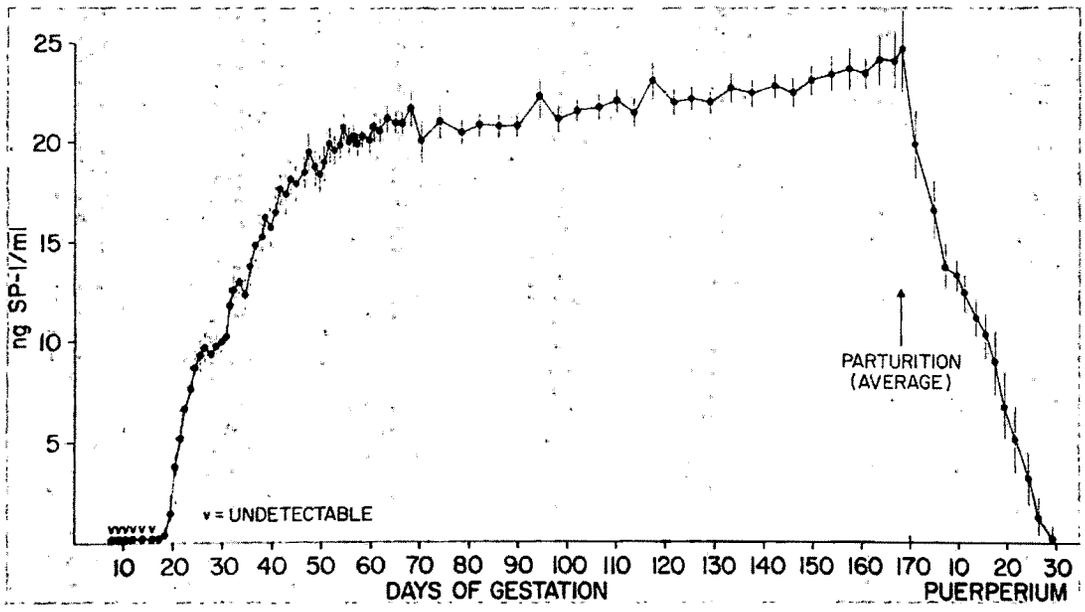

Fig. 3. Mean serum Sp-1 levels from six normal baboon pregnancies. Date of parturition indicated was the mean for all animals. Vertical lines represent the standard error.

Assay buffers, incubation procedures, and statistical analyses of data used have been described previously.[4] A typical dose-response line in an Sp-1 assay is shown in Fig. 1. The minimum detectable amount of Sp-1 in this system was 1.5 ng. per milliliter and the mean intra-assay coefficient of variation within 22 assays was 3.5 per cent. Also illustrated in Fig. 1 is the obvious parallelism in responses of Sp-1, human pregnancy sera, and baboon pregnancy sera. This observation was statistically confirmed ($P < 0.001$).

Varying amounts of sera were assayed depending upon the stage of gestation when samples were collected (20 to 200 μl). Assay sensitivity was intentionally reduced for the second- and third-trimester samples to increase assay precision. All values were reported as nanograms per milliliter equivalents of highly purified human Sp-1 since the same material used for radiolabeling was used for assay standard.

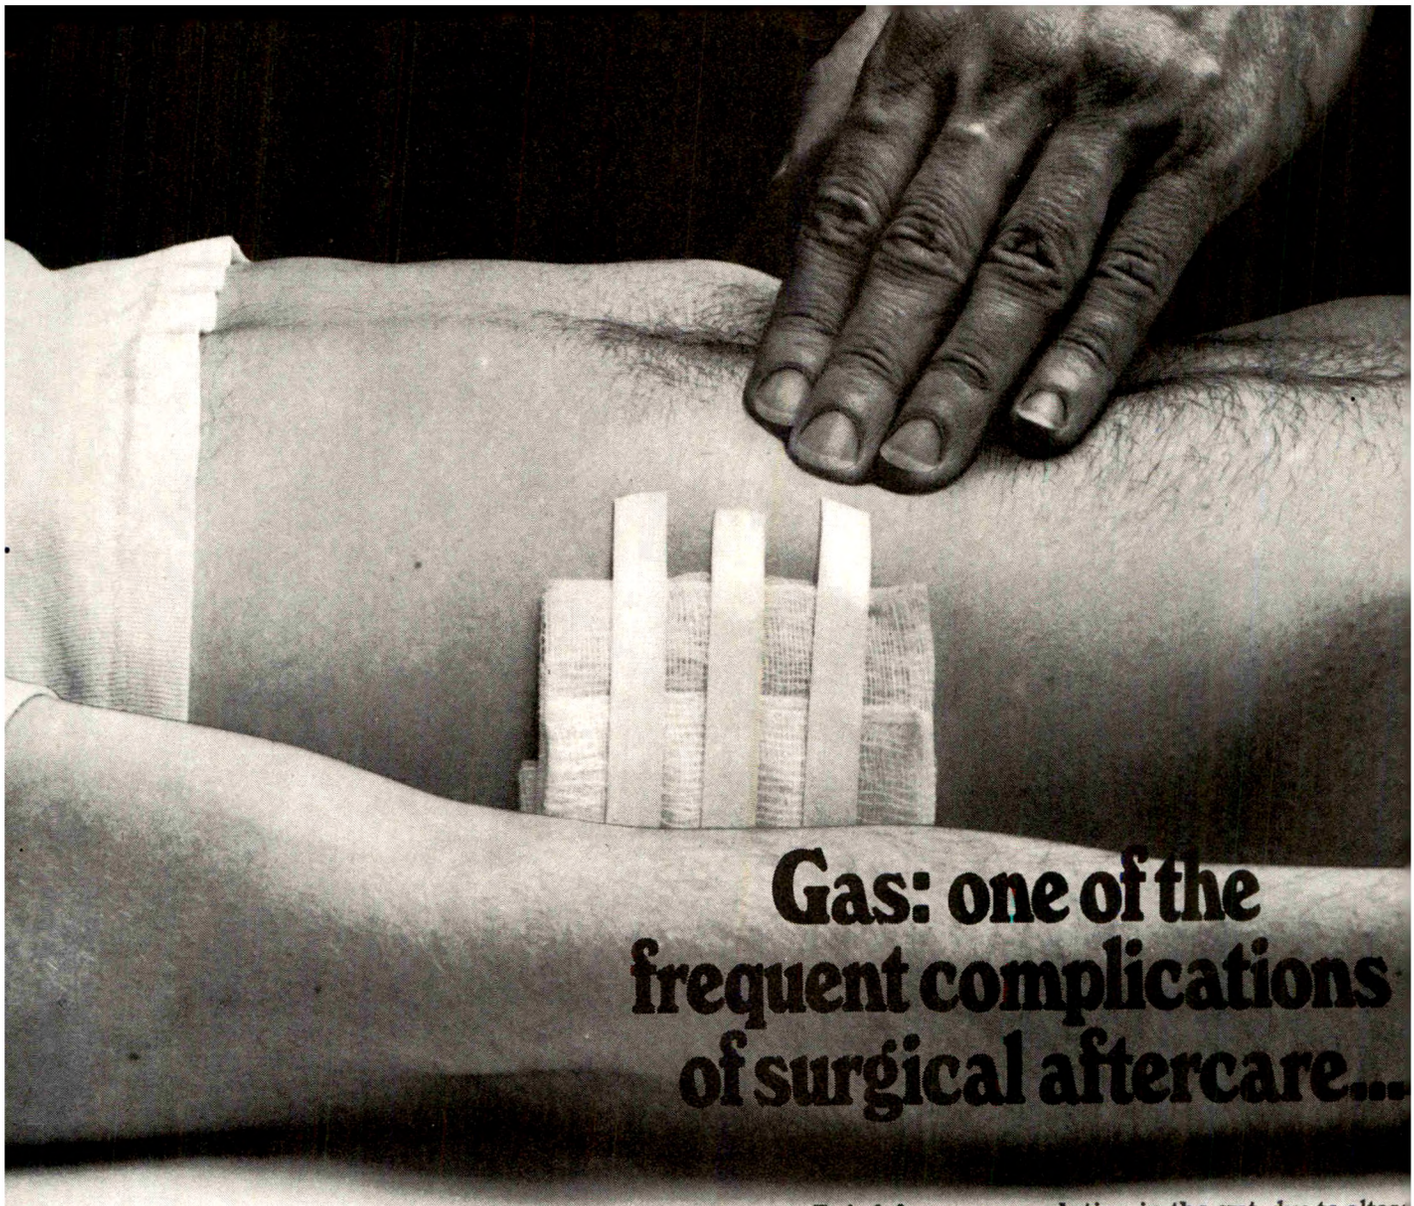
Results

Patterns of Sp-1 levels during pregnancy in the baboon were very consistent among the six animals studied. Sp-1 was detected on day 17 or 18 in each animal, although pregnancy dating could be in error ±1 day. Levels rose rapidly from day 20 to day 50 of gestation to about 18 ng. per milliliter, then increased very slowly thereafter to a level of approximately 24 ng. per milliliter prior to parturition. Following delivery of the infant, Sp-1 levels declined very slowly and undetectable levels were not reached until 26 to 34 days post partum in the six baboons.

The slight variation observed in Sp-1 patterns was characterized by a flat plateau of levels from day 65 until term in one female and a slight decline in levels prior to parturition in another. Maximum levels and rate of increase during early gestation was quantitatively virtually identical in all animals. Rates of postpartum disappearance were also remarkably similar. A pattern of Sp-1 levels during pregnancy for an individual animal is illustrated in Fig. 2 together with patterns of baboon chorionic gonadotropin and chorionic somatomammotropin for comparison. A composite pattern of mean Sp-1 levels for all six animals is shown in Fig. 3.

Comment

Specific antibodies to Sp-1 raised in rabbits do not react immunologically with pregnancy sera from rat, dog, rabbit, mouse, hamster, or guinea pig,[7] but do react with sera from rhesus monkeys, cynomolgus monkeys, and baboons. The rabbit anti-Sp-1 sera have also been shown to produce abortions in pregnant cynomolgus monkeys passively immunized between days 19 and 55 of gestation.[8] Thus, it appears that this substance is secreted by the placentas of several primate species and is important to the maintenance of pregnancy.



Measurements of Sp-1 by radial immunodiffusion tests in human serum at various weeks of pregnancy have been reported.[1, 9] Levels of Sp-1 around 2.0 mg. per milliliter were detected during the twentieth week of human gestation and continued to rise slowly until

around the thirty-sixth week, when a plateau was retained until term. This pattern is distinctly different from that of the baboon, which reached plateau levels by the end of the first trimester of pregnancy. In addition, the concentration of Sp-1 in human pregnancy sera was one- to 5,000-fold higher than in baboons. Differences in the assay methodology used may account for the differences in time of Sp-1 detection and the large differences in quantitative levels attained during gestation, but the difference in species patterns cannot be ascribed to measurement procedures.

Levels of Sp-1 in the sera of women experiencing problem pregnancies appear worthy of investigation. Since levels of this substance are very high during most of gestation, significant changes in the level of Sp-1 may be associated with alterations in placental structure or function. Depending upon the variation in serum levels in normal pregnancies, such changes in Sp-1 levels may be useful in the diagnosis of abnormal placental function. Further, the observation that specific antibodies to Sp-1 will terminate normal pregnancy in monkeys suggests that this protein may be useful in the development of methods of human fertility control.

Gas: one of the frequent complications of surgical aftercare...

Painful gas accumulation in the gut, due to altere intestinal motility, aerophagia and increased salivation, often complicates surgical aftercare.

To help avoid or dispel the acute discomforts of post-op pain in the gut, Phazyme provides simethicone, *"...an effective, safe and simple method of preventing abdominal distention, gas pain and reducing the incidence of ileus."*[1]*

Phazyme's unique dual-phase action releases 20 mg. of specially-activated simethicone initially to the stomach for immediate dispersion of entrapped g

The protected inner core delivers an additional 40 mg. of specially-activated simethicone to relieve pain of entrapped gas throughout the lower G.I. tract

Phazyme also provides 240 mg. of pancreatin directly to the small intestine to help assure normal digestion.

And Phazyme is safe... no systemic effects... no untoward reactions... no contraindications other than known allergy to an ingredient.

Pharmacia

PHARMACIA LABORATORIES INC.
PISCATAWAY, NEW JERSEY 08854

PRESCRIBING INFORMATION

HYSKON® HYSTEROSCOPY FLUID

32% (W/V) dextran 70 in dextrose

DESCRIPTION: Hyskon Hysteroscopy Fluid is a clear, viscid, sterile, non-pyrogenic solution of dextran 70 (32% W/V) in dextrose (10% W/V). Dextran 70 is that fraction of dextran, a branched polysaccharide composed of glucose units, having a weight average molecular weight of 70,000. The fluid is electrolyte-free and non-conductive. At room temperature Hyskon Hysteroscopy Fluid has a viscosity of 220 cSt.

Hyskon has a tendency to crystallize when subjected to temperature variations or when stored for long periods. If flakes of dextran are present, heat at 100°-110° C until complete dissolution is achieved.

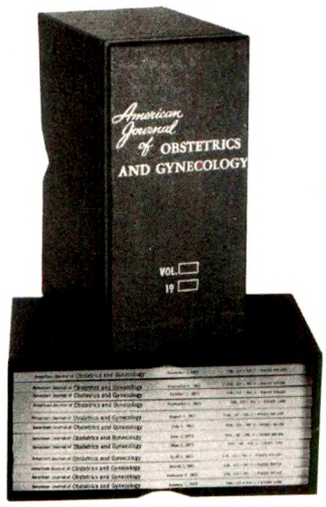
INDICATIONS: Hyskon Hysteroscopy Fluid is indicated for use with the hysteroscope as an aid in distending the uterine cavity and in irrigating and visualizing its surfaces.

CONTRAINDICATIONS: Hyskon Hysteroscopy Fluid should not be instilled in patients known to be hypersensitive to dextran. All other contraindications are those relative to the hysteroscopic procedure itself, such as pregnancy, endometrial carcinoma, etc.

WARNINGS: It is not known whether systemic absorption of dextran 70 occurs from the uterine and peritoneal cavities. Because of the possibility that absorption can occur, the physician should familiarize himself with the systemic effects of this drug. The most alarming are severe, sometimes fatal anaphylactoid reactions, which are quite rare. Other noteworthy effects include plasma volume expansion and transient prolongation of bleeding time.

ADVERSE REACTION: Undesirable effects directly attributable to the use of Hyskon Hysteroscopy Fluid have not been reported. However, the physician should be mindful of the fact that adverse reactions are known to occur with the intravenous administration of dextran 70 (MACRODEX 6% W/V). Such reactions have included: allergic phenomena (anaphylactoid reactions, urticaria, nasal congestion, wheezing, tightness of chest and mild hypotension), nausea, vomiting, fever and joint pains.

DOSAGE AND ADMINISTRATION: The amount of Hyskon Hysteroscopy Fluid required per patient depends on a number of factors, such as the type and length of the diagnostic procedure, whether or not manipulation or surgery is performed, etc. Most often, however, the amount of Hyskon instilled into the uterus will be between 50 and 100 milliliters.



Hyskon should be introduced into the uterine cavity through the cannula of a hysteroscope under low pressure (approximately 100 mm Hg) until the uterus is sufficiently distended to permit adequate visualization. During the hysteroscopic examination, Hyskon should be infused at a rate that keeps the cavity suitably distended. To avoid injection of the fluid into the tissues of the uterus and parametria and to avoid having unnecessary amounts of the fluid pass into the peritoneal cavity and backwards along the side of the hysteroscope, infusion pressures greater than 150 mm Hg should not be used.

HOW SUPPLIED: Hyskon Hysteroscopy Fluid (32% W/V dextran 70 in 10% W/V dextrose) is available as a sterile, nonpyrogenic solution in 100 ml bottles packed 12 to a carton.
NDC No. 0016-0231-61

PERSONALIZED LIBRARY CASES

Keep your personal copies of AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY in these specially designed library file cases. Two files hold an entire year's issues. Designed to keep your journal copies near at hand in your office, library, or home.

Your case is heavy bookbinder's board in a rich red Kivar cover. Files are scuff-resistant and washable.

Lettering is stamped in gold leaf and the cases make a fit companion for the most costly binding.

Files are reasonably priced—only $4.25 each, postpaid (3 for $12., 6 for $22.). Add $1.00 postage per case for orders outside U. S. Satisfaction unconditionally guaranteed or your money back! Use the coupon for prompt shipment.

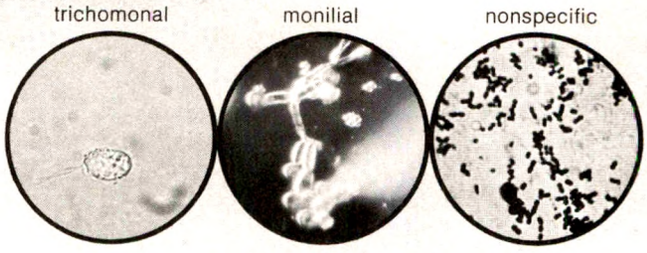
Infectious vaginitis!
monilial?
trichomonal?
nonspecific?

a microbicidal douche

for triple target therapy
of infectious vaginitis



BETADINE® douche

Infectious vaginitis often involves a mixed infection. Systemic or topical therapy directed against a single pathogen may miss or encourage another.

BETADINE DOUCHE is a broad-spectrum topical microbicide that promptly kills trichomonads, monilia and bacteria. It is active in the presence of blood, pus or vaginal secretions, and is virtually nonirritating to vaginal mucosa. Low surface tension assists penetration into vaginal crypts and crevices.

Suggested regimen for therapeutic use: In the office, swab the cervix and vulvovaginal area with BETADINE SOLUTION. Prescribe BETADINE DOUCHE: Two (2) tablespoonfuls to a quart of lukewarm water once daily, preferably before bedtime, through the entire menstrual cycle. If further therapy is warranted, douching may be continued through the next cycle. The patient may be instructed to return for an office visit following two weeks of therapy.

Directions for routine cleansing: One (1) tablespoonful to a quart of lukewarm water once or twice a week.

Supplied: 8 oz. and 1 gal. plastic bottles; 1/2 oz. packettes (6 per carton).

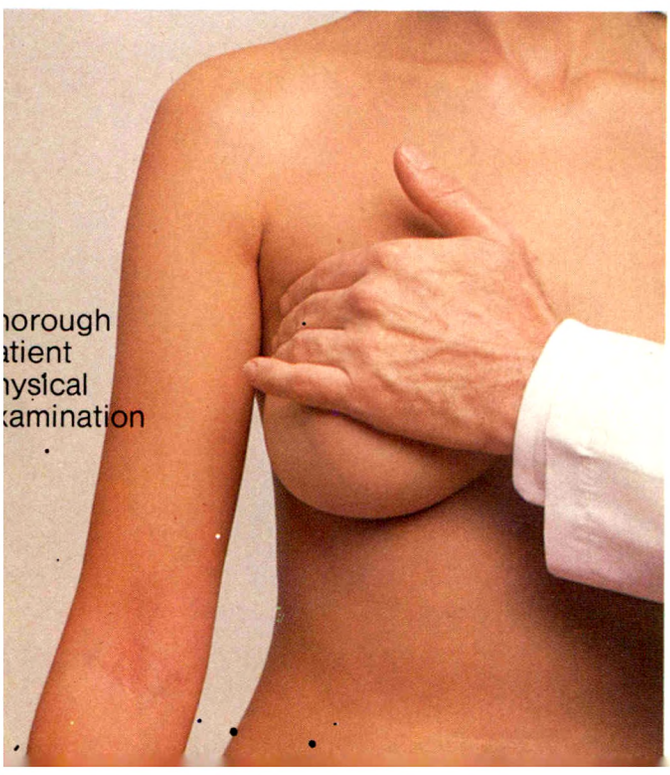
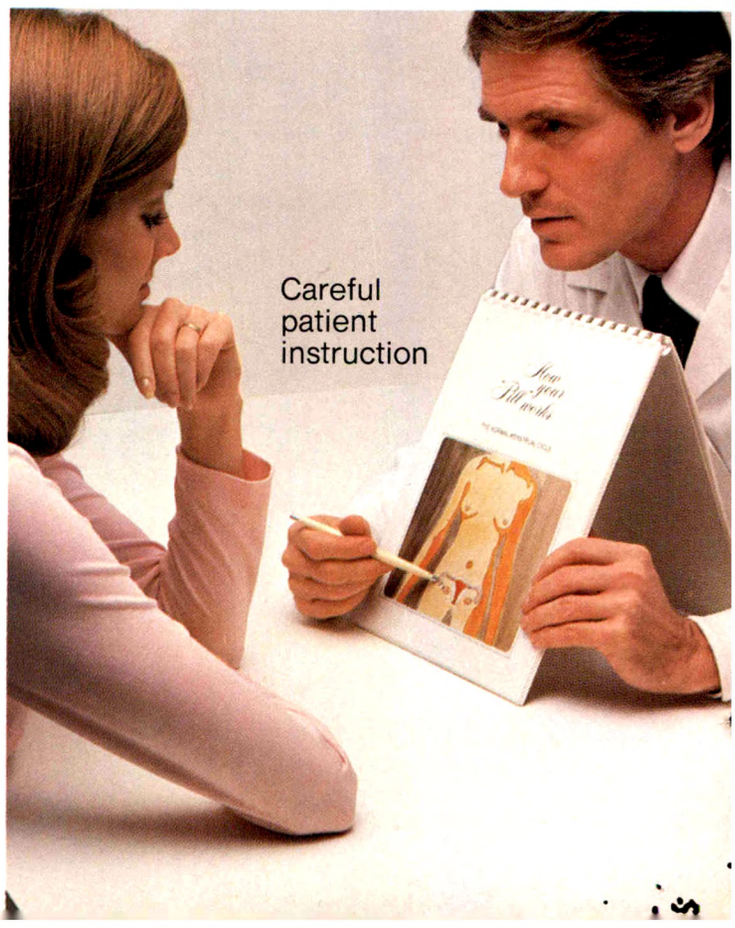
Prudent Practice...



Some sensible steps physicians take before prescribing an oral contraceptive



A complete medical history

Appropriate laboratory procedures

horough
atient
hysical
kamination

Careful patient instruction

And when you prescribe a combination oral contraceptive, it's also prudent practice to employ the lowest effective dose of estrogen that is otherwise acceptable.

For many women, this could mean Loestrin 1/20—20 mcg of ethinyl estradiol in combination with 1 mg of norethindrone acetate.

As you would expect, irregular bleeding and occasionally the absence of bleeding, especially during the first few cycles, are more frequent with Loestrin 1/20 than with combinations containing larger doses of estrogen. Nevertheless, clinical trials demonstrated that more than 85% of the subjects, some of whom experienced such irregular cycles, found Loestrin 1/20 an acceptable oral contraceptive.

Effective contraception... with a low dose of estrogen—a tough combination to beat.

The lowest dose of a proven effective estrogen in a combination oral contraceptive

LOESTRIN® 1/20

Each white tablet contains 1 mg norethindrone acetate and 20 mcg ethinyl estradiol; each brown tablet contains 75 mg ferrous fumarate, USP.

PARKE-DAVIS

See next page for prescribing information.

LOESTRIN 1/20

Each white tablet contains:
norethindrone acetate (17 alpha-ethinyl-19-nortestosterone acetate) . . . 1 mg
ethinyl estradiol (17 alpha-ethinyl-1,3,5 (10)-estratriene-3, 17 beta-diol) . . . . . 20 mcg
Each brown tablet contains
75 mg ferrous fumarate, USP

BRIEF SUMMARY OF
PRESCRIBING INFORMATION

SPECIAL NOTE

Oral contraceptives have been marketed in the United States since 1960. Reported pregnancy rates vary from product to product. The effectiveness of Loestrin 1/20 is somewhat lower than that of the higher-dose combination products. Both provide almost completely effective contraception.

The dropout rate for medical reasons, as observed in the clinical trials that were conducted with Loestrin 1/20, appears to be somewhat higher than observed with higher-dose combination products. This higher dropout rate was observed to be due particularly to irregular bleeding.

An increased risk of thromboembolic disease associated with the use of hormonal contraceptives has now been shown in studies conducted in both Great Britain and the United States. Other risks, such as those of elevated blood pressure, liver disease, and reduced tolerance to carbohydrates, have not been quantitated with precision.

Long-term administration of both natural and synthetic estrogens in subprimate animal species in multiples of the human dose increases the frequency for some animal carcinomas. These data cannot be transposed directly to man. The possible carcinogenicity due to the estrogens can neither be affirmed nor refuted at this time. Close clinical surveillance of all women taking oral contraceptives must be continued.

INDICATION

Loestrin 1/20 is indicated for the control of conception.

CONTRAINDICATIONS

1. Thrombophlebitis, thromboembolic disorders, cerebral apoplexy, or a past history of these conditions.
2. Markedly impaired liver function.
3. Known or suspected carcinoma of the breast.
4. Known or suspected estrogen-dependent neoplasia.
5. Undiagnosed abnormal genital bleeding.
6. Pregnancy.

WARNINGS

1. The physician should be alert to the earliest manifestations of thrombotic disorders (thrombophlebitis, cerebrovascular disorders, pulmonary embolism, and retinal thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately.

Retrospective studies of morbidity and mortality in Great Britain and studies of morbidity in the United States have shown a statistically significant association between thrombophlebitis, pulmonary embolism, and cerebral thrombosis and embolism and the use of oral contraceptives. There have been three principal studies in Britain [1-3] leading to this conclusion, and one[4] in this country. The estimate of the relative risk of thromboembolism in the study by Vessey and Doll[3] was about sevenfold, while Sartwell and associates in the United States found a relative risk of 4.4, meaning that the users are several times as likely to undergo thromboembolic disease without evident cause as nonusers. The American study also indicated that the risk did not persist after discontinuation of administration, and that it was not enhanced by long continued administration. The American study was not designed to evaluate a difference between products. However, the study suggested that there might be an increased risk of thromboembolic disease in users of sequential products. This risk cannot be quantitated, and further studies to confirm this finding are desirable.

2. Discontinue medication pending examination if there is sudden partial or complete loss of vision, or if there is a sudden onset of proptosis, diplopia, or migraine. If examination reveals papilledema or retinal vascular lesions, medication should be withdrawn.

3. Since the safety of Loestrin 1/20 in pregnancy has not been demonstrated, it is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period.

4. A small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The long-range effect to the nursing infant cannot be determined at this time.

PRECAUTIONS

1. The pretreatment and periodic physical examinations should include special reference to breasts and pelvic organs, including Papanicolaou smear, since estrogens have been known to produce tumors, some of them malignant, in five species of subprimate animals.

2. Endocrine and possibly liver function tests may be affected by treatment with Loestrin 1/20. Therefore, if such tests are abnormal in a patient taking Loestrin 1/20, it is recommended that they be repeated after the drug has been withdrawn for two months.

3. Under the influence of estrogen-progestogen preparations, preexisting uterine fibromyomata may increase in size.

4. Because these agents may cause some degree of fluid retention, conditions which might be influenced by this factor, such as epilepsy, migraine, asthma, cardiac or renal dysfunction, require careful observation.

5. An alteration in menstrual patterns in many patients is likely to be induced by using Loestrin 1/20 The amount and duration of flow and cycle length may be variable. Because of these irregular bleeding patterns, it is important that the physician take this into consideration when attempting to determine if persistent bleeding is from organic causes.

6. Patients with a history of psychic depression should be carefully observed and the drug discontinued if the depression recurs to a serious degree.

7. Any possible influence of prolonged Loestrin 1/20 therapy on pituitary, ovarian, adrenal, hepatic, or uterine function awaits further study.

8. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. The mechanism of this decrease is obscure. For this reason, diabetic patients should be carefully observed while receiving Loestrin 1/20 therapy.

9. The age of the patient constitutes no absolute limiting factor, although treatment with Loestrin 1/20 may mask the onset of the climacteric.

10. The pathologist should be advised of Loestrin 1/20 therapy when relevant specimens are submitted.

11. Susceptible women may experience an increase in blood pressure following administration of contraceptive steroids.

ADVERSE REACTIONS OBSERVED IN PATIENTS RECEIVING ORAL CONTRACEPTIVES

A statistically significant association has been demonstrated between use of oral contraceptives and the following serious adverse reactions:

Thrombophlebitis
Cerebral thrombosis
Pulmonary embolism

Although available evidence is suggestive of an association, such a relationship has been neither confirmed nor refuted for the following serious adverse reactions:

Neuro-ocular lesions, e.g, retinal thrombosis and optic neuritis

The following adverse reactions are known to occur in patients receiving oral contraceptives:

Nausea
Vomiting
Gastrointestinal symptoms (such as abdominal cramps and bloating)
Breakthrough bleeding
Spotting
Change in menstrual flow
Amenorrhea during and after treatment
Edema
Chloasma or melasma
Breast changes: tenderness, enlargement, and secretion
Change in weight (increase or decrease)
Changes in cervical erosion and cervical secretions
Suppression of lactation when given immediately postpartum
Cholestatic jaundice
Migraine
Rash (Allergic)
Rise in blood pressure in susceptible individuals
Mental depression

Although the following adverse reactions have been reported in users of oral contraceptives, an association has been neither confirmed nor refuted:

Anovulation post treatment
Premenstrual-like syndrome
Changes in libido
Changes in appetite
Cystitis-like syndrome
Headache
Nervousness
Dizziness
Fatigue
Backache
Hirsutism
Loss of scalp hair
Erythema multiforme
Erythema nodosum
Hemorrhagic eruption
Itching

The following laboratory results may be altered by the use of oral contraceptives:

Hepatic function: increased sulfobromophthalein retention and other tests

Coagulation tests: increase in prothrombin, factors VII, VIII, IX, and X.

Thyroid function: increase in PBI and butanol extractable protein-bound iodine, and decrease in T^3 uptake values

Metyrapone test

Pregnanediol determination

DOSAGE AND ADMINISTRATION

Special Notes on Administration

Menstruation usually begins two or three days, but may begin as late as the fourth or fifth day, after the brown tablets have been started. Because of the relatively low estrogenic content, Loestrin 1/20 is not a good cyclic regulator. There are patients whose inherent hormone balance will require larger amounts of estrogen to achieve cyclic regularity than that contained in Loestrin 1/20. These patients experience altered bleeding patterns, which do not conform to treatment schedules, while taking the white Loestrin 1/20 tablets. However, it is important that patients adhere to the dosage schedule regardless of when bleeding occurs.

The occurrence of altered bleeding is highest in Cycle 1. The majority of patients will have seven days or less of total bleeding during the 28-day cycle (including both withdrawal bleeding and breakthrough bleeding and spotting). Should irregular bleeding occur, patients should be reassured and instructed to continue taking the tablets as directed. If by the third cycle the irregular patterns are unacceptable, consideration should be given to changing the medication to a product with higher estrogen content (Norlestrin®-1 mg or Norlestrin-2.5 mg). The physician should be alert to the fact that the irregular bleeding patterns could mask bleeding from organic causes, and appropriate diagnostic measures should be taken if the bleeding persists or continues after changing to a higher estrogen-content product.

GYNECOLOGY

Pure gonadal dysgenesis with an XY chromosomal constitution (Swyer's syndrome): Report of two cases

DANIEL W. BRUNETEAU, M.D.*
ISMET B. SIPAHIOGLU, M.D.*
J. ROGERS BYRD, PH.D.
ROBERT B. GREENBLATT, M.D.
Augusta, Georgia

Two cases of Swyer's syndrome, characterized by rudimentary streaks in association with a 46,XY chromosome karyotype are reported. Both individuals were tall, with sparse axillary and pubic hair, and breasts were undeveloped in one and well developed in the other (she had some estrogen therapy). One had infantile but otherwise normal external genitals, while the other had poor development of labia majora and no clitoris. The vagina in each was normal, with a small cervix and uterus, and vaginal smears of the preadolescent type. Urinary 17-ketosteroids were normal, while gonadotropin levels were elevated. The gonadal streaks were extirpated, and histologic examination revealed the presence of fibrous stroma but no ova or follicles. Scattered clumps of Leydig cells and mesonephric remnants were found in one patient. Both patients responded well to cyclic hormonal therapy, i.e., menstrual withdrawal bleeding and breast development.

GONADAL DYSGENESIS, stricto sensu, applies to a primary congenital gonadal defect due to failure of differentiation of the gonad before its full sexualization. The prototype of gonadal dysgenesis is the multidystrophic syndrome of Turner with its extragenital somatic anomalies as dominant features of the disorder. There is a possibility of normal genital function associated with dystrophic states (similar to those encountered in Turner's syndrome) as well as the existence of gonadal dysgenesis without them. The presence of chromosomal aberrations serves to confuse the situation. Even though 45,X sex chromosome compliment seems to be the most frequent single pattern, there are other karyotypes including chromosome mosaicism and those with normal sex chromosome patterns, male or female.

The XY sex chromosome compliment may be encountered in isolation or in mosaicism. We previously reported five cases of gonadal dysgenesis with XO/XY mosaicism[1]; four of these were assymetric gonadal dysgenesis with a gonadal streak on one side and an immature testis on the other. The normal male sex chromosome pattern, XY, may be encountered in three different types of gonadal dysgenesis: gonadal dysgenesis with gonocytoma, male Turner's syndrome, and so-called pure gonadal dysgenesis with which this article is concerned.

In 1955, Swyer[2] described two chromatin-negative

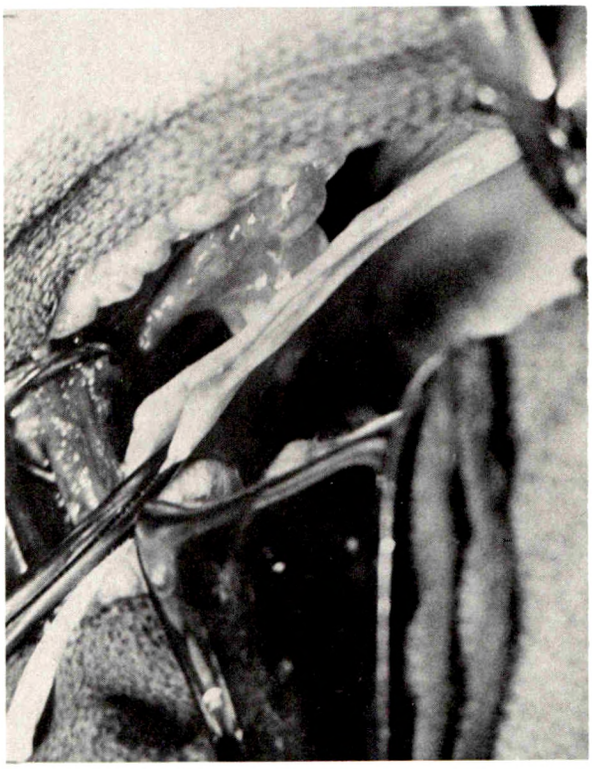

Fig. 1. Case 1. surgical findings, showing rudimentary gonadal streaks.

girls who were of tall stature and lacked the anomalies and malformations usually encountered in Turner's syndrome. Hoffenberg and Jackson[3] suggested that the cases described by Swyer were a variant of gonadal dysgenesis. In 1959, Harnden and Stewart[4] found a normal male chromosome compliment in a tall 19-year-old girl with primary amenorrhea, and they named the disorder "pure gonadal dysgenesis." Since then, this appellation has been used for patients with a variety of karyotypes, provided they did not have the somatic anomalies usually found in Turner's syndrome. If the chromosomal compliment 45,X is never found in pure gonadal dysgenesis, there may be justification for separating those subjects who have a female phenotype and XY sex chromosome complex (Swyer's syndrome) from those with the other karyotypes encountered, including various mosaics and a normal female XX chromosomal constitution. It is believed that this entity is an intrauterine castration syndrome in a subject who is genetically male. It mimics Jost's[5] castration experiment in rabbits, a condition different from those in which the gonad appears destined to form an ovary.[6]

Case reports

Case 1. L. H. was a 17-year-old girl with primary amenorrhea and failure of sexual development.

Fig. 2. Case 1. Photomocrograph showing mesonephric remnant.

Height was 166 cm. Positive physical findings included sparse axillary and pubic hair, undeveloped breasts, and infantile but otherwise normal external genitals. On pelvic examination, a tight virginal introitus precluded visualization of the cervix, but no masses were palpable rectally. Radiologic examination of hands and wrists revealed all epiphyses to be open. Urinary 17-ketosteroids were 6.9 and 7.5 mg. per 24 hours. Urinary follicle-stimulating hormone (FSH) determinations were greater than 52 and less than 104 mU. per 24 hours. Vaginal smears were preadolescent in type, and the nuclear sex chromatin pattern was negative. Chromosome counts from leukocyte cultures consistently showed 46 chromosomes, and analysis revealed an XY sex chromosome complex no different from that of a normal male subject. At laparotomy, typical gonadal streaks were found (Fig. 1). The uterus was represented by a small rudimentary structure. Microscopically, the gonadal streaks showed a small amount of fibrous stroma, scattered clumps of Leydig cells, mesonephric remnants, but no ova or follicles (Figs. 2 and 3).

Case 2. A. B. was a 25-year-old female subject with primary amenorrhea who failed to menstruate following various hormonal regimens. Height was 170 cm. Sexual hair pattern was typical of an adult female but

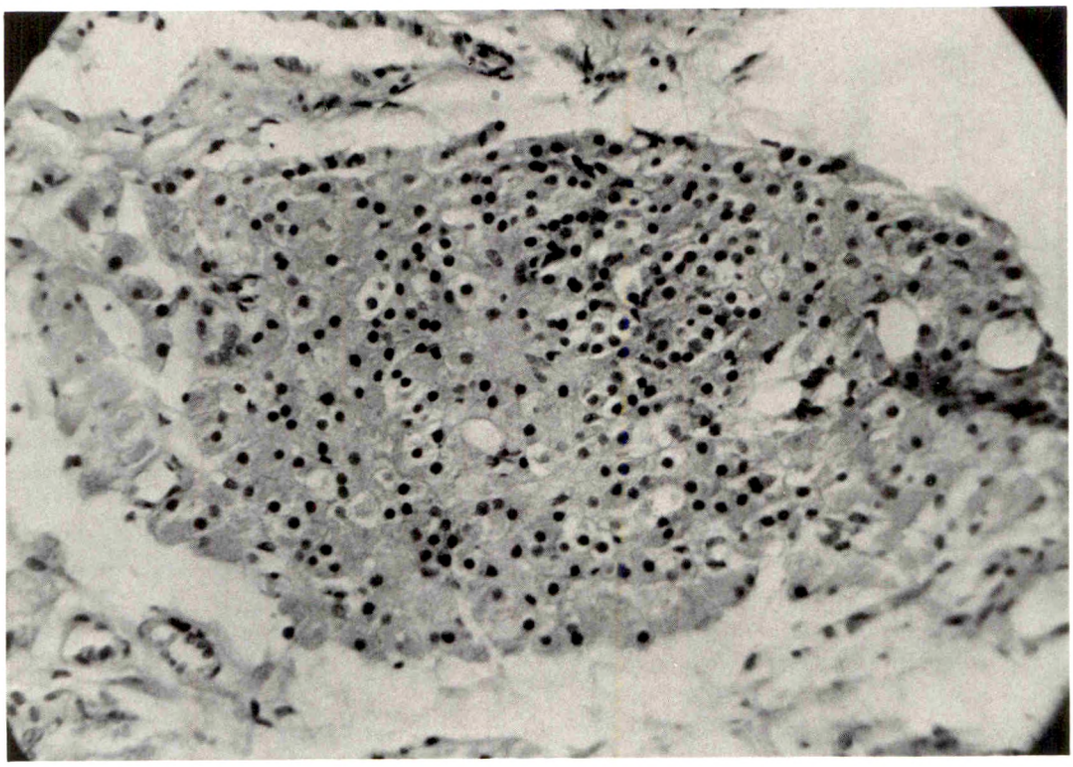

Fig. 3. Case 1. Photomicrograph showing typical clump of Leydig cells.

quantitatively poor, and breasts were well developed (she had received some estrogen therapy in the past). The external genitals showed an absence of development of the labia majora and an almost nonexistant clitoris. Pelvic examination revealed a normal vagina and small cervix and uterus with nonpalpable adnexa. Endocrine studies were performed, and a castrate vaginal smear was obtained. 17-Ketosteroids were 8 and 9.6 mg. per 24 hours. Plasma gonadotropin levels obtained by radioimmunoassay were: FSH, 43.7 mI.U. per milliliter, and LH, 4.5 mI.U. per milliliter.

Gynecography combined with a hysterosalpingogram showed the existence of a small uterine cavity of normal configuration with Fallopian tubes of normal caliber. There was no clearly defined ovarian density. Sex chromatin was negative, and chromosome analysis from a leukocyte culture demonstrated a 46,XY karyotype (Fig. 4). A laparotomy was performed; the uterus was infantile, and bilateral gonadal streaks were present. Both Fallopian tubes and streaks were removed. Histologic study of the gonadal streaks revealed dense cellular connective tissue, and neither primary oocytes nor Leydig cells were present in the sections examined.

Comment

The classical cases of gonadal dysgenesis (Turner's syndrome) are characterized by amenorrhea, diminished stature, webbed neck, increased carrying angle of arms, low hairline, a "shield" chest, and a 45,X chromosome karyotype. In some exceptional subjects with very well-developed breasts, normal axillary and pubic hair, normal menstruation, and even pregnancy have been reported.[7, 8]

In 1955, when Swyer[2] reported two cases of pure gonadal dysgenesis with a 46,XY karyotpye, he found several common features. Both subjects were tall with little or no mammary development. Axillary and pubic hair distribution, the vagina, and the cervix were within normal limits. The uterus was small, and the vaginal cytology was hypoestrogenic. Urinary output of 17-ketosteroids was normal. The two subjects differed in that in one there was an enlarged clitoris.

In our cases, histopathologic examination of the gonadal streaks revealed the presence of fibrous stroma but no ova or follicles. Scattered clumps of Leydig cells and mesonephric remnants were found in one case. Kinch and associates[9] also reported the same histopathologic findings with the exception of a lack of Leydig cells.

Fibrous tissue is the major component of the gonadal streak.[1, 10] It is not clear that germ cell migration is necessary for gonadal development. In pure gonadal dysgenesis with an XY sex chromosome pattern, normal migration of germ cells may not occur. If this does occur, then the environment probably proves

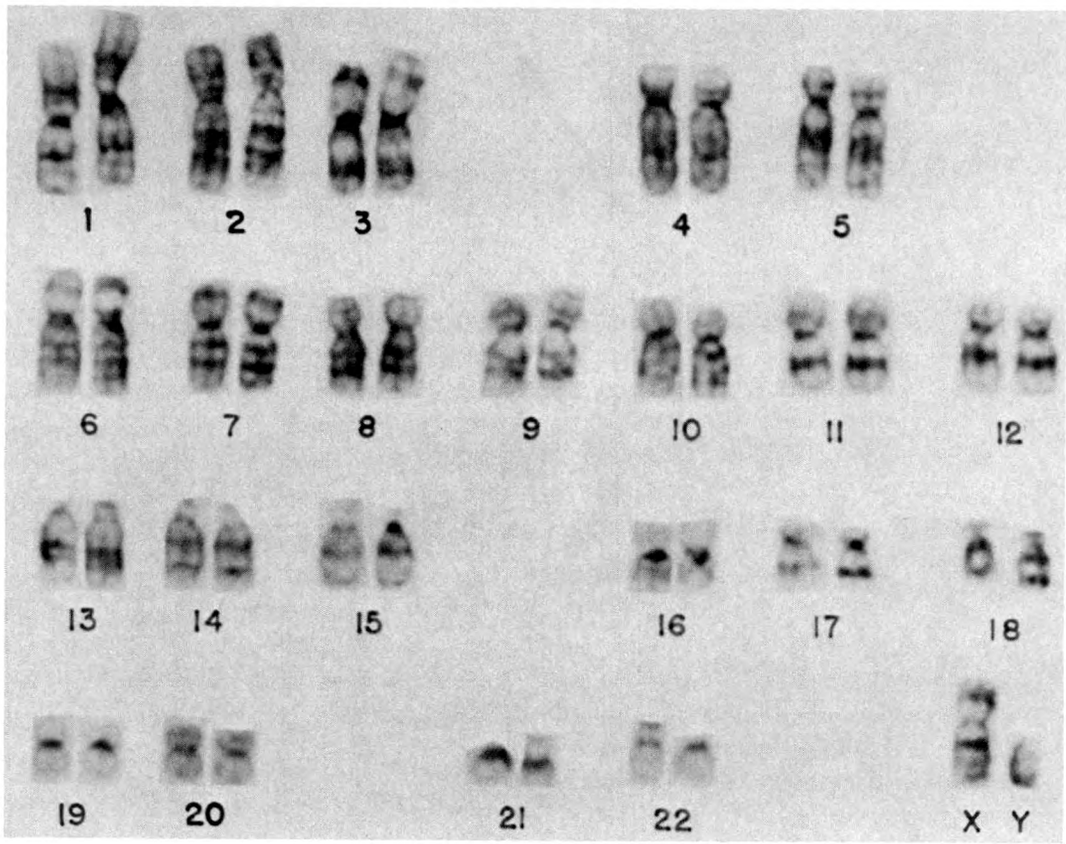

Fig. 4. Case 2. Karyotype showing 46,XY. G-banded.

unsatisfactory for normal development. The belief that gonadal dysgenesis has a genetic etiology is fairly well accepted while the specific genetic mechanism remains unknown. If it is related to multiple genes, the specific alleles and their loci have not been detected.[9, 11, 12] Whatever the cause, the destined testicular development fails to occur early enough in fetal life so that internal and external genitals develop along female lines.[11]

In pure gonadal dysgenesis, one third of the subjects have a 46,XX karyotype.[12] Primary ovarian failure may be due to some early embryonic accident not of chromosomal origin. Two thirds apparently have the 46,XY karyotype, though some of these may be 46,XX and the apparent Y is really the remaining short arm of an X.[12] Libido and breast development may be due to end-organ sensitivity to extragonadal estrogens.

It is recommended in cases of Swyer's syndrome, as well as in other cases of gonadal dysgenesis with an XY cell line, that the streaks be extirpated because of the risk of germ cell tumor development.[13]

Testosterone metabolism in endometrial cancer

ANTHONY CALANOG, M.D.
SANFORD SALL, M.D.
GARY G. GORDON, M.D.
JAIME OLIVO, M.D.
A. LOUIS SOUTHREN, M.D.
New York, New York

Plasma testosterone (PC^T), metabolic clearance (MCR^T), and production rates (PR^T) of testosterone and conversion ratio of testosterone to androstenedione (CR^{TA}_{pp}) were performed on 11 patients with endometrial cancer and on a control group of five postmenopausal women. The PC^T, MCR^T, and PR^T of patients with endometrial cancer are in the normal postmenopausal range. The conversion of testosterone to androstenedione in patients with endometrial cancer was significantly decreased.

EPIDEMIOLOGIC studies suggest that estrogens may play an etiologic role in the development of malignancy in women, particularly in breast and endometrial cancer.[1–3] Recent studies have also indicated alterations in androgen metabolism in breast and endometrial cancer.[4, 5] Bulbrook and associates[6–8] found that a discriminant function can be derived from a study of the urinary excretion patterns of 17-ketosteroids and 17-hydroxycorticoids. Patients with a positive discriminant, i.e., those with a high etiocholanolone and/or androsterone excretion relative to the 17-hydroxycorticoids, tended to benefit from adrenalectomy with oophorectomy or hypophysectomy, whereas those with a negative discriminant did not respond. De Waard and associates[9] applied Bulbrook's concept of a hormonal discriminant function to patients with endometrial cancer and have shown that those patients excreted less etiocholanolone relative to 17-hydroxycorticoids or estrogens (mainly estriol) than normal controls.

Moreover, the polycystic ovary syndrome (PCOS), characterized by anovulation and sclerocystic ovaries, is associated with a reported 20 per cent incidence of endometrial cancer.[10–12] This condition is associated with increased plasma levels, production and metabolic clearance of testosterone, as well as elevated gonadotropins.[13, 14]

Sall and Calanog[15] evaluated the urinary steroid excretion patterns of postmenopausal women with benign and neoplastic endometrium and corroborated the findings of low androsterone and etiocholanolone excretions in women with endometrial hyperplasia and cancer. The introduction of precise methods for measuring plasma levels and production rates of the various androgens and their conversions to the estrogens has provided a unique opportunity to determine whether a distinct abnormality in androgen metabolism is indeed present in endometrial cancer.

Our study in endometrial cancer patients encompassed three areas: (1) the evaluation of testosterone metabolism, (2) the evaluation of androstenedione metabolism and its conversions to estrogens, and (3) the evaluation of estrogen metabolism. This initial report concerns itself with the testosterone levels, metabolic clearance rates, production rates, and interconversions to androstenedione of patients with endometrial cancer.

Materials and methods

Eleven patients (two premenopausal and nine postmenopausal) with abnormal uterine bleeding were hospitalized at the New York Medical College and the diagnosis of endometrial cancer was made by fractional

curettage. A group of five postmenopausal patients served as controls. Clinical summaries of both groups are in Tables I and II.

All patients were hospitalized under basal conditions. The pertinent history and physical examination were obtained. The metabolic clearance (MCR) and production (PR) rates of testosterone and conversion of testosterone to androstenedione were determined with a constant infusion procedure.[13] After an overnight fast the patients were kept in a supine position for at least 1 hour before the start until the end of the constant infusion. The plasma concentration of free testosterone was measured by the protein displacement method of Mayes and Nugent.[16]

In the constant infusion procedure, a priming dose of either 4 or 6 μCi of 1,2^{3}H-testosterone (sp. gr. 137 μCi/μg and found to be 97 per cent pure by paper chromatography in a modified Bush B 3 System) was first administered intravenously as a single injection. Thirty minutes later, an intravenous infusion was started containing either 8 or 12 μCi of 1,2^{3}H-testosterone dissolved in 50 ml. of 8 per cent ethanol in saline. The labeled steroid was given at a constant rate with the aid of a Harvard pump (Model No. 600/900). Then 40 ml. of blood were withdrawn at 105, 120, and 135 minutes after initial injection. The plasma was separated, added to tubes containing 4-^{14}C-testosterone and processed. The value of the radioactivity in each plasma sample present specifically as testosterone and corrected for losses during the isolation procedure was calculated. The mean of the three estimates and the value for the rate of the radioactive infusion (R) were taken to calculate the metabolic clearance rate (MCR) according to the following expression: MCR (L./day) = r (mμCi/day)/Ci(mμCi/L.).

The production rate (PR) of testosterone was then calculated from the expression (PR [mg./day] = MCR [L./day] × MPC [mg./L.]), where MPC is the mean plasma concentration of testosterone.

Results

The kinetic parameters of testosterone metabolism in normal postmenopausal women and in patients with endometrial cancer are given in Tables III and IV, respectively.

Plasma testosterone (PC^T). The mean PC^T (0.60 ± 0.34 [S.D.] μg/L.) in the endometrial cancer group was compared to the mean PC^T (0.40 ± 0.20 [S.D.] μg/L.) of the normal postmenopausal patient group and to a group of 14 normal premenopausal women (0.54 ± 0.11 [S.D.] μg/L.) previously evaluated in our laboratory.[17] There was no significant difference between the mean PC^T in the endometrial cancer group and the normal premenopausal and postmenopausal groups.

Metabolic clearance rates of testosterone (MCR^T). The mean MCR^T (735 ± 180 [S.D.] L./day) in the

endometrial cancer group was compared to the mean MCR^T (730 ± 53 [S.D.] L./day) of the normal postmenopausal patient group and to a group of 14 normal premenopausal women (675 ± 139 [S.D.] L./day) previously evaluated in our laboratory.[17] There was no significant difference between the mean MCR^T in the endometrial cancer group and the normal premenopausal ($P > 0.4$) and postmenopausal groups ($P > 0.6$).

Production rates of testosterone (PR^T). The mean PR^T (502 ± 238 [S.D.] μg/day) in the endometrial cancer group was compared to the mean PR^T (364 ± 218 [S.D.] μg/day) of the normal postmenopausal patient group and to a group of 14 normal premenopausal women (350 ± 130 [S.D.] μg/day) previously evaluated in our laboratory.[17] There was no significant difference between the mean PR^T in the endometrial cancer group and the normal premenopausal ($P > 0.6$) and postmenopausal groups ($P > 0.1$).

Conversion ratios of testosterone (CR^{TA}_{pp}). The mean CR^{TA}_{pp} (0.02 ± 0.01 [S.D.]) in the endometrial cancer group was compared to the mean CR^{TA}_{pp} (0.04 ± 0.01 [S.D.]) of the normal postmenopausal patient group and to a group of 12 PCOS patients[13] (0.034 ± 0.019 [S.D.]) as previously evaluated in our laboratory. The endometrial cancer group had a statistically lower mean CR^{TA}_{pp} than the post menopausal group ($P < 0.05$).

Comment

During the past decade, there has developed the concept that endometrial cancer is a malignancy associated with an underlying endocrinopathy. The fact that it occurs mostly in women in the postmenopausal age group, in the presence of abnormal and/or unopposed estrogen stimulation, in association with diabetes and obesity, or in women with a history of infertility and anovulation such as in polycystic ovary syndrome, suggests a relationship between the derangement in the endocrine metabolism of these women and the development of the neoplasm.

When the MCR^T, PC^T, and PR^T are compared there is no significant difference noted between the endometrial cancer and the normal postmenopausal patient. Although the mean PR^T of the two groups of patients are not statistically different, there is a suggestive increase in the PR^T in the endometrial cancer patient. The conversion ratio of testosterone to androstenedione, however, is significantly decreased in the endometrial cancer group, as compared to the control group.

The significance of the decreased conversion of testosterone to androstenedione is not known.

Studies on the cytodynamics of human endometrial regeneration

I. Scanning electron microscopy

ALEX FERENCZY, M.D.

Montreal, Quebec, Canada

Stereoscopic morphologic studies on regenerating cyclic endometrium indicate that endometrial repair lasts 48 hours, beginning between cycle Days 2 to 3 and ending between cycle Days 4 to 5. During this period, endometrial repair is focused on the neoformation of surface epithelium and is initiated only when and where the zona basalis is denuded from the overlying secretory spongiosa. The surface epithelium is derived from a simultaneous proliferation of dual origin: first from the exposed ends of basal glands and second from the persistent and intact surface lining of cornual and isthmic regions, bordering the denuded areas. The lack of estrogen-dependent morphologic alterations (mitosis and ciliogenesis) in the uterine mucosa during the regenerative period suggests that the initial factors and cellular processes operating in endometrial reconstruction are purely a reflection of tissue repair and are independent of cyclic hormonal stimuli.

MORPHOLOGICALLY, THERE are two reasons for regarding the endometrium as unique and as one of the most dynamic target tissues in the human body. First, the endometrium is subject to hormone-mediated cyclic morphologic modifications which, throughout reproductive life, are programmed to create an optimal environment for the reception and nidation of the fertilized egg. Second, the nongestational endometrium undergoes partial autodestruction and shedding followed by complete reconstruction. In normal menstruating women, both phenomena alternate in a continuous biorhythmic pattern and have a spectacularly rapid turnover rate.

Cyclical endometrial morphologic changes have been extensively investigated by means of light,[1] transmission, and scanning electron microscopy,[2] histo-[3] and ultracytochemistry,[4] Feulgencytophotometry,[5] and historadioautography.[6–8] However, surprisingly little attention has been paid to the study of postmenstrual endometrial repair. Indeed, ever since the first classical description of cyclic changes in human endometrium nearly 70 years ago by Hitschmann and Adler,[9] opinions vary regarding the process of endometrial regeneration and the site of origin of the postmenstrual surface epithelium.

The most accepted view is that the regenerating surface epithelium in human endometrium originates from the residual epithelium of basal gland stumps.[10] Sturgis and Meigs,[11] on the basis of histologic observations, estimated the time renewal of surface epithelium to be 48 hours following the menstrual period. In the opinion of the authors, resurfacing probably occurs by migration of epithelial cells from the exposed ends of the glands. McLennan and Rydell[12] have suggested that the zona basalis remains intact during the menstrual period and that the newly regenerated endometrial surface derives from glandular cells which were involved in the progestational secretory events of the previous cycle. Furthermore, they have suggested that early endometrial regeneration begins as early as the third menstrual day and by the fourth day there are large areas of a new epithelial surface overlying a thin layer of spongiosa. By the fifth day of the cycle, a proliferating surface epithelium is seen throughout the

uterine mucosa. Concomitantly, the stroma is rapidly restored by mitotically active stromal fibroblasts which are engaged in the production of extracellular collagen.

According to investigators,[12] the ability of secretory endometrium to revert to the proliferative pattern would explain the great speed of endometrial regeneration. However, others[13] believe that the rapidity of epithelial renewal without significant mitotic activity and with nearly constant diploid DNA values[14] in the postmenstrual period does not support the view that the covering surface epithelium regenerates from glandular epithelium which has escaped destruction. In view of these arguments, Baggish and associates [13] favor the concept of transformation of endometrial stromal cells into regenerating surface epithelial cells.

Parallel to morphologic studies on human endometrium, similar investigations have been carried out in experimental animals. Endometrial regeneration was studied in rats,[15] in rabbits following curettage[16] or complete excision of the endometrium,[17] and in the monkey.[18] These studies have shown that the earliest sign of repair, as evidenced by the presence of flattened epithelial cells covering part of denuded surfaces, occurs three hours after curettage.[16] By Day 2[16] to 3[17] the endometrial surface was completely covered by regenerated surface epithelial cells. The resurfacing epithelium was seen to arise chiefly from the persisting surface (in rabbit)[16, 17] or glandular (in monkey)[18] epithelial cells, and mitotic activity became evident only two days following trauma in the rabbit[16] and three days in the monkey.[18] In great contrast to these observations, Singer and co-workers[15] felt that in the rat endometrium regeneration of new surface epithelial cells operates by the transformation of peritoneal cells after their migration through the oviducts.

The presently available data are based solely on histologic observations which, by virtue of their static nature, provide limited and indirect information on the cytodynamics of endometrial renewal. Further and complementary studies with the use of a variety of investigative techniques, such as transmission and scanning electron microscopy as well as histochemistry and radioautography, are therefore needed to obtain additional data on the cellular events which are involved in endometrial repair.

The purpose of this report is to take advantage of the scanning electron microscopy (SEM) by presenting a high-resolution study focusing on the topographic alterations of the human uterine surface epithelium which occur during the process of cyclic endometrial reconstruction.

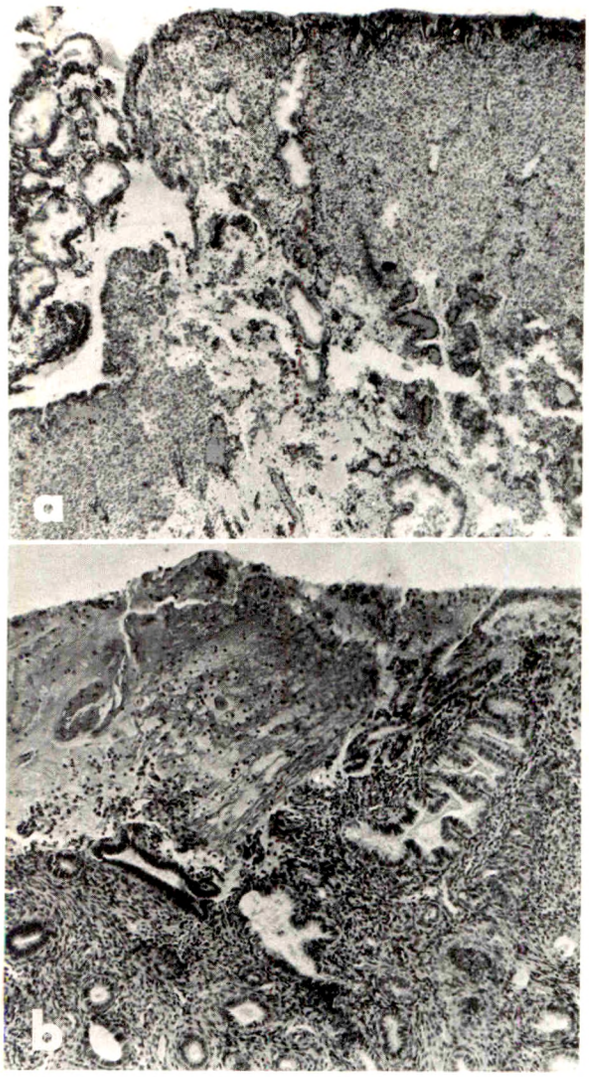

Fig. 1. *a*, Menstrual endometrium, Cycle Day 1. Large fragments of functionalis are dissociated from the underlying endometrium. Hematoxylin and eosin. (Hematoxylin and eosin. Original magnification × 65.)

Material and methods

Normal menstruating uteri devoid of gross and microscopic pathology were obtained from a series of 24 patients ranging from 22 to 41 years of age. In order to achieve diagnostic accuracy and reproducibility in dating endometrial specimens, detailed information was secured in each case regarding the dates of at least six previous menstrual periods and basal body temperature (BBT), exact time (as to the hour) of onset of bleeding in progress, cycle pattern in previous years, and time of removal of uteri. The indication for hysterectomy included postconization hysterectomy

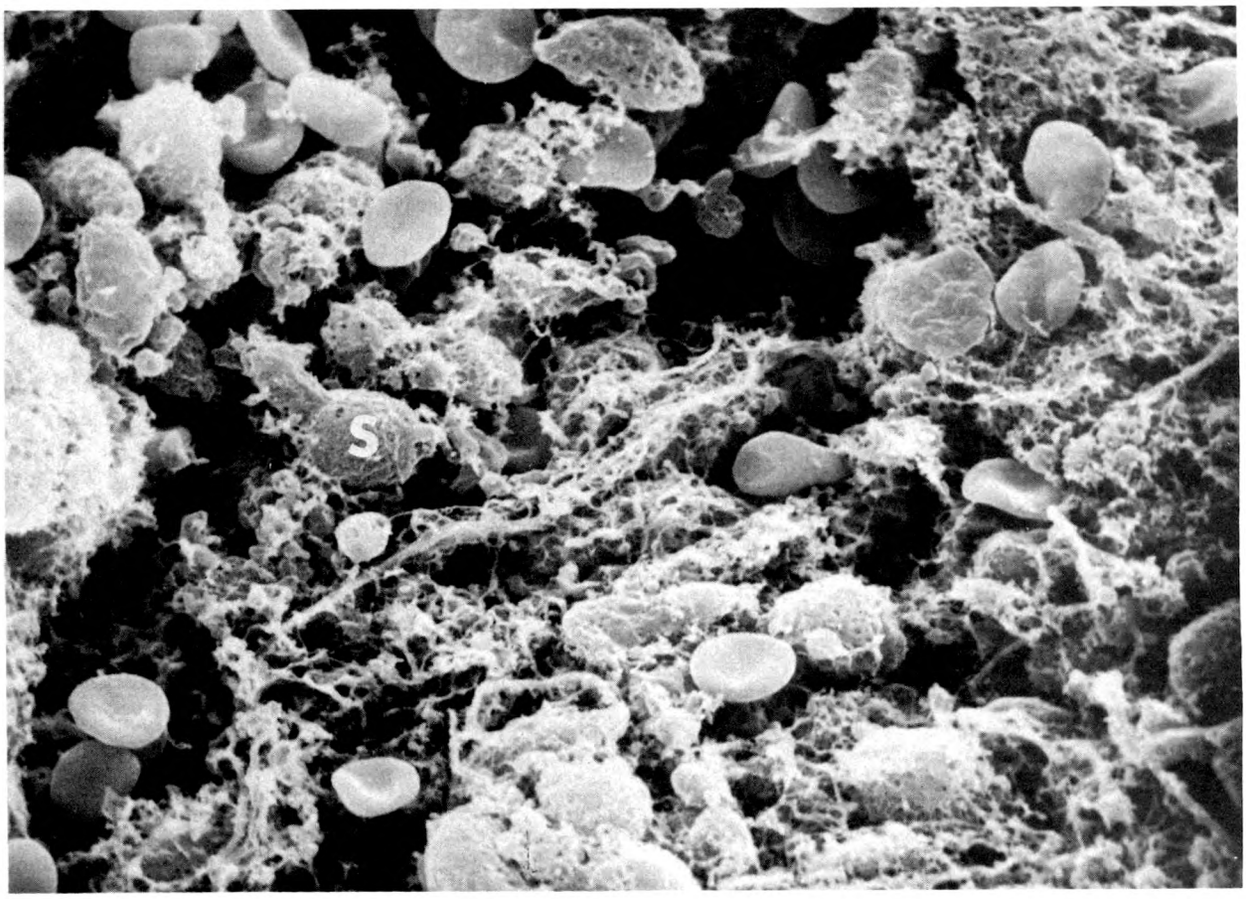

Fig. 2. Menstrual stroma, Cycle Day 2. White and red blood cells are enmeshed in fibrin and reticulum fibers intermingling with degenerated cellular debris, probably of stromal cell *(S)* origin. (Original magnification ×2,000.)

for cervical intraepithelial neoplasia, prolapse of the uterus, and "pelvic congestion syndrome."

Three uteri from each of the first six cycle days starting with the fifteenth day following the rise of BBT, whether or not the first day of menstrual bleeding had occurred, and two uteri from the mid and late proliferative phases of the cycle, respectively, were obtained. All uteri, immediately after their excision, were opened along the lateral borders in order to obtain undistorted anterior and posterior endometrial surfaces. In each cases, under the guidance of a dissecting microscope, the entire uterine cavity was sampled, including the fundal, cornual (peritubal), and isthmic portions. Blocks of tissue measuring 2.0 by 1.0 by 0.5 cm. including the basalis were submitted for scanning and transmission electron microscopy[21] and light microscopy, and were processed and examined as previously described.[2] In an effort to achieve maximum confidence in identification of tissue examined with SEM, scanned specimens were subsequently rehydrated and verified histologically. For rehydration, samples were placed in 100, 95, 80, 70, and 50 per cent alcohol, each step lasting three hours, and then in distilled water. Following Bouin's fixation, they were placed and processed in an autotechnicon in the usual fashion. The results of rehydrating critical point dried specimens were adequate in evaluating their histologic appearance.

Results

Because morphologic alterations during the menstrual phenomenon varied among specimens obtained on the same cycle day (at the same time) as well as within the same uterine cavity, accurate correlation between morphology and time of removal was impossible. For this reason, the sequence of events will be described and evaluated according to the day (24 hours period) during which the specimens were recovered.

Uteri removed on the first and second menstrual days contained histologic (Fig. 1, *a* and *b*) and scanning

Fig. 3. Isthmic and uterine corpus junction, Cycle Day 2. Electron micrograph illustrating the well-preserved surface epithelium of the isthmus *(LUS)* bordering the denuded basal layer in which the gland mouths are greatly dilated (arrow). electron microscopic (Fig. 2) evidence of surface epithelial, stromal and glandular fragmentation, and disintegration with extravasation of red blood cells and inflammatory exudate. These alterations involved both the compacta and spongiosa and occurred chiefly in the fundal and corporeal regions of the uterine cavity. As a result, large fragments of functionalis were seen to be dissociated from the underlying tissue (Fig. 1, *a*). Although the degree of endometrial disruption displayed no topographic uniformity in uteri obtained on the same cycle day, tissue destruction and loss were, in general, more conspicuous on the second than on the first menstrual day. Indeed, two of three specimens obtained on Day 2 of the cycle exhibited considerable tissue loss resulting in large zones of denuded basal layer (Fig. 2, *b*). In these regions the hemorrhagic stroma had numerous, wide, open gland stumps, a few of them showing curved edges with occasional short epithelial extensions onto the surrounding tissue. These changes are regarded as the earliest sign of surface epithelial reconstruction.[19] Examination of the uterine mucosa of the isthmic and cornual segments revealed foci of stromal hemorrhage and inflammatory exudate but the endometrial architecture, including the surface epithelium, remained intact (Figs. 3 and 4). The latter, with the SEM, was composed of well-preserved ciliated and dome-shaped nonciliated cells with hairlike microvilli and occurred in a ratio of approximately 1:30 (Fig. 4, inset).

On the third menstrual day, most of the basal zone appeared denuded, containing only a few foci of the residual spongy layer. It had an irregular, ragged surface because of the extent of endometrial shedding. While many basal gland crypts were oriented parallel to the long axis of the uterine cavity, their body and neck were arranged obliquely or perpendicular to the

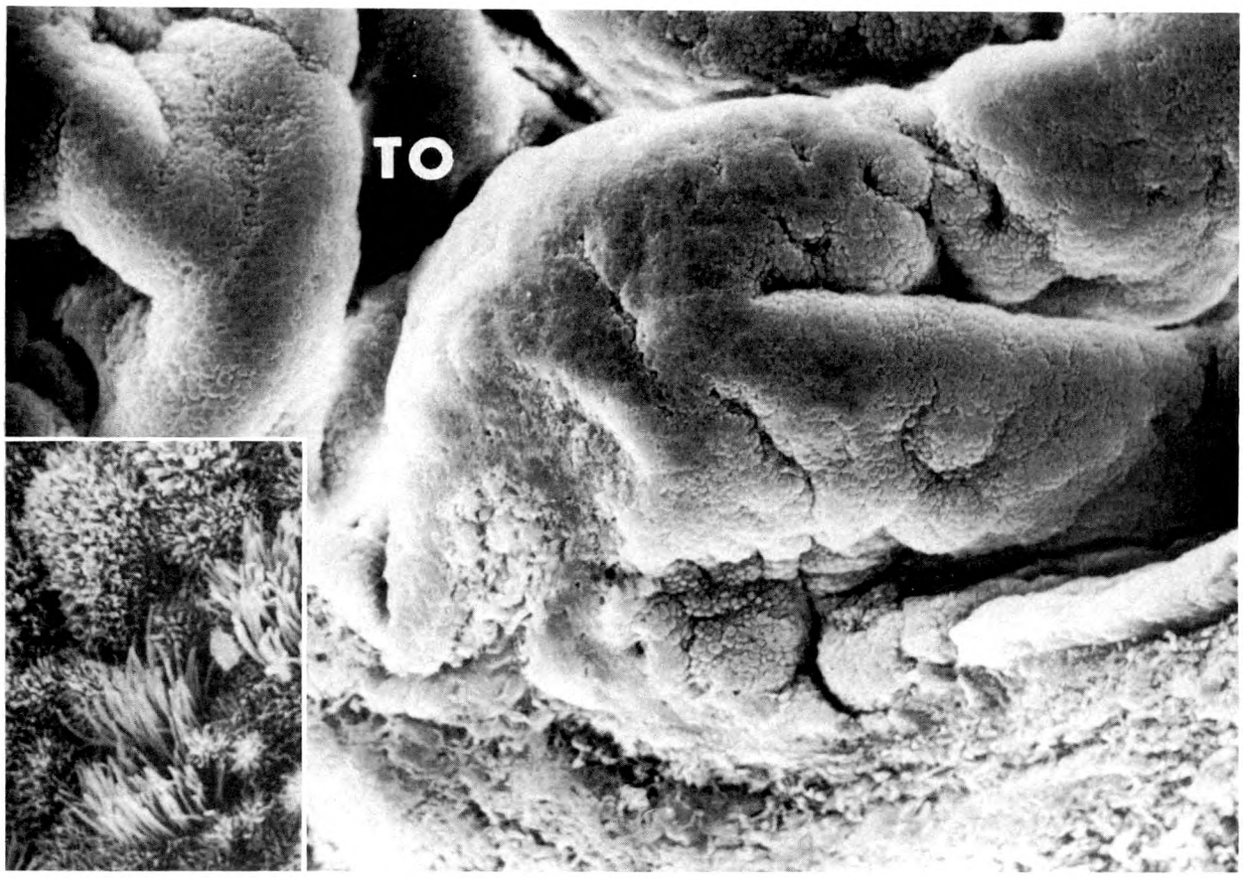

Fig. 4. Fundus-cornual junction, Cycle Day 2. The mucosa near the tubal ostium *(TO)* appears well preserved with an undulating surface and irregular edges bordering the zona basalis of the fundus. surface into which opened haphazardly spaced gland mouths (Fig. 5, *A*). In contrast to the previous day of the menstrual period, specimens of the third menstrual day had most of their gland stumps with rolled edges, from which varying sized and randomly oriented epithelial masses extended onto the adjacent stroma (Fig. 6). In several areas, adjacent gland mouths were interconnected by surface epithelial bridges. Light microscopic verification of rehydrated SEM specimens revealed the epithelial surface extensions to be continuous with the neck of basal glands, providing histologic confirmation of their site of origin (Fig. 6, inset). The topographic architecture of developing surface epithelium exhibited a certain degree of cellular pleomorphism (Fig. 7, inset). In addition, cellular cohesion and organization were impaired, as compared to the fully reconstructed surface lining of the mid and late proliferative phase of the cycle. The surface plasma membrane of migrating epithelial cells was often wrinkled or flattened and the microvillous processes were short and sparse. Ciliary shafts were not observed in these cells. At the light microscopic level, the epithelium was cuboidal to low columnar near the glandular ostia and decreased in height near its distal end. In this region the epithelial cells were flat to spindle shaped with dark cytoplasmic matrix and the nuclei were enlarged and hyperchromatic. There was no histologic continuity between the resurfacing epithelial and underlying stromal cells, as evidenced by the presence of a well-defined basal membrane separating the two-cell populations. During Day 3 of the cycle, the periphery of the endometrial surface of the isthmic and cornual segments showed irregular tongues of surface epithelium extending onto the adjacent and denuded zona basalis of the body and fundus, respectively. Both the surface ultrastructural and light microscopic characteristics of this advancing epithelium were similar to those found in its counterpart of basal gland neck origin.

Uteri possessed comparatively better developed

surface epithelial extensions on Cycle Day 4 than on the previous cycle day (Fig. 7). These, by centripetal expansions and ramifications were seen to merge into and eventually fuse with their adjacent counterparts. Simultaneously, tongues of surface epithelium of isthmic and cornual origin established anastomoses with the peripheral portions of the surface lining originating in the gland stumps of the zona basalis. As a result of rapid surface re-epithelialization, most denuded areas were obliterated on Day 4 of the cycle (two of three specimens had fully repaired surface covering), coinciding with the decrease and eventual cessation of endometrial shedding and menstrual flow. Histologically, the subepithelial stroma was loose, edematous with scattered spindle-shaped fibroblasts devoid of mitotic figures (Fig. 5, *B*).

Specimens received on Cycle Days 5 and 6 had an entirely reconstructed surface epithelium, covering an irregular and often hemorrhagic basal layer. The lining epithelium contained randomly distributed glandular ostia around which ciliated cells were concentrated in a crownlike fashion (Fig. 8). The closely apposed nonciliated cells had a penta- to hexa-gonal contour, and the distended surface plasma membrane was covered by short and stubby microvilli (Fig. 8, inset). Histologically, the surface epithelium varied from cuboidal to tall columnar, and the nucleocytoplasmic ratio was in favor of the cytoplasm. Cells with cilia and mitoses were scattered throughout the surface epithelial membrane, with greater concentration in the periglandular region and the upper half of the glandular epithelium. Serial histologic sections of endometria obtained on Cycle Days 5 and 6 demonstrated short, straight basal glands with narrow lumina, connecting the surface and the basal layer.

Uteri obtained on Cycle Days 8 and 10 (mid-proliferative phase of the cycle) were covered by an undulating surface membrane in which numerous ciliated cells, either single or in clusters, were found not only in a periostial location but also on the interglandular surface areas (Fig. 9). The bulging nonciliated cells were covered by abundant, 0.5 μ long microvillous projections with occasional microvillous promontories (Fig. 9, inset). Several glands were seen to divide at the junction of the basalis-spongiosa layers, and the stromal cells displayed numerous mitotic divisions. Because of accelerated epithelial and stromal cell growth, the number and length of endometrial glands and their supporting stroma rapidly increased, leading to the over-all expansion of the uterine mucosa.

The endometrial surface of the late proliferative phase (twelfth to fourteenth day of the cycle) contained a further increase in the number of ciliated cells which were arranged in large clusters alternating with microvillous nonciliated cells in a ratio of about 1 to 30.

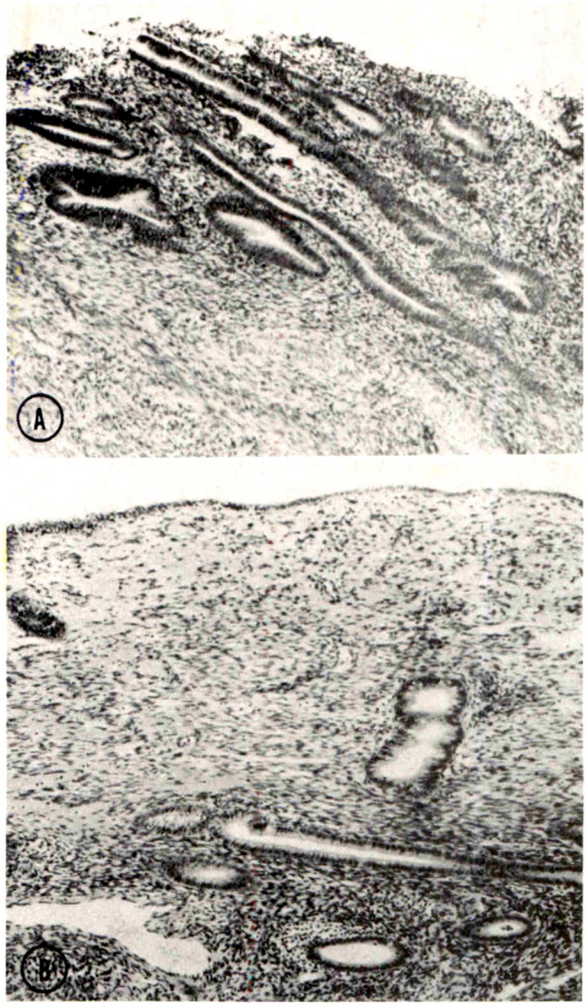

Fig. 5. *A*, Regenerative endometrium, Cycle Day 3. The zona basalis is completely denuded from the overlying spongiosa and contains obliquely oriented glands surrounded by a compact stroma. (Hematoxylin and eosin. Original magnification ×85.) *B*, Regenerative endometrium, Cycle Day 4. Newly formed surface epithelium covers the thin uterine mucosa in which the stroma is loose and glands are sparse. (Hematoxylin and eosin. Original magnification ×73.)

Comment

The present SEM study on regenerating human endometrium concurs with earlier histologic investigations[11, 12] showing that the total generation time for postmenstrual surface re-epithelialization is about 48 hours. The regenerative period begins between Cycle Days 2 and 3 and ends between Cycle Days 4 and 5. This time interval coincides with the maximum area of denuded zona basalis.

Surface epithelial repair occurs by a simultaneous

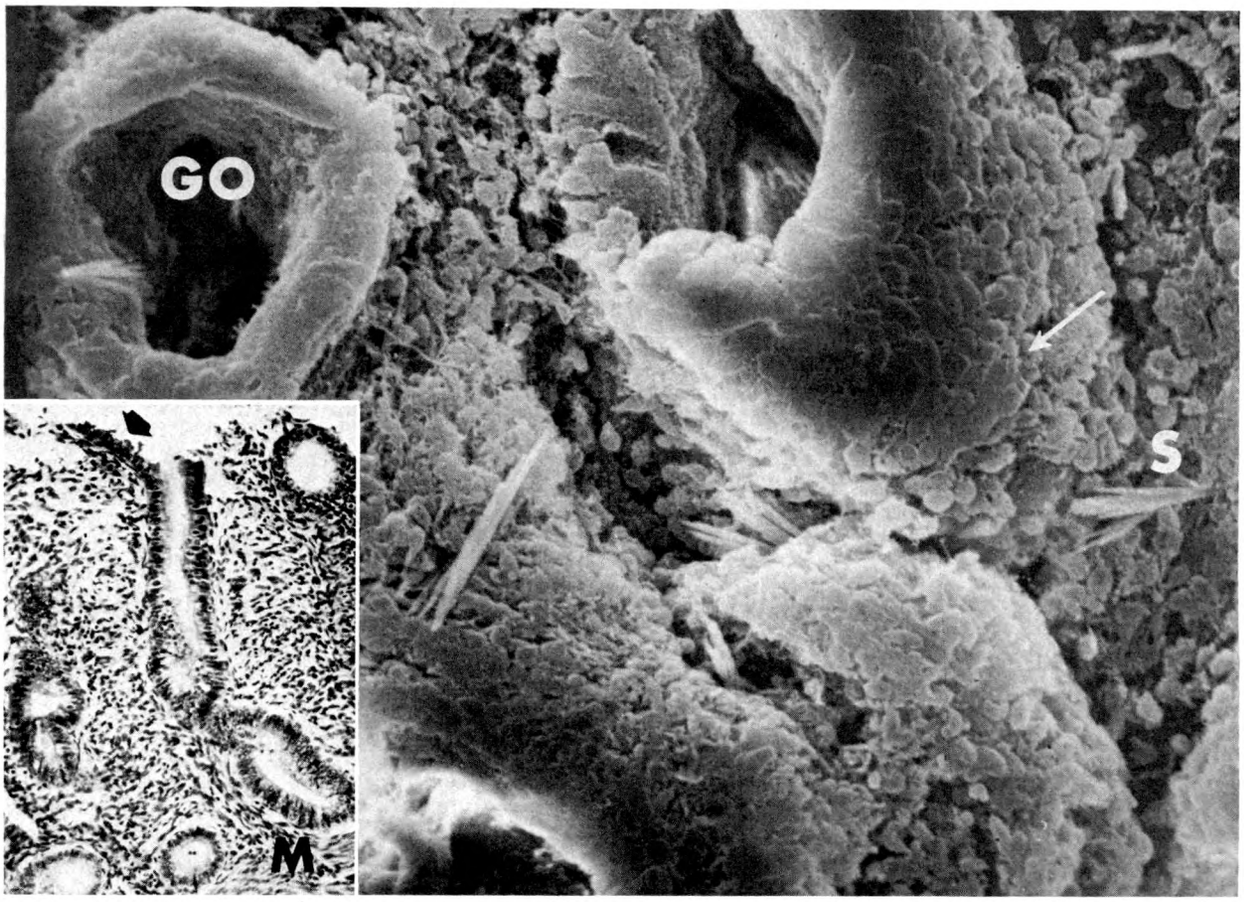

Fig. 6. Regenerative endometrium, Cycle Day 3. The gland stumps *(GO)* of the zona basalis have prominent openings with rolled edges and epithelial extensions *(arrow)* on the adjacent stroma *(S)*. Original magnification ×380. Inset, Histologic appearance of rehydrated SEM specimen shown in the figure. The resurfacing epithelial extension (arrow) is continuous with the lining epithelium of the basal gland. *M*, Myometrium. (Hematoxylin and eosin. Original magnification ×210.)

and progressive epithelial outgrowth from the mouths of basal glands and by ingrowth from the surface epithelium adjacent to the denuded areas, namely, the isthmic and cornual regions. Both the basal glands and surface epithelium of peripheral uterine regions remain intact during the entire menstrual period. On Day 4 of the cycle, the rapid development of interanastomoses between converging epithelial proliferations leads to complete or near-complete restoration of the new surface epithelium. By the fifth day of the cycle, the endometrial surface is fully re-epithelialized.[19, 20] These observations indicate that while the first half of menstruation is dominated by tissue destruction and loss, reconstruction prevails in the second half. The latter period, therefore, is recognized as the regenerative phase of the menstrual cycle.

Furthermore, the results indicate that the regenerating surface epithelium has a dual rather than a single anatomic[10, 13, 18] origin — first, and in agreement with most previous light microscopic studies,[10, 11, 18] in the exposed stumps of the basal glands and second, in the surface epithelium of isthmic and cornual regions. With regard to this surface epithelium, a somewhat similar situation was reported in the rabbit's endometrium,[16, 17] in which the newly repaired surface lining derived from the intact surface epithelium bordering the artificially denuded area. In the woman, the proliferative activity and considerable number of epithelial extensions of basal gland origin are believed to represent the dominant mechanism of endometrial surface renewal. The basal glands are the main source of the new surface epithelium.

Certain investigators[12] have expressed the view that endometrial healing develops by rapid metamorphosis of the residual secretory endometrium to proliferative tissue. According to these authors, such a process would also explain the normal length cycle with prolonged or delayed period of menstrual shedding.

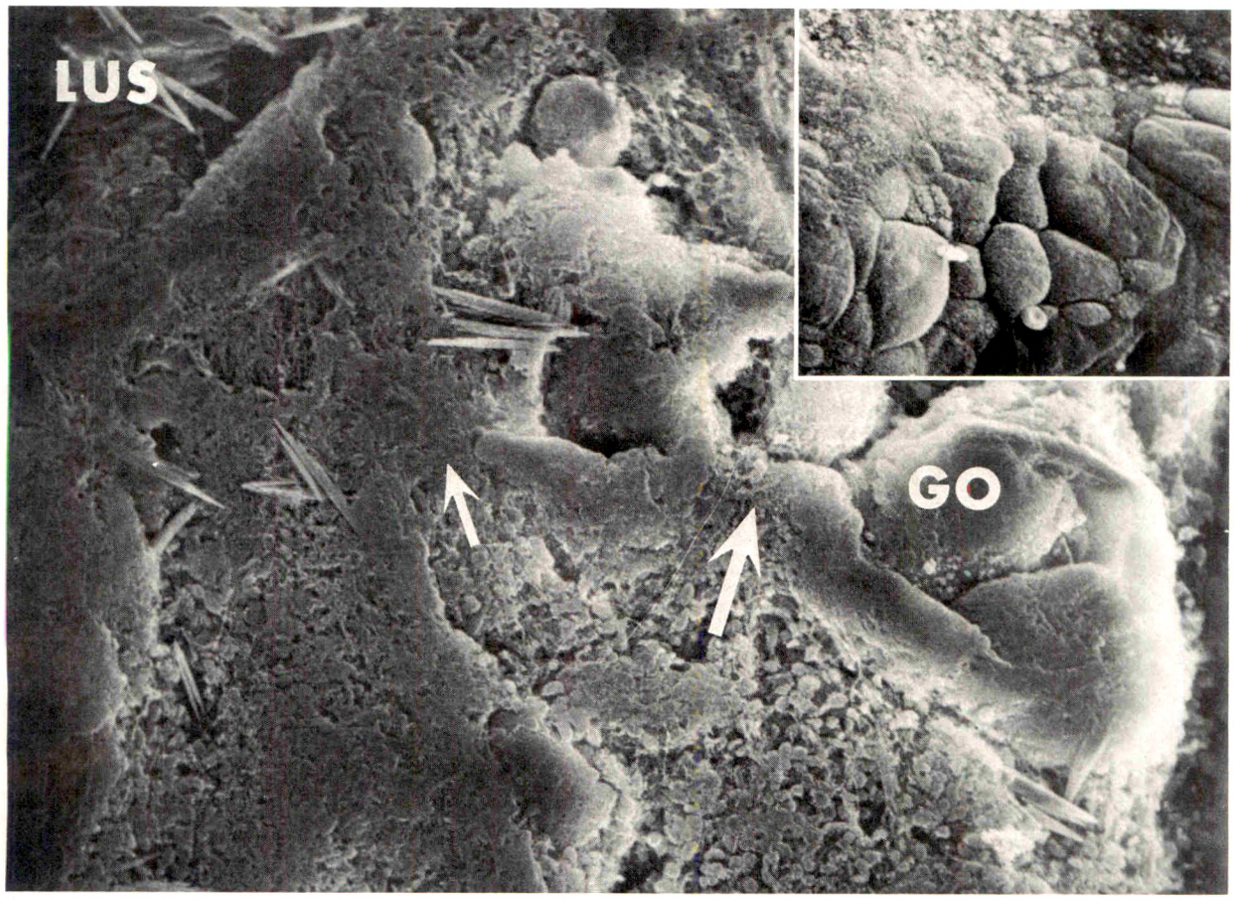

Fig. 7. Regenerative endometrium, Cycle Day 4. Anastomoses between surface epithelial extensions of basal gland and isthmus origin (short arrow) as well as between adjacent gland openings *(GO)* are established (large arrow). Because of inadequate washing of specimens following fixation with phosphate-buffered glutaraldehyde, needlelike structures representing phosphate-crystals remain on the surface. (Original magnification ×230.) Inset, The developing surface epithelium is made of cells of various sizes and shapes with generally flattened surface plasma membrane. (Original magnification ×900.)

The residual progestational endometrium would "catch up" with the proliferative endometrium later in the cycle. Our studies, however, suggest that surface epithelial restoration is initiated only when and where gland stumps of the basal layer are denuded from the overlying spongiosa. This phenomenon, together with the segmental rather than the diffuse nature of menstrual dissolution, would account for the focal distribution of resurfacing epithelium and for the alternating pattern of regenerating and disintegrating regions. Thus, in agreement with McMinn,[18] " . . . regeneration begins before menstruation ceases" and terminates by the fifth day of the menstrual cycle. Assuming that loss of secretory spongiosa is a prerequisite for stimulation of endometrial repair, prolonged menstrual bleeding may be related, at least in part, to delayed separation of the functionalis from the basalis. Similarly, the superficial loss of uterine mucosa, not extending to the basalis, may partly be responsible for prolonged anovulatory bleeding. In both situations denudation of the basal layer would be impaired, precluding rapid surface reepithelialization and thus promoting abnormal uterine bleeding. Consequently, once the basal zone is freed either endo- or exogenously (curettings) of the overlying tissue, epithelial regeneration will resume and bleeding will cease. Admittedly, a good number of detailed investigations of uteri removed from patients with history of various abnormal bleeding is needed to substantiate our hypothesis.

Contrary to earlier suggestions,[9, 12, 13] we were unable to demonstrate morphologic features (transformation of stromal cells into surface epithelial cells,[13] collagen synthesis, or mitosis in stromal cells[12] that gave

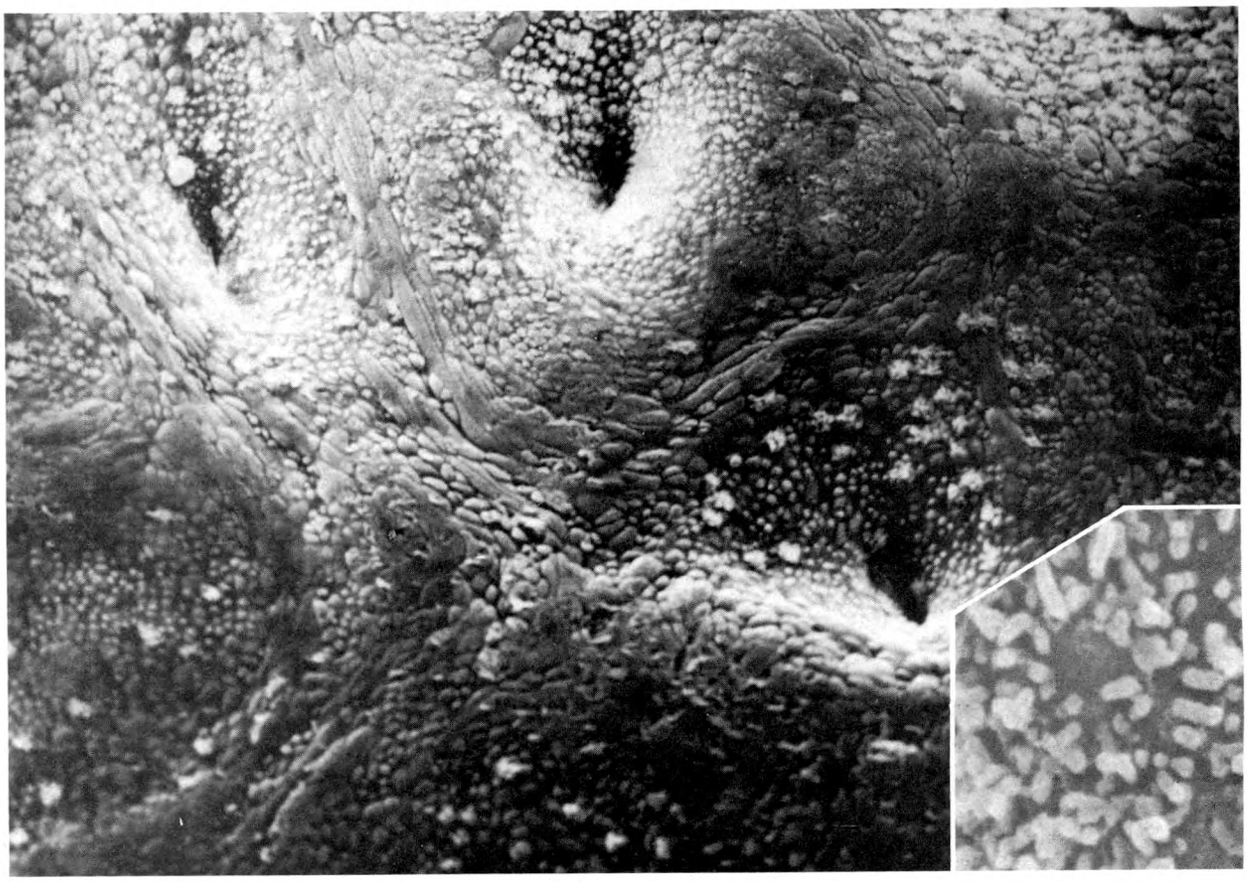

Fig. 8. Early proliferative endometrium, Cycle Day 5. The surface is fully reconstructed and contains several glandular openings, typically surrounded by ciliated cells. evidence of significant participation of stromal cells assisting in the formation of resurfacing epithelium or restoration of the uterine stroma during the regenerative period. In fact, our SEM and preliminary transmission electron microscopy and histochemical studies[21] reveal that the predominant proliferative activity during endometrial regeneration is confined to generation of the surface epithelium. The stromal cells remain inactive until surface re-epithelialization is completed by Cycle Day 5. Since estrogen-dependent changes, such as mitosis and ciliogenesis, are not seen before the surface epithelium is restored, one can assume that endometrial surface repair is initiated by, and is in response to, tissue loss rather than under the influence of ovarian hormones. This contention seems to be supported by studies on endometrial regeneration in hormonally intact experimental animals[16, 17] in which proliferation of a new surface epithelium is reported to begin as early as three hours after artificially induced endometrial injury. Moreover, the lack[1, 13] of epithelial mitoses during the period of regeneration suggests that the developing epithelium proliferates by either amitotic division or endoreduplication or that the S phase of mitosis is so accelerated as to escape morphologic detection. The newly formed epithelial cells may possibly migrate by ameboid motion over the denuded stroma.

At this point, however, several questions remain to be clarified:

1. What are the dynamics of the subcellular sequence of events in both the epithelial and stromal cells during the process of repair in cyclically shedding endometrium?

2. What is the precise mechanism of endometrial proliferation during endometrial reconstruction in the absence of significant mitotic activity?

3. What is the rate and distribution of DNA synthesis and renewal time of surface epithelial cells as well as

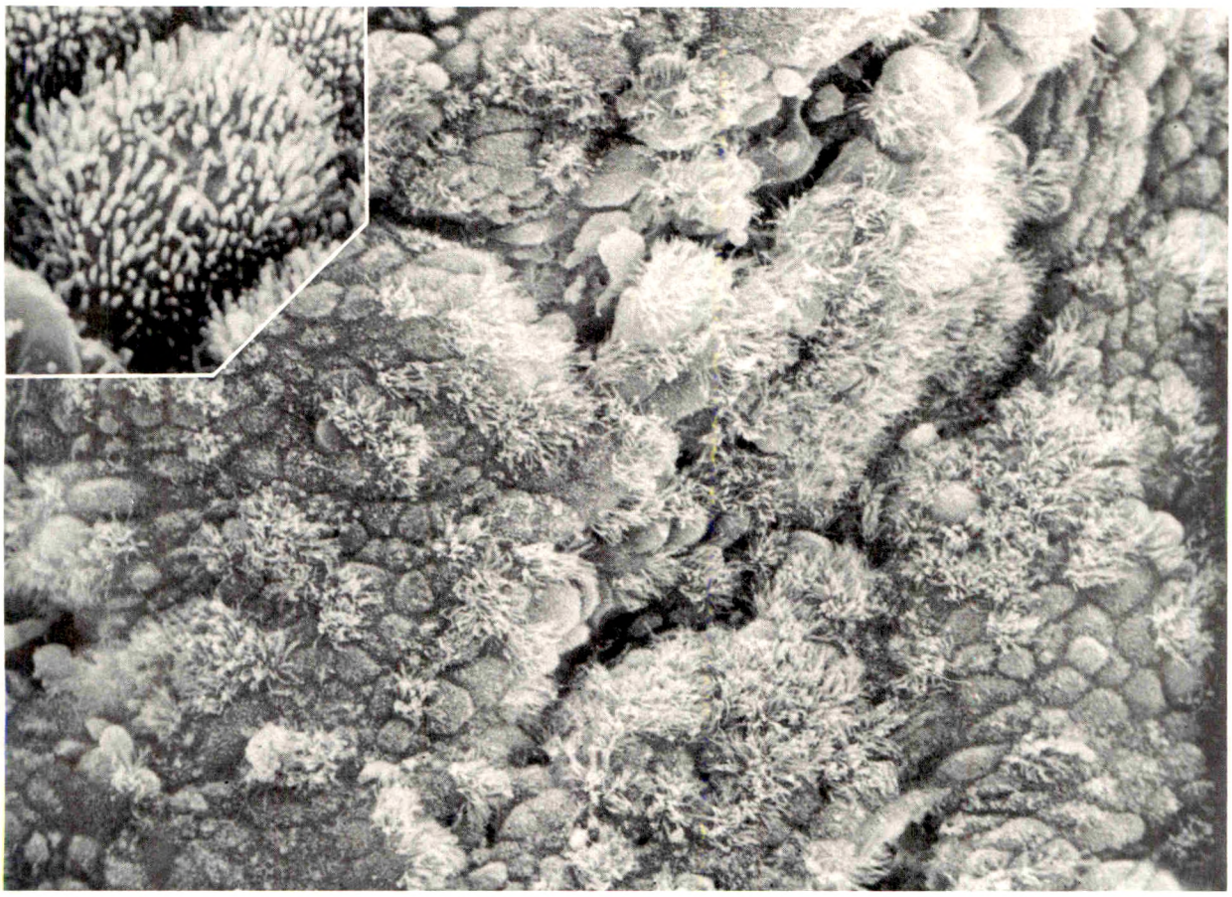

Fig. 9. Mid proliferative endometrium, Cycle Day 10. By Cycle Days 9 to 10, ciliated cells become visible on the interglandular surface plateaus, arranged in clusters or as single units. glandular and stromal cells during the regenerative period?

Experiments with the use of transmission electron microscopy[21] and historadioautography are underway to elucidate these questions, to test certain details of our hypotheses, and to substantiate the presently available morphologic observations concerning the regenerative process of cyclic endometrium.

Pituitary responses to LRH in the postpartum periods

C. FRIEDMAN*
M. E. GAEKE
V. FANG
M. H. KIM*
Chicago, Illinois

Pituitary responses to luteinizing-hormone–releasing-hormone (LRH) in the postpartum periods were studied. Following a subcutaneous injection of 100 μg of synthetic LRH to postpartum subjects, no statistically significant changes in the levels of LH and FSH could be demonstrated in five subjects on postpartum day 1 or 3 and in three subjects on postpartum day 8. A normal elevation of LH and FSH following LRH was demonstrated in one subject 36 days post partum. The findings are in agreement with previous studies demonstrating a persistence of pituitary suppression during the early postpartum period. No correlation could be drawn between the pituitary responses to LRH and the plasma levels of estradiol-17β and progesterone.

WITH PREGNANCY, suppression of the hypothalmic-pituitary axis occurs as a result of the abundant steroid hormones produced by the fetoplacental unit. Following parturition the high levels of estrogen and progesterone drop precipitously.[1] The levels of LH-HCG similarly decreases,[2] as do prolactin levels in non-nursing females.[3] This alteration in hormonal milieu is probably responsible for the delayed resumption of the ovulatory cycle post partum.[4] Synthetic LRH has repeatedly been shown to stimulate the pituitary to release LH and FSH in nonpregnant females.[5, 6] as well as during pregnancy.[7] Recently, limited studies concerning the pituitary response to LRH postpartum have been reported.[8, 9] The purpose of this study is to further investigate the changes in pituitary responsiveness to LRH during the postpartum period and to correlate with plasma estradiol and progesterone levels.

Materials and methods

The five subjects of this study were all patients at the Chicago Lying-in Hospital ranging in age from 17 to 28 years. All had a previously normal menstrual history and no endocrinologic abnormalities were noted in history or physical examination. All subjects had a spontaneous vaginal delivery at term. Medications at the time of the study included the usual analgesics for postpartum patients, one subject (D.B.) received antibiotics. Consents were obtained from all participants prior to delivery. No lactation-suppressive drugs were given and none of the patients breast fed.

An indwelling catheter was placed in the antecubital vein and kept open with isotonic saline infusion. After baseline blood samples were taken at −30 minutes and zero time, a single dose of LRH 100 μg (Ayerst AY-24031) was injected subcutaneously. Blood samples were then collected at 30 minute intervals for 2 hours and at hourly intervals thereafter.

Prior to LRH injection, additional blood samples were obtained for the measurement of estradiol-17β and progesterone. Blood samples were collected at 24 hours (postpartum day 1) and at 72 hours (postpartum day 3) after delivery, and on postpartum days 8 and 36 sampling started between 8 and 9 A.M. All five subjects participated on days 1 and 3, three subjects participated on day 8, and one subject participated on day 36. Plasma and serum were subsequently separated and

kept frozen at −18° C. until assayed. Each individual's samples for a given day were analyzed in the same assay. FSH and LH-HCG (HCG cross-reacts in the LH assay) were measured by a double antibody radioimmunoassay as described by Odell and associates[10] and expressed as nanograms per milliliter using LER 907 distributed by NIAMD, NIH, as the standard reference. In our gonadotropin assay system the intra- and interassay coefficients of variation are 5 and 20 per cent respectively. The limit of sensitivity is 10 nanograms per milliliter for both LH and FSH. Plasma levels of estradiol-17β and progesterone were determined as previously reported.[11]

Results

Baseline levels of FSH and LH. The results of FSH and LH concentration are shown in Tables I and II. In all subjects the levels of FSH on postpartum days 1, 3, and 8 are significantly below those of normal follicular phase (80 to 410 ng. per milliliter). Of the five subjects, three on day 1 and two on day 3 had no detectable levels of FSH in multiple samples. On day 8 all had detectable FSH values. The levels of FSH in one subject (L.B.) on postpartum day 36 was in the normal follicular phase range.

LH-HCG concentrations ranged widely for day 1 (1,820 to 2,330 ng. per milliliter) and for day 3 (860 to 2,380 ng. per milliliter), and declined with time. The level of subject L. B. at 36 days was in the follicular phase range (30 to 210 ng. per milliliter).

Effects of LRH. Table I lists the values of FSH following injection of LRH. Increases of 200 per cent or greater above the mean baseline were noted on day 1 and 3 in two of five subjects (N. R. and R. G.) at 30 and 60 minutes, respectively. Secondary elevations in FSH levels, all at 180 minutes after LRH injection, exist in three subjects (R. G., L. B., and N. R.,) on day 1, and in two of these subjects (R. G. and L. B.) on day 3. In

*LH in terms of ng./ml. (LER-907).
†Time, in minutes, before (−) and after (+) LRH injection.

subject R. G. on day 8 a prolonged rise of FSH occurred some time after 60 minutes following LRH injection. With the use of a one-tailed Student t test, as a group, no statistical difference is demonstrable for the various peaks.

In contrast, no spikes in the levels of LH-HCG occurred following LRH administration on day 1, 3, or 8, as demonstrated in Table II. A wide range of LH concentrations was observed in the study subjects.

Fig. 1 shows the results in subject L. B. at 36 days post partum. A sustained elevation of FSH occurred at 30 minutes, reaching its maximum value at 120 minutes. The level of LH increased at 30 minutes after injection, peaking at 60 minutes (greater than sevenfold increase) and declined to baseline levels at 240 minutes.

Estradiol-17β and progesterone. Estradiol and progesterone values are listed along with FSH values in Table I. The sample for R. G. on day 8 was inadvertantly destroyed prior to analysis. A general trend of decreasing values of E_2 and P was demonstrated with increasing days post partum. The levels of E_2 and P returned to the range of follicular phase (21 to 120 pg. per milliliter and < 1.5 ng. per milliliter, respectively) by the third postpartum day except for subject V. H., in whom elevated E_2 and P

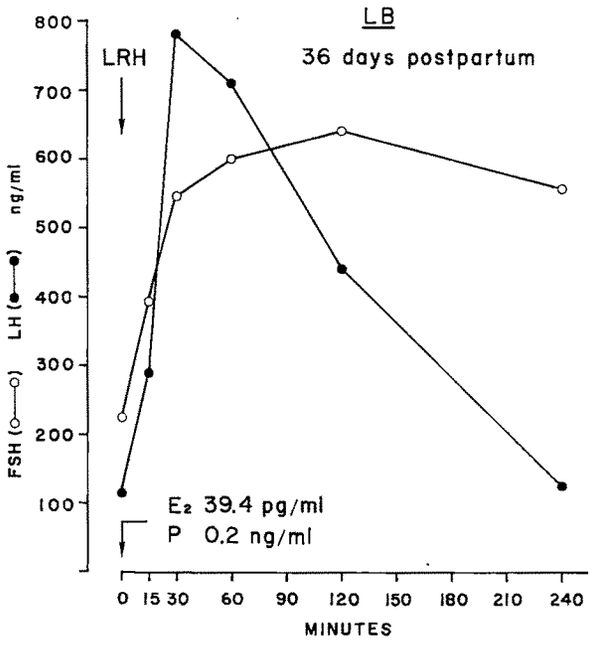

Fig. 1. Levels of FSH and LH after LRH 100 μg subcutaneously in a patient 36 days post partum.

values persisted up to postpartum day 8. No correlation could be drawn between the pituitary responses to LRH and the plasma levels of estradiol-17β or progesterone.

Comment

Zarate and associates[7] previously reported that FSH values are detectable throughout pregnancy. In a recent report by Canales and associates,[9] FSH values in all 11 patients studied were nondetectable 2 days post partum, before and after a 50 μg intravenous bolus of LRH (Hoechst). We have found detectable FSH levels on days 1 and 3 in all subjects, though some individual samples showed nondetectable FSH levels on day 1 and in two individuals on day 3 post partum. The use of lactating subjects by Canales and our choice of nonlactating subjects may account for some of the variance between the two reports. In agreement with Canales, however, is the notably low level of FSH postpartum.

Values obtained from the LH assay due to cross-reactivity with HCG were markedly elevated post partum. Despite the progressive disappearance of HCG, significant interference was still present at 8 days post partum, which is in agreement with other investigators.[12] The values of LH for our one subject at 36 days post partum is in the range of normal follicular phase, most likely representing pituitary LH rather than residual HCG.

Zarate and associates[7] intravenously injected 50 μg of LRH at various stages of pregnancy and reported FSH peaks occurring in nine of 10 subjects within the first 64 minutes. They concluded that the pituitary remained responsive during pregnancy to hypothalamic releasing hormones, finding 10 of 13 subjects who did respond to LRH injections. Canales and associates,[9] again using 50 μg of LRH intravenously, found no effect on LH or FSH release at 2 days post partum. At 2 weeks post partum the pituitary was responsive to LRH, showing significant changes in FSH and LH values, LH peaking at 30 minutes post injection and FSH reaching its maximum between 30 and 60 minutes and declining thereafter. The present study and that of LeMaire and associates[8] used 100 μg LRH (Ayerst) subcutaneously. Arimura and his associates[6] had previously studied the course of LH and FSH in normal males after subcutaneous injection of 100 μg of LRH. LH values were seen to peak between 30 and 45 minutes with a secondary spike appearing at 180 minutes. LeMaire and associates,[8] observing only LH response, found no change at 2 weeks postpartum but a significant response at 6 weeks. In the present study two of five subjects on day 1 and 3 post partum demonstrated elevations of FSH values at or before 60 minutes following a LRH challenge, with secondary increases being noted at 180 minutes in both subjects on day 1 and in one of the two subjects on day 3. These time periods of peaks are in agreement with the findings of Arimura and associates.[6] At 8 days post partum the minimal elevations noted appear much later following LRH injection. As described previously, none of these elevations was of statistical significance. The response of one subject at 36 days post partum appears to correlate well with the observation by LeMaire and associates[8] at 6 weeks post partum.

It is well known that the menstrual period is generally delayed following conception, the delay being longer for those mothers who are lactating. The cause for the delay remains unsettled. Zarate and associates[13] injected human menopausal gonadotropins into postpartum volunteers and found no elevation of estrogen or progesterone, concluding that the ovaries were the primary refractory organ. Crystle and colleagues[14] found that estrogen in low doses would produce elevation in LH and FSH concentrations post partum in comparison to controls and patients receiving high-dose estrogen supplementation. They hypothesized that the ovaries were the primary refractory organ and that pituitary stimulation post partum was dependent on low-dose estrogen priming. During the normal menstrual cycle estrogen and progesterone appear to have a priming effect on the pituitary following LRH injections during the midcycle and the luteal phase.[5, 14–16] Yen and associates[5] proposed that estrogen and progesterone have an additive effect in enhancing LH-FSH release and synthesis. In contrast, Thompson and associates[17] and Kastin and associates[18] found that synthetic estrogen apparently depressed pituitary secretion of LH and FSH following LRH challenge, though normal qualitative responses were obtained. Thompson and associates[17] also reported similar results with progesterone. The possibility of pituitary sensitivity dependent on various ratios of hormones or concentrations was raised to explain the variance between estrogen and progesterone supplementation and the normal menstrual cycle.

In a sense our results may resemble those obtained with estrogen and progesterone supplementation, qualitatively normal but of decreased magnitude. However, the small number of subjects demonstrating FSH surges, the high interassay coefficient of variation, and the substantially decreased size of the FSH surge, leave doubt concerning any responsiveness of the pituitary in the early postpartum period.

Last, we attempted in a limited number of subjects to show some relationship between responders and plasma levels of estradiol-17β or progesterone. Despite the levels of E_2 and P returning to the follicular phase levels in the majority of the subjects studied during the early postpartum period, no pituitary responses to LRH administration similar to nonpregnant women were demonstrated. It suggests an altered sensitivity of the postpartum pituitary due to a prolonged suppression. However, the possible effects of persistently high concentrations of sex-steroid binding globulin in the postpartum period on the available endogenous E_2 should also be considered. It raises the need for further study of the causes of variance at the time of resumption of normal pituitary responsiveness in a larger population with more frequent sampling of hormonal levels including prolactin.

The authors are grateful to Dr. Guy Rochefort for supplying the Ayerst LRH and to Carmelita Gloria for her expert technical assistance.

C. S. Mott Center Colloquium in Andrology: Techniques of Human Andrology

The C. S. Mott Center for Human Growth and Development is holding a colloquium on Techniques of Human Andrology, May 6-7, 1976, at Wayne State University School of Medicine, Detroit, Michigan. Research papers on techniques will be accepted before February 1, 1976. Invited papers will deal with evaluation of testicular biopsy; physical, biochemical, and bacteriologic tests of semen; cytochemistry of spermatozoa; histochemistry of male sex organs; ultrastructural localization of enzymes; endocrine profiles and karyotyping of men; clinical examination of infertile men; biochemical and immunologic evaluation of the prostate; postcoital tests; freezing of semen; artificial insemination; and behavioral therapy of male sexual inadequacies. A film entitled "Sexual Therapy of Male Inadequacies" will be shown; there will be a panel discussion on analysis of male "menopause" and erectile and ejaculatory disorders. For information, write to: Dr. E. S. E. Hafez, Department of Gynecology-Obstetrics, 550 E. Canfield, Detroit, Michigan 48201. Telephone: (313) 577-1011. Registration before March 1, 1976, is for a limited number.

Effectiveness of prophylactic Rh immunosuppression after transfusion with D-positive blood

HERBERT S. BOWMAN, M.D.

Harrisburg, Pennsylvania

In a published investigation 42 D-negative men were transfused with single units of D-positive R_1r (CDe/cde) blood to mimic the D-incompatible transfusion accidents occasionally seen in young D-negative women. Twenty-two men received no therapy and 20 were treated with Rh immunoglobulin in a calculated dose of 20 μg of anti-Rh per milliliter of infused red cells. The reported incidence of serologic D alloimmunization was 81.8 per cent in control and zero per cent in treated recipients. Posttransfusion ^{51}Cr clearance studies with a challenge with the use of 5 ml. of D-positive cells from the same donor at five months in these identical subjects vary from the results based upon the presence of circulating anti-D active antibody. Exponential immune clearance curves occurred in two control and nine treated recipients. As the first evidence of D alloimmunization is an immune Cr clearance curve followed at some later time by circulating active anti-D antibodies, these data could suggest that Rh immunization actually was 90.9 per cent in untreated control subjects and 45 per cent in treated men. The dose of passive Rh immunoglobulin effective in prophylaxis of transfusion Rh immunization of a D-negative person is still not definitely established, but apparently it is greater than 20 μg of anti-Rh per milliliter of D-positive erythrocytes received.

CONTINUED REPORTS document the inadvertent transfusion of large volumes of Rh_0 (D)–positive blood to D-negative women of child-bearing age.[1–3] With two recent exceptions[1, 2] it is common knowledge that attempts to suppress primary Rh immunization in such disadvantaged D-negative women have failed.[4, 5] Similar lack of success toward D-immune prophylaxis has been seen in mothers exposed to 100 milliliters or more of D-positive fetal blood by a massive fetomaternal hemorrhage.[6] This dilemma is due chiefly to an uncertainty regarding the exact dose of Rh immunoglobulin to administer per milliliter of circulating D-positive erythrocytes.

Excellent experiments in male D-negative volunteers[7] transfused with small volumes of D-positive red cells (range 11.6 to 37.5 milliliters initially suggested a therapeutic ratio could be derived determining the dosage of anti-Rh passive antibody for the volume of D-incompatible red cells administered. Approximately 20 μg of Rh immunoglobulin to 1 milliliter of D-positive red cells was believed necessary to achieve complete Rh immunosuppression.[7]

This concept was tested subsequently in male subjects receiving much larger volumes of D-incompatible cells, as might occur in these transfusion accidents involving a D-negative woman.[8] Forty-two D-negative volunteers who completed follow-up received single 500 milliliter units of ABO-compatible. D-incompatible R_1r (CDe/cde) blood. Twenty-two were given no immunotherapy, and twenty others were treated with Rh immunoglobulin (Rh_0GAM, Ortho Diagnostics, Raritan, New Jersey) calculated from the optimal ratio of 20 μg of anti-Rh per milliliter of D-positive infused cells. A single nontransfused volunteer was injected with a comparable large amount of Rh immunoglobulin.

Five months after these transfusions, none of the treated volunteers (0/20) exhibited detectable serum anti-D antibodies by several serologic methods. However, 81.8 per cent of the control recipients (18/22) formed active serum anti-D transfusion-induced alloantibodies. Passive anti-Rh was still present in the single control person who was never transfused.

It is the intent of this paper to report ^{51}Cr clearance studies of labeled D-positive red cells given five months

after transfusion to seven control and 19 of the 20 prophylactically treated recipients of this previous investigation on Rh immunosuppression. Results of the Cr clearance curves suggesting D immunization and the serologic presence of serum anti-D antibodies in this Rh-incompatible transfused population will be compared and interpreted.

Materials and methods

Volunteer subjects. These were the identical population of D-negative men selected with informed consent as previously reported.[8] Two additional healthy D-positive persons, who had never been transfused, also volunteered to receive the same compatible group O,D–positive ^{51}Cr red cells with the posttransfusion challenge studies.

^{51}Cr clearance procedure. The red cell donor was identical for all Cr clearance studies. She was a healthy woman whose red cells had been transfused before without hazard. The serum contained no measured hepatitis-associated antigen (HBAg). Blood groups were O, R_1r (CDe/cde),Ns,P_1,kk.

At the conclusion of the posttransfusion period (five months) each of seven control and 19 treated subjects were injected with 5 ml. of ^{51}Cr packed red cells. Each aliquot was labeled with 50 μc of ^{51}Cr as previously described.[9] The two normal D-positive persons were infused similarly. Except for the initial three subjects listed in Table I, the serum of each recipient was serologically compatible for the ^{51}Cr-treated red cells of the donor.

Equilibration samples for ^{51}Cr radioactivity of the R_1r donor cells were drawn from recipients on Days 1,3,7, and 14 after injection. The aliquots were saved and counted simultaneously for gamma radioactivity. The Cr regression lines were plotted by a method of least squares,[10] and the 100 per cent intercept and the half-life of ^{51}Cr derived mathematically.[9] The mean normal half-life (T/2) of ^{51}Cr for normal random persons by this technique in this laboratory is 27.7 ± 2.6 days.

Serologic techniques. Active anti-D alloantibodies after transfusion were detected with the use of trypsinized screening and panel cells, as has been published.[8]

Results

The data from the seven persons in the control series and the two normal volunteers are found in Table I. The appearance of active anti-D antibody either at the time of the Cr study or 14 days after receipt of the challenge of R_1r radioactive red cells is included. Three of the seven D-negative untreated persons had serologic evidence of Rh immunization before and following the R_1r cells. The Cr curves were typical of exponential immune clearance. The other two untreated subjects (D. K. and O. K.) never demonstrated active anti-D antibody and had Cr clearance times comparable to those of the normal D-positive control subjects (D. H. and R. N.). The mean ^{51}Cr T/2 in these four individuals equalled 25.4 days, which was slightly less than the mean for random normal persons. Two men in the control group (R. S. and J. C.) had no detectable anti-D antibody at either interval in the study, but their Cr clearance times were grossly abnormal.

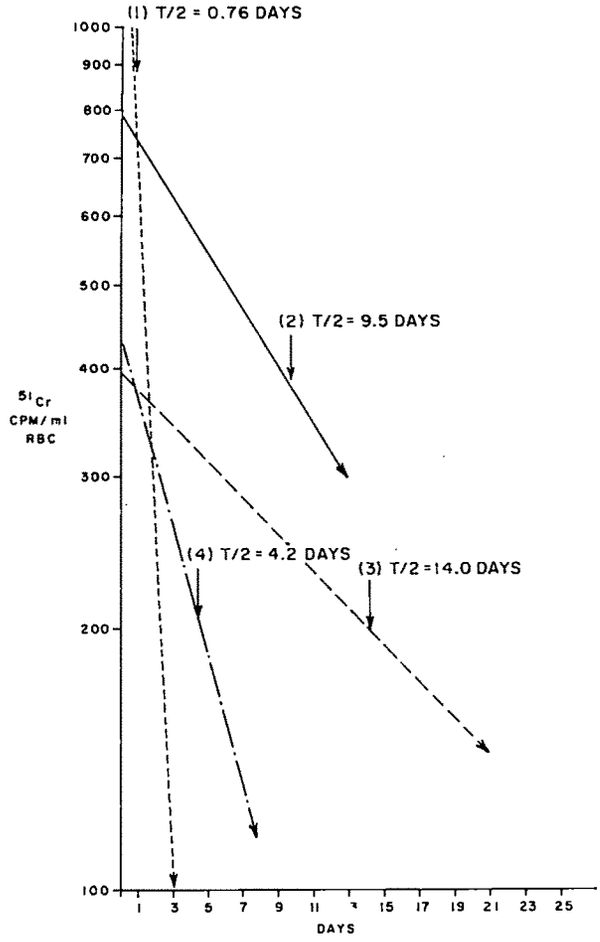

Fig. 2. Cr clearance curves from four treated subjects (R. K., E. A., L. E., D. H.) exhibiting expontential immune cell destruction.

Information on the 19 D-negative men treated prophylactically with Rh immunoglobulin is shown in Table II, as divided into three sections. Since minute amounts of passive Rh immunoglobulin were still found in the nontransfused control subject at five months, an arbitrary criterion for a normal Cr clearance in the treated population was set as a T/2 greater than 20 days. The first section *(A)* contains data of six men believed to have normal Cr clearance. The second *(B)* lists results in four recipients with early normal or just subnormal initial Cr survival curves, all of which exhibited an abrupt collapse between Days 7 and 14. The last section *(C)* contains values of nine subjects whose Cr regression lines were rapid (T/2 less than 18 days) with a single exponential function. By the serologic methods used, no treated recipient exhibited active anti-D alloimmunization then or 14 days after challenge with the R_1r red cells.

The Cr investigations from the four men with biphasic regression "collapse" curves in Section B are illustrated by Fig. 1. Figs. 2 and 3 show Cr elimination curves from eight of the nine volunteers in Section C.

Comment

In the untreated volunteers (Table I) who received experimental R_1r whole blood, the five-month Cr clearance data and serologic presence of active anti-D were at variance in just two recipients (R. S. and J. C.). T/2 Cr values of these two subjects were 4.8 and 12.3 days, respectively. If their rate of exponential disposal of D-positive challenge radioactive cells is due to true Rh immunization even in the absence of serologic anti-D, then the numbers of sensitized transfused untreated D-incompatible volunteers in this experiment would be 20/22, or 90.9 per cent. This figure emphasizes the exceptional risk when a D-negative woman is erroneously given Rh-incompatible blood

and the need to determine the correct dose of passive Rh immunoglobulin.

An even greater disparity exists in the data from the D-negative subjects receiving D-positive whole blood and treated with Rh immunoglobulin. While none of these 20 men formed demonstrable anti-D active antibody,[8] in 13 of them the Cr clearances definitely were unusual.

Twenty-two individuals comprised this original group of treated volunteers, two later being lost to follow-up.[8] Seven days after the injection with passive anti-Rh immunoglobulin in 21/22 recipients some transfused D-positive cells were still noted. At one month after transfusion this incidence decreased to just 8/22.[8] While the rate of immune clearance of the Rh-incompatible segment of the erythron is not the primary factor in preventing D immunization, individuals who exhibit delayed regression curves appear more susceptible to sensitization.[3, 11, 12] This gradual elimination of D-incompatible cells by passive antibody suggests that the encouraging 100 per cent rate of success in Rh immunosuppression reported by serologic data alone may be optimistic.

Six of the 19 treated volunteers had apparently normal Cr elimination curves (range, T/2 20.7 to 32.4 days) as listed in Table II. Four individuals (Group B) had ^{51}Cr curves whose slope was probably normal for the initial seven days, although in one the T/2 value was 18 days. Between Days 7 and 14, in each person there was a uniform rapid negative slope of the regression line. This implied biphasic collapse curves, as illustrated in Fig. 1 as *A, B, C,* and *D.* Although circulating anti-D antibody was then undetected, the similarity and times of these four brisk collapse curves may represent early IgM anti-D production as a primary immune response.

In nine treated recipients (Group C), the ^{51}Cr clearance were rapid and represented by a single exponential curve. Plots from eight of these nine persons are found in Figs. 2 and 3 and can be seen to be characteristic of immune red cell clearance (T/2's 0.76 to 17.4 days). Five of this group formed either active anti-D or anti-CD alloantibodies five months later.

The finding of immune red cell survivals without demonstrable serum antibodies is not new.[13] In many instances no blood group incompatibility exists contrary to that present in this study. Repeating these Cr survival studies with the use of several D-negative–labeled red cells in the 13 volunteers with unusual clearances would have been useful in completely documenting covert D-specific sensitization. Repeated

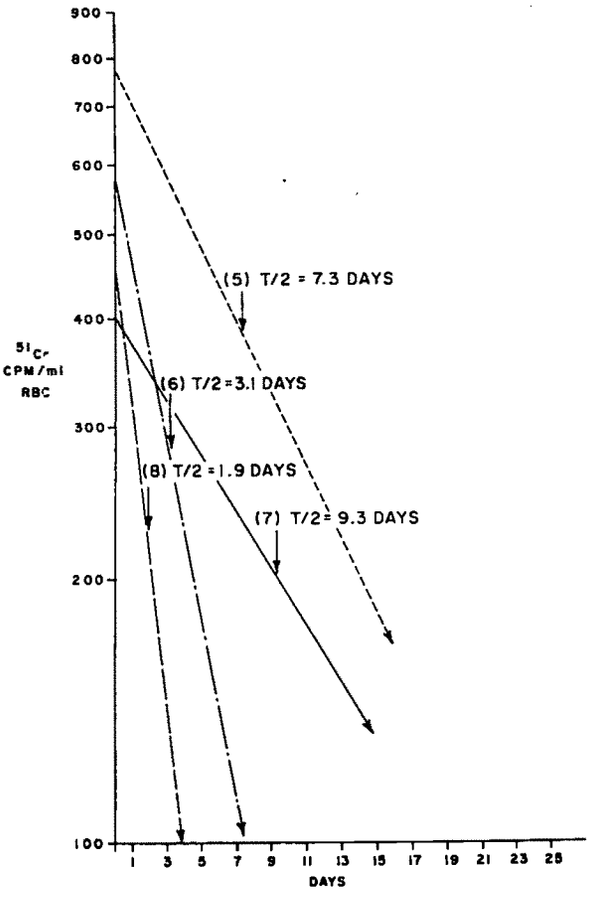

Fig. 3. Cr clearance curves from four treated subjects (R. G., R. H., R. L., W. N.) exhibiting expontential immune cell destruction.

efforts to again recruit these volunteers for this appropriate study became impossible, and they were lost from observation.

Mollison and associates[14] recently investigated Rh-negative subjects injected in varied schedules with 1 milliliter of D-incompatible cells. While approximately 50 per cent became immunized, in some subjects serologic anti-D developed only after several small D-positive stimuli. However, when judged by Cr clearance, Rh immunization was more often apparent after the *initial* injection and *before* the circulating active anti-D alloantibodies appeared. They state ". . . that accelerated clearance of red cells is a more sensitive index for the presence of isoantibodies than any serologic test." Similar findings were reported by Woodrow and associates[3, 12] and by Krevans and co-workers.[15]

From the former investigation it seems reasonable to conclude that the nine treated volunteers (Group C)

received adequate passive immunosuppression preventing circulating anti-D isoantibodies. By the Cr immune clearance rates, however, they would be classed as suspect for Rh immunization. The actual rate of Rh sensitization among treated subjects of this work,[8] judged by these data, could be nine of 20, or 45 per cent rather than 0 per cent.

It is difficult to completely agree with a statement ". . . that administration of approximately 20 μg of anti-Rh_0 (D) per milliliter of Rh-positive red blood cells will suppress the primary immune response to the Rh factor *regardless* of how large the volume of blood . . ."[8] until additional conclusive data become available. Mollison and colleagues[11] concluded that 75 μg of anti-D antibodies inhibited primary immunization by 1 milliliter of Rh_0 (D)–positive red cells. Lower dosages probably would also be effective when Rh-negative subjects are accidently transfused with D-positive blood. Amounts such as 25 μg of anti-Rh per milliliter of red cells have been recently recommended.[5, 16–18]

In instances in which transfusion accidents, especially in D-negative parturient women, were published, apparently successful primary immunization has been achieved when large amounts of Rh immunoglobulin were given. Keith and co-workers[2] used about 36 μg of anti-Rh per milliliter of D-positive red blood cells. Other investigators used 49 μg per milliliter and from 16 to 51 μg of anti-Rh per milliliter of D-incompatible cells,[17] respectively. Only one study[1] involved a subsequent D-positive specific challenge through another D-positive pregnancy which assured that complete Rh immunosuppression was actually accomplished.

Until more data are available involving D-negative persons given volumes of 500 milliliters or more of D-positive blood combined with attempts at passive antibody Rh immunosuppression, a dose between 25 and 35 μg of anti-Rh per milliliter of D-incompatible red cells may prove a useful therapeutic estimate.

I appreciate Dr. William Pollack and his associates providing me with data on these volunteers and permitting the performance of the ^{51}Cr studies. The competence of Mrs. Darlene Tyler (M.T., A.S.C.P.) in radioisotope technique is acknowledged with gratitude.

Psychometric testing as a basis for counseling patients choosing a method of contraception

A retrospective survey

G. GARY BROOKS, M.D.
MARY R. BUTCALIS, M.S.N.
Shreveport, Louisiana

To investigate the merits of using psychometric testing as a predictive adjunct to counseling patients in the choice of a contraceptive method, 134 family-planning patients using an oral contraceptive for one year or longer completed the Neuroticism Scale Questionnaire. Clinic records of these patients were examined to determine consistency of contraceptive usage. Patients who were inconsistent in contraceptive usage scored significantly higher on the anxiety factor of the questionnaire. This indicated a greater presence of free-floating anxiety and emotional immaturity for inconsistent users. Results of this study provided support for the findings of two similar studies but failed to provide support for others. However, the over-all predictive ability of the questionnaire scores proved to be low. Further study is recommended.

THE THEORETICAL effectiveness of a contraceptive method in many cases seems unrelated to its effectiveness rate in actual usage. Women who are consciously motivated to prevent the occurrence of a pregnancy choose methods of contraception they are unwilling or unable to use consistently.[1] Social and psychological variables can be as pertinent in the prevention of unwanted pregnancies as the theoretical effectiveness of the contraceptive methods used.[2–5] Studies have shown significant differences in personality traits of consistent and inconsistent contraceptive users as measured psychometrically.[1, 6, 7] Counseling patients in the choice of a contraceptive method could be a more useful process if consistent or inconsistent usage could be predicted by psychometric testing.

Materials and methods

A total of 134 family-planning patients completed the study. These patients were participants in the Louisiana Family Planning Program and had been receiving an oral combination contraceptive pill. The mean age of the study population was 22.9 years (range, 16 to 36). The mean number of years of formal education was 10.8. Twelve of the patients were nulligravid; for the remainder of the population, age at first conception ranged from 13 to 32 years. The mean age at first conception was 17.4 years. The mean number of years the patients had been using oral contraception was 2.4 years. For those patients who had been pregnant, the mean number of pregnancies was 2.0. Fifty-seven of the patients were or had been married and 77 had never been married.

The Neuroticism Scale Questionnaire (NSQ), a brief, 40 item questionnaire, was administered to all subjects of the study.[8] The NSQ is designed to measure bipolar differences in four personality traits which indicate neurotic trends within the normal range. These four factors of the NSQ include (1) sensitivity vs. practicality, (2) depressiveness vs. cheerfulness, (3) submissiveness vs. dominance, and (4) anxiety. The fifth factor of the NSQ is the sum of the four traits measured, or total neuroticism. The higher the standard ten score, the more sensitive, depressive, submissive, anxious, or neurotic the test subject is considered to be.

A patient was considered to be a consistent user of the oral contraceptive if she fulfilled each of the following criteria: (1) kept appointments regularly in a

manner assuring her a constant supply of medication; (2) pill count was correct when patient kept supply appointments; (3) she had not been pregnant while using the oral contraceptive method. A patient was considered to be inconsistent if she was deficient in any one of the following criteria: (1) failed to keep appointments regularly enough to prevent running out of pills; (2) wrong pill count without a satisfactory reason; (3) she became pregnant while on the oral contraceptive pill.

This patient population was carefully selected to eliminate those patients who were lost to follow-up or changed methods before the completion of one full year. We believe one year of objective data is needed to establish a pattern of consistent or inconsistent usage for this method.

Results

A significant difference in personality traits of consistent and inconsistent contraceptive users was found for only one of the NSQ factors. Anxiety was shown to be increased significantly ($P \leq 0.05$) for the inconsistent contraceptive users. The mean scores for depressiveness vs. cheerfulness, submissiveness vs. dominance, and total neuroticism were not statistically significant. The values of the means of the standard ten scores on the five factors of the NSQ for consistent and inconsistent users with the resultant T scores are shown in Table I. For the total study population, the mean of the standard ten scores for sensitivity vs. practicality was lower than the average range indicating all of the patients leaned more toward tough practicality rather than sensitivity. The actual number of inconsistent patients with their standard ten scores and per cent of total for each factor tested is found in Table II. The same information for consistent patients is found in Table III.

Comment

An inverse relationship exists between the findings of this study and the findings of Kane and associates[6] for postpartum patients in North Carolina. In the North Carolina study, significant differences were found for all factors of the NSQ with the exception of

anxiety, for which no significant difference was shown. The findings of Kane in a study of motivational factors of abortion patients did show a significant increase in anxiety scores of patients seeking abortion as contrasted to the scores of a nonpregnant group. Kane discounted this finding because a higher level of anxiety was expected in patients awaiting abortion.

Emotional immaturity is one of the dimensions measured by the anxiety scale of the NSQ. Bakker and Dightman[1] found pill-forgetting women possessed a "considerable degree of immaturity." Thus, the result of this study seems to lend support to the findings of Bakker and Dightman.

The intent of this study was to administer a standard NSQ to a family-planning patient population in an effort to uncover a patient profile which would correlate with the continuation or lack of continuation of a contraceptive method. The only factor which appears to have any statistically significant relationship is anxiety, which was significantly increased in inconsistent users. Since anxiety seems to be the key factor in this particular study, perhaps the questions relating to the scoring of anxiety on the questionnaire could be extracted which would make testing a simpler process in a large population. The predictability of a patient's consistent and effective continuation of a contraceptive method would be valuable in counseling patients choosing a method of contraception. If inconsistence of usage were predicted, perhaps it could be suggested that the patient choose a method which would require less individual motivation. Certainly women with medical conditions which make them at high risk for pregnancy would benefit if one could predict that a selected method would have its best continuation rate. We believe further studies into developing tools able to uncover certain motivational factors in patient populations will prove beneficial. A prospective study of this kind on a larger scale needs to be done to validate our findings in this small retrospective study.

The authors with to express their appreciation to Dr. John McCluhan, Director of the Graduate Program in Nursing, for his assistance in reviewing this study and to the Louisiana Family Planning Program for cooperating in the performance of the study.

Amenorrhea following oral contraception

JOHN R. EVRARD, M.D., M.P.H.
BERTRAM H. BUXTON, JR., M.D.
DONNA ERICKSON
Providence, Rhode Island

A prospective study was done on 326 nulliparous women who ceased oral contraception. Follow-up was obtained on 311. The mean age was 20.3 years (S.D. 2.5). Eighty-nine per cent began menstruating within 60 days after stopping therapy, and only 7 took 180 days or longer to menstruate. Late menarche strongly correlated with post-pill amenorrhea (PPA), but continous length of time on oral contraceptives and type of oral contraceptive showed no significant relationship. The incidence of PPA was 2.2 per cent. All women did eventually menstruate spontaneously, the longest period of amenorrhea being 540 days.

WOMEN ELECTING oral contraception as a method of choice for pregnancy prevention are frequently young and nulliparous. Post-pill amenorrhea (PPA) may be a threat to future conception. Amenorrhea following oral contraception has been well documented, but the predisposing factors which correlate with this syndrome have not been well defined. Since most papers discussing the problem of PPA are retrospective studies, the precise incidence is difficult to determine. Larsson-Cohn[1] described four cases of amenorrhea over 6 months' duration in 516 women who were on oral contraceptives. Golditch[2] has estimated the incidence of PPA to be 2.2 per 1,000 users. In a study of 210 women with secondary amenorrhea of 6 months' duration 30 per cent were PPA cases,[3] and in another series of 439 cases of secondary amenorrhea, 9.3 per cent occurred after the cessation of oral contraceptives.[2] Most authors have defined PPA as amenorrhea of 6 months or more after the cessation of oral contraceptives. Irregular menses prior to the institution of oral contraceptive therapy,[4] late onset of menarche,[5] length of time on oral contraceptive agents, and the use of combined oral contraceptives have all been suggested as predisposing factors. Table I shows the experience of previous authors on the relationship of prior irregular menses to PPA.

Late menarche was implicated as a predisposing factor by Grant,[6] and Steele and associates[3] noted menarche at age 16 or older in 8 of 132 women with PPA. Golditch[2] and Shearman[7] stated that PPA is in no way correlated with the length of time the woman has been on oral contraceptive agents and Goldfarb[8] recommended that women in the childbearing age be allowed to have a spontaneous menses after being on the pill 2 or 3 years.

PPA was found only after the use of combined oral contraceptive agents by MacLeod and associates[9] and Starup.[10] Other authors have reported amenorrhea after sequential pills with much less frequency.[2, 7] This phenomenon probably is an artifact produced by virtue of the fact that many more women are on combined pills than sequential pills.

In the attempt to delineate the parameters which may predispose to PPA of 6 months' or more duration a prospective study was done on 326 women at Brown University.

Material and methods

A total of 326 nulliparous women were studied from August 1, 1971, to August 1, 1974. All women who requested oral contraception, and who had no medical contraindication, were included in the study providing that they had not been on oral contraceptives previously. Follow-up was obtained on 311 cases and 15 were lost to study. Of the 311, the age range was from 16 to 38 years of age, with a mean of 20.3 years (S.D. 2.5). History of the patient's menses during the year prior to

going on oral contraceptive agents was obtained. The mean number of days between menstrual periods was calculated and the variance of the cycle was considered one half the number of days of the difference between the longest and shortest cycle in the last year. PPA was defined as a lack of spontaneous menses for 180 days or more after ceasing oral contraceptive medication. The group was somewhat selective since any woman having six or fewer periods per year or having a period of amenorrhea of longer than 165 days was not placed on oral contraceptive medication. Ninety-eight per cent of the patients had not been amenorrheic for longer than 60 days in the year prior to oral contraception.

Results

Only 11 patients took 120 to 179 days to menstruate and seven began their post-pill menstrual period after 179 days. Table II depicts the time of onset of menses after oral contraception. Eighty-nine per cent began menstruating within 60 days after pill therapy. Women with PPA of 180 days or greater began menstruating at 180, 206, 240, 330, 345, 450, and 540 days, respectively. The number of months any patient was on the pill continuously before stopping oral contraception showed no correlation with the time of onset of first menses. Of the seven patients with PPA, three patients had their menarche at age 16 years. Seven of the 311 patients were on sequential contraceptives and none was amenorrheic longer than 65 days after pill therapy. A total of 153 (49 per cent) menstruated within their mean cycle plus their normal variance. All 311 patients did eventually menstruate spontaneously.

Comment

An incidence of PPA of 2.2 per 100 in this study reflects a tenfold increase to the estimate by Golditch.[2] Most students of PPA have incriminated previous irregular menses as a predisposing factor. The present study does not confirm this opinion. This study, however, is biased in two ways. (1) No woman was placed on oral contraceptive therapy unless her cycle was reasonably regular (as defined in Materials and Methods). (2) The authors considered only the year prior to the beginning of oral contraceptive agents in determining regularity of the cycle. No doubt, if a past menstrual history dating back to menarche was obtained, a much higher incidence of menstrual irregularity would have been discovered. In the present study, menstrual irregularity in the year prior to institution of oral contraception showed no correlation with PPA. Only 11 patients took 3 to 6 months to begin menstruating and all of these in the year prior to therapy had a cycle plus variance of 42 days or less. Also the seven patients with PPA of 6 months or greater all had a cycle plus variance of 42 days or less.

The four patients who were amenorrheic for 9 months or longer had studies performed to exclude other endocrinopathies. Skull x-rays, visual field examination, T3, T4, 17-ketosteroid, and 17-hydroxycorticoid studies were undertaken and found to be within normal limits.

Medroxyprogesterone acetate, 10 mg. daily for 6 days, was administered orally to five of the seven patients with PPA (the patients who were amenorrheic 180, 330, 345, 450, and 540 days). Withdrawal bleeding was induced in four patients (180, 345, 450, and 540 days). It was suggested to the woman who did not exhibit progesterone withdrawal bleeding that she have a serum FSH and LH assay but she refused. It is interesting that the patient with the longest period of PPA (540 days) did bleed after progesterone withdrawal 3 months after oral contraceptive therapy but did not have progesterone withdrawal bleeding after 12 months of PPA. At this time Premarin, 2.5 mg. daily orally for 20 days, with medroxyprogesterone acetate, 10 mg. daily orally on the last 6 days of the Premarin therapy, was used to induce bleeding. On the fifth day of bleeding clomiphene citrate, 50 mg. daily, was administrated orally for 5 days. Her basal temperature remained flat and she did not menstruate. Although she was not apparently under weight, her menses did

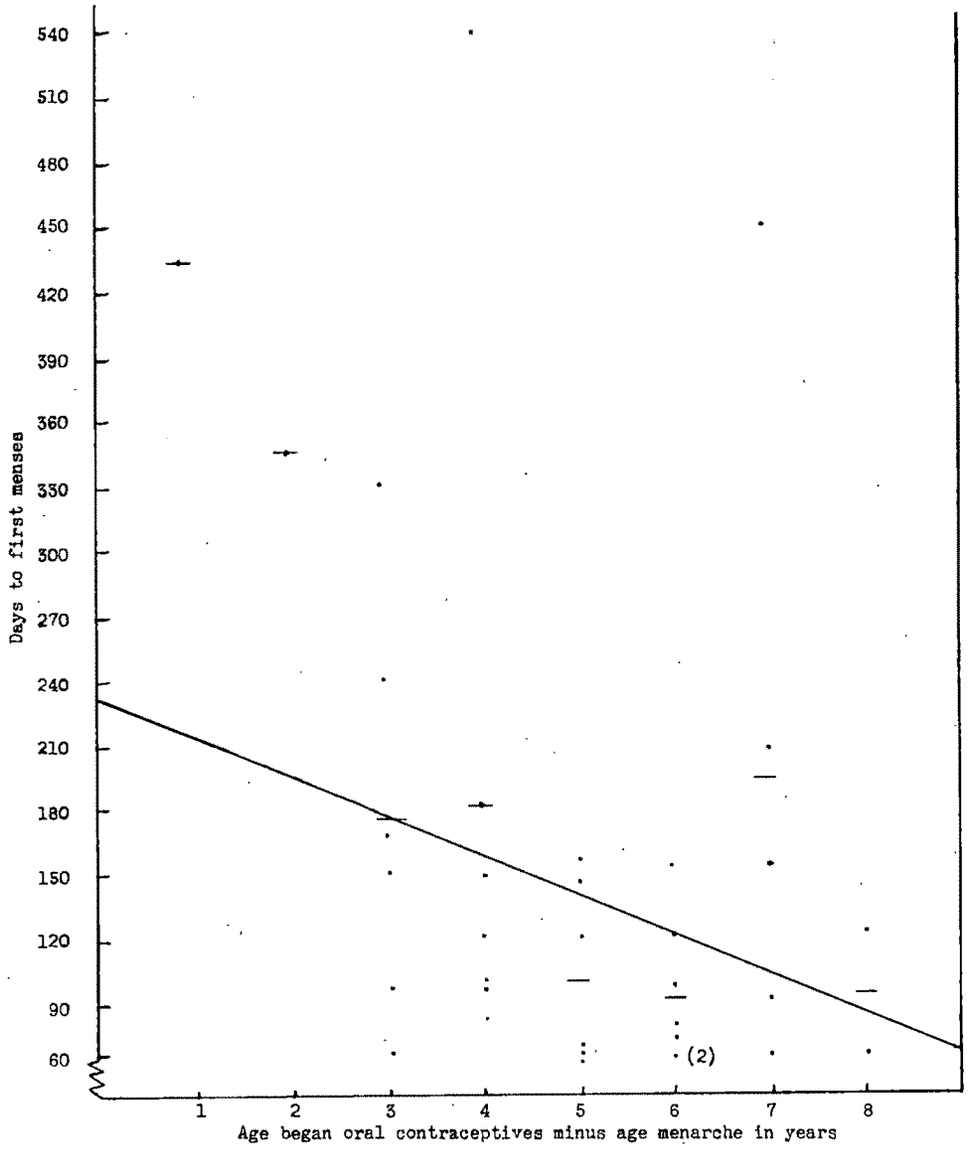

Fig. 1. Relationship of days to first menses to years between menarche and age at which OC were begun. Pearson's regression coefficient = −16.73. (2) = Two values at same position. − Indicates mean value.

resume spontaneously at 540 days after she had gained 10 pounds, and her menses did remain regular.

Late menarche (16 years) was associated with PPA. Only 12 patients had their menarche at age 16 (none older than 16) and three of these had PPA compared to four of the remaining 299 patients ($P < 0.001$).

The high correlation of late menarche with PPA suggests another predisposing factor for PPA. Should oral contraceptive therapy be instituted close to the menarche, while the hypothalamic-pituitary-ovarian axis is still in a fragile state of equilibrium, PPA might result. To test this hypothesis the age at which oral contraception was begun minus the age of menarche was calculated in all patients who took 60 days or longer to begin menstruation after pill therapy. Indeed, the less the number of years between menarche and beginning the oral contraceptives the longer it took those patients to menstruate. Fig. 1 is a scattergram depicting the age at which the oral contraceptive was instituted minus the age of menarche and the time of onset of menses in patients who took 50 days or longer to menstruate after oral contraceptive

therapy. Although the regression line shows a negative correlation between the years between menarche and onset of oral contraceptives and length of time to resume menses after stopping therapy, the numbers are too small to be statistically significant. Obviously, this relationship would apply only when there is not a great interval between menarche and beginning of oral contraceptive therapy.

Several authors have suggested that PPA occurs only after combined pills.[9, 10] We could not test this theory since only seven patients were on sequential pills and none was amenorrheic. Other authors report a lesser incidence of PPA on sequential pills. Two explanations for this phenomenon must be considered. It is true that the progestational agents in oral contraceptives are potent LH suppressors and on a theoretical basis sequential pills may produce less suppression than combination pills. However, marketing figures in the United States for the years 1971 through 1973 document that sequential pills accounted for only 6 per cent of the total oral contraceptive market.[12] The infrequency of PPA after sequential pills could therefore be due to less frequent use of this type of agent.

Length of continuous time on oral contraceptives revealed no correlation to PPA. For the entire group, the range of time on the pill was from 1 to 84 months, with a mean of 11.2 months (S.D. 9.29). In those women with PPA, the range was from 7 to 18 months, with a mean of 9.7 months (S.D. 3.9). As a group the women of PPA were on oral contraceptive agents fewer continuous months than the entire group.

Conclusions

In these 311 patients the incidence of PPA was 2.2 per cent. Menarche at age 16 appeared to be a predisposing factor and the closer a woman was to her menarche when she commenced therapy the longer it took her to re-establish her menstrual cycle. The number of continuous months on oral contraceptives does not appear to be correlated with PPA.

Symposium on Medical Genetics

The Hungarian Society of Human Genetics will present an international symposium, "Symposium on Medical Genetics," with World Health Organization support in Debrecen-Hajdúszoboszló, Hungary, on April 27-29, 1976. Topics of the Symposium include: (1) Cytogenetics, (2) Population Genetics, (3) Prenatal Diagnosis and Genetic Counseling, (4) Chromosomal Mapping, (5) Clinical Genetics on the Molecular Level—Hemoglobinopathies and Immunogenetics. Further inquiries should be addressed to: Human Genetics Laboratory, H-4012 Debrecen, P. O. Box 37, Hungary.

Infertility following wedge resection of the ovaries

R. TOAFF
M. E. TOAFF
M. R. PEYSER
Tel-Aviv, Israel

Seven cases of polycystic ovarian disease were investigated by laparoscopy and endocrinologic tests after failure of ovarian resection to restore fertility. One case of bilateral and two cases of unilateral ovarian atrophy were recorded. In all seven patients the common features were extensive periovarian and peritubal adhesions. Four of the six patients amenable to cure were submitted to reconstructive surgery; three of them conceived and had normal deliveries. The present observations support the plea to relegate the surgical approach to a minor position in patients with Stein-Leventhal syndrome and stress the importance of meticulous surgical technique in the performance of ovarian surgery. Laparoscopic investigation is mandatory in all cases of unsuccessful ovarian resection.

DESPITE the growing interest in conservative methods for induction of ovulation in polycystic ovarian disease, wedge resection of the ovaries is still very much in use. Its beneficial effects are well documented.

According to Goldzieher's[1] survey of published results, regular cycles follow surgery in 80 per cent of patients and desired pregnancy is achieved in 63 per cent. In some series, however, less than 10 per cent of subjects experienced regulation of menses and only 13 per cent conceived.[2] It is generally agreed that fertility is restored less often than the menstrual rhythm.[1, 3] Questionable diagnosis and surgical complications may be involved in the failure of ovarian wedge resection to achieve its aim.

The present report describes a series of seven cases of polycystic ovarian disease submitted to laparoscopic and endocrinologic investigations after the failure of surgery to restore fertility.

Material and methods

During a 6 year period (1967-1972) 11 women, who had previously been submitted to wedge resection of the ovaries in other hospitals with diagnosis of Stein-Leventhal syndrome, were investigated. Their complaint was persistent sterility, with or without obvious menstrual disorders. Four of them, whose operation records showed that at operation other pathology, such as malformations, tumors, or sequelae of pelvic inflammatory disease, was found beside polycystic ovaries, were not included in the present series in spite of similar findings.

Six of the seven patients of the series were 26 to 28 years of age and one was 39. Ovarian surgery had been performed 2 to 9 years previously. All the patients had been treated, after endocrine studies were carried out before and after surgery, in different institutions and by private practitioners. As reliable data were not available in most cases, however, only information known to the patient and surgical records were used in establishing the early history.

The investigations performed included the following. (1) Endocrine evaluation, including 17-ketosteroid excretion and their fractionation, adrenocortical suppression and ovarian stimulation (dexamethasone-HCG test according to Jayle[4]) plasma LH studies under basic conditions and after clomiphene administration, estrogen excretion, evaluation of thyroid function. (2) Hysterosalpingography with water-soluble contrast medium. (3) Laparoscopy, generally within 2 to 4 days after occurrence of the thermal shift in clomiphene-treated cycles.

Case reports

Case 1. A. B., 27 years of age, sought advice for secondary sterility and oligomenorrhea. Following

menarche at 13, she had normal periods for 3 days' duration every 30 days up to the age of 21. Married at 17, she had at 19 a normal pregnancy and delivery. For the last 6 years she menstruated for 10 days every 45 to 60 days and she could not conceive. In 1965, at the age of 25, following culdoscopic examination which revealed enlarged, white, smooth ovaries, she was submitted to bilateral ovarian resection. The postoperative course was complicated by fever and abdominal pains. The menstrual rhythm remained unchanged and no conception followed.

On examination, no physical abnormalities were observed. The endocrine findings were within normal limits. At laparoscopy, abundant pelvic peritoneal adhesions were found. The left adnexae were included in a single fibrotic mass. The right ovary was slightly enlarged, micropolycystic, and partially covered by the adherent, distorted tube.

The patient was operated on again in 1967. The left ovary was reduced to a fibrotic band. The right ovary was freed from its extensive adhesions to the tube, the posterior wall of the uterus, and broad ligament. The peritoneal lining of the right tube was carefully reconstructed.

The postoperative course was uneventful. One year later the patient conceived under clomiphene treatment (500 mg. per cycle, five cycles) and had a normal term delivery.

Case 2. S. M., 28 years of age, had been married 8 years when first seen. Since menarche at the age of 10, she had menstruated 4 to 5 days every 1 to 4 months. For that reason she had been submitted to bilateral ovarian resection at the age of 19, shortly before marriage, in 1962.

After operation she had normal menses for 3 years, followed by recurrence of oligomenorrhea. She was never pregnant. On physical examination, no endocrine stigmas were recorded. The only positive finding at endocrine evaluation was hypothyroidism. Her LH plasma values were 20 to 24 mU per milliliter. Under thyroxine treatment (100 μg per day) her periods became regular, but were apparently anovulatory. At laparoscopy, a few months later, dense peritubal and periovarian adhesions were seen. The patient underwent reconstructive surgery in December, 1971. Both ovaries were enlarged and polycystic, almost completely covered by adhesions involving omentum and tubes. The distal part of the left tube was completely buried by adhesions deep into the pelvis. The left tube was only partially covered by adhesions, but the fimbriae were almost completely adherent to the ovarian surface.

Following careful reconstruction and endocrine treatment which included thyroxine (100 μg per day) and clomiphene therapy (750 mg. per cycle), the patient conceived after the third clomiphene course and delivered at term in April, 1973. She delivered again in November, 1974.

Case 3. D. Y., 39 years of age, had been married 19 years when first seen. She had been amenorrheic since the age of 16, after 1 year of almost regular menstruations, and was never pregnant. She was investigated and treated in several hospitals up to the age of 33, when wedge resection of the ovaries was performed in 1965. After operation she remained amenorrheic, but under HMG (Pergonal) therapy she menstruated and apparently had ovulatory cycles. No pregnancy, however, followed.

On examination, we found a normally developed woman, without acne or hirsutism. Excretion of 17-ketosteroids was in the upper range (11 to 14 mg. per 24 hours), with a high excretion of dehydroepiandrosterone (1.6 mg. per 24 hours). Excretion of estrogens was very low (6.4 μg per 24 hours). Repeated LH plasma estimations gave values of 20 to 22 mU per milliliter.

Dexamethasone suppression, followed by ovarian stimulation according to Jayle,[4] seemed to establish heightened adrenal androgenic function. At laparoscopy, the right ovary appeared as a thick fibrotic band with the tip of the appendix attached. The left ovary was small and atrophic, adherent to the uterus. Uterus and tubes were normal. As ovarian resection had resulted in a condition very close to surgical castration, the patient was advised that further treatment was futile.

Case 4. S. H., 26 years of age, had been married 8 years when she consulted us because of primary sterility. Since menarche at the age of 15, she had suffered from oligomenorrhea, with periods of 6 days' duration every 2 to 3 months. In 1965, at the age of 19, shortly after marriage, she was submitted to bilateral ovarian resection. The menses became more regular, lasting 3 to 5 days every 29 to 35 days, but conception did not occur. Under clomiphene treatment she had apparently ovulatory cycles. Three years previously, hysterosalpingography demonstrated normal tubal patency.

On examination we found a normally developed woman, with abundant acne, no hirsutism. The BBT curve was biphasic, with a short luteal phase. Endocrine work-up did not reveal any abnormality. 17-Ketosteroid excretion and fractionation findings were well within normal limits. Serial daily LH plasma estimations showed values of 23 to 25 mU. per milliliter and a peak of 84 mU. per milliliter. Early luteal laparoscopy demonstrated a normal uterus, a right ovary covered by adhesions joining the sygmoid to the broad ligament. The distal part of both tubes was covered with adhesions. Tubal patency was preserved. No signs of ovulation were seen.

The patient was operated on again in January, 1973. The dense peritoneal adhesions were carefully dissected and ovaries and tubes freed. A remarkable finding was that the adhesions on both ovaries converged to a linear scar, the suture line of the wedge resection.

Table I. Pre- and postoperative menstrual pattern, and relevant postoperative findings in seven infertile women

Serial No.	*Presenting Age*	*Age at wedge resection*	*Preoperative symptoms*	*Postoperative course*	*Postoperative menstrual function*
1. A.B.	27	25	Oligomenorrhea 6 yr. dur. Sec. sterility. No hirsutism, no acne	Fever, abdominal pains	Oligomenorrhea, anovulation
2. S.M.	28	19	Oligomenorrhea 9 yr. No hirsutism, no acne	Normal	Regular 3 yr. then oligomenorrhea
3. D.Y.	39	33	Sec. amenorrhea of 17 yr. dur. Primary sterility. No hirsutism	Normal	Amenorrhea. Normal cycles under Pergonal treatment
4. S.H.	26	19	Oligomenorrhea of 4 yr. dur. No conception during 1 yr. Acne, no hirsutism	Normal	Almost regular, but anovulatory cycles
5. M.E.	28	25	Oligomenorrhea 5 yr., then amenorrhea, 7 yr. Primary sterility. No hirsutism	Normal	Amenorrhea. Satisfactory reaction to induction of ovulation with clomiphene or Pergonal
6. A.Z.	27	24	Regular periods, anovulation. Primary sterility. No hirsutism	Normal	Regular, ovulatory cycles
7. W.S.	28	21	Oligomenorrhea of 8 yr. dur. Primary sterility. Hirsutism, marked acne	Normal	Regular for a few months, then oligomenorrhea

Following operation, the woman was treated for several months with clomiphene (750 mg. per cycle). The cycles were apparently normal but the luteal phase remained short. A trial with prednisone (5 mg. per day) was successful and the patient conceived in the second month of prednisone therapy. She was delivered at term by cesarean section in May, 1974.

Case 5. M. E., 28 years of age, was first seen after 8 years of marriage. Following menarche at the age of 13 and up to the age of 18 she had menstrual periods of 8 to 12 days' duration every 2 to 4 months, then she became amenorrheic. Before and after marriage she was treated with prednisone, later with clomiphene, and then with HMG (Pergonal). Under clomiphene or Pergonal therapy she had apparently normal cycles but did not conceive. Conservative treatment was then abandoned and wedge resection performed at the age of 25, in 1970. As the menstrual rhythm remained unchanged, the patient was treated again with clomiphene and HCG and her periods became more regular.

On admission, 3 years later, no physical abnormality was observed. Endocrine work-up was uncontributory. Following clomiphene, the patient had a normal menstruation, with typical BBT curve and elevated urinary excretion of pregnanediol. LH plasma estimations in consecutive days were 23, 25, 26, 48, and 72 mU. per milliliter, and FSH plasma estimations in the same days were 91, 84, 93, and 130 mU. per milliliter. At laparoscopy the ovaries were found to be almost completely covered by thick adhesions involving both tubes and intestine loops. The patient has been advised that reconstructive surgery is mandatory in her present condition, but up to now has refused operation.

Case 6. A. Z., 27 years of age, married 9 years, consulted us for primary sterility. Since the age of 13 she had regular periods of 4 days, every 28 days. After 1 year of marriage without conception, she sought medical advice and was treated with clomiphene for long periods. In 1970, at the age of 24, shortly after a laparoscopic examination, she was submitted to ovarian resection. Following operation her periods remained regular but the desired pregnancy was not achieved.

When examined, she had a biphasic BBT curve, normal LH plasma values with an ovulatory peak of 81 mU. per milliliter. At laparoscopy, a very small, micropolycystic, nonfunctioning ovary and a normal tube were seen on the right side. On the left, a normal ovary with a hemorrhagic corpus luteum was joined by adhesions to a patent tube, the fimbrial part of which was included in transparent membranes. The pouch of Douglas was obliterated by adhesions. Reconstructive surgery has been advised.

Case 7. W. S., 28 years of age, had been married 10 years when first seen because of primary sterility. Since the age of 13 she had scanty menstrual periods every 2 to 4 months. In 1968, at the age of 21, she had been submitted to wedge resection of the ovaries. Her periods became regular and remained so for several

submitted to wedge resection of ovaries

months, then oligohypomenorrhea recurred. Since puberty she had suffered from acne, especially on the face.

Physical examination revealed a fat woman with feminine habitus, normally developed breasts without galactorrhea, marked hirsutism on the face, lips, neck, and buttocks, and a male-type pubic escutcheon. Her external genitalia were normal, the uterus was of normal size, and the ovaries did not appear enlarged.

The relevant endocrinologic findings were upper-normal values of 17-ketosteroid excretion (10.8 to 15.2 mg. per 24 hours) with high levels of androsterone (5.6 to 6.1 mg. per 24 hours) and dehydroepiandrosterone (1.8 to 3.0 mg. per 24 hours) on fractionation. Those high levels were reduced to within the normal range (1.9 and 0.8 mg. per 24 hours, respectively) under dexamethasone suppression, and remained normal under HCG stimulation. The total estrogen excretion was 7 to 15.7 μg per 24 hours. LH plasma estimations gave values of 14 to 16 mU. per milliliter.

At laparoscopy, the left adnexae were found to be buried in a mass of thick adhesions. Peritubal and periovarian adhesions were present in lesser measure on the right side, where the ovary was polycystic, partially covered by the adherent ampullar part of the patent tube.

The patient was classfied as having a mild case of adrenal androgenic hyperactivity. In December, 1973, she was submitted to reconstructive pelvic surgery. Under maintenance dexamethasone therapy she has regular, apparently ovulatory cycles. Her husband is currently under treatment for oligospermia.

Comment

Relevant data on the seven cases of unsuccesful ovarian resection described here are presented in Table I.

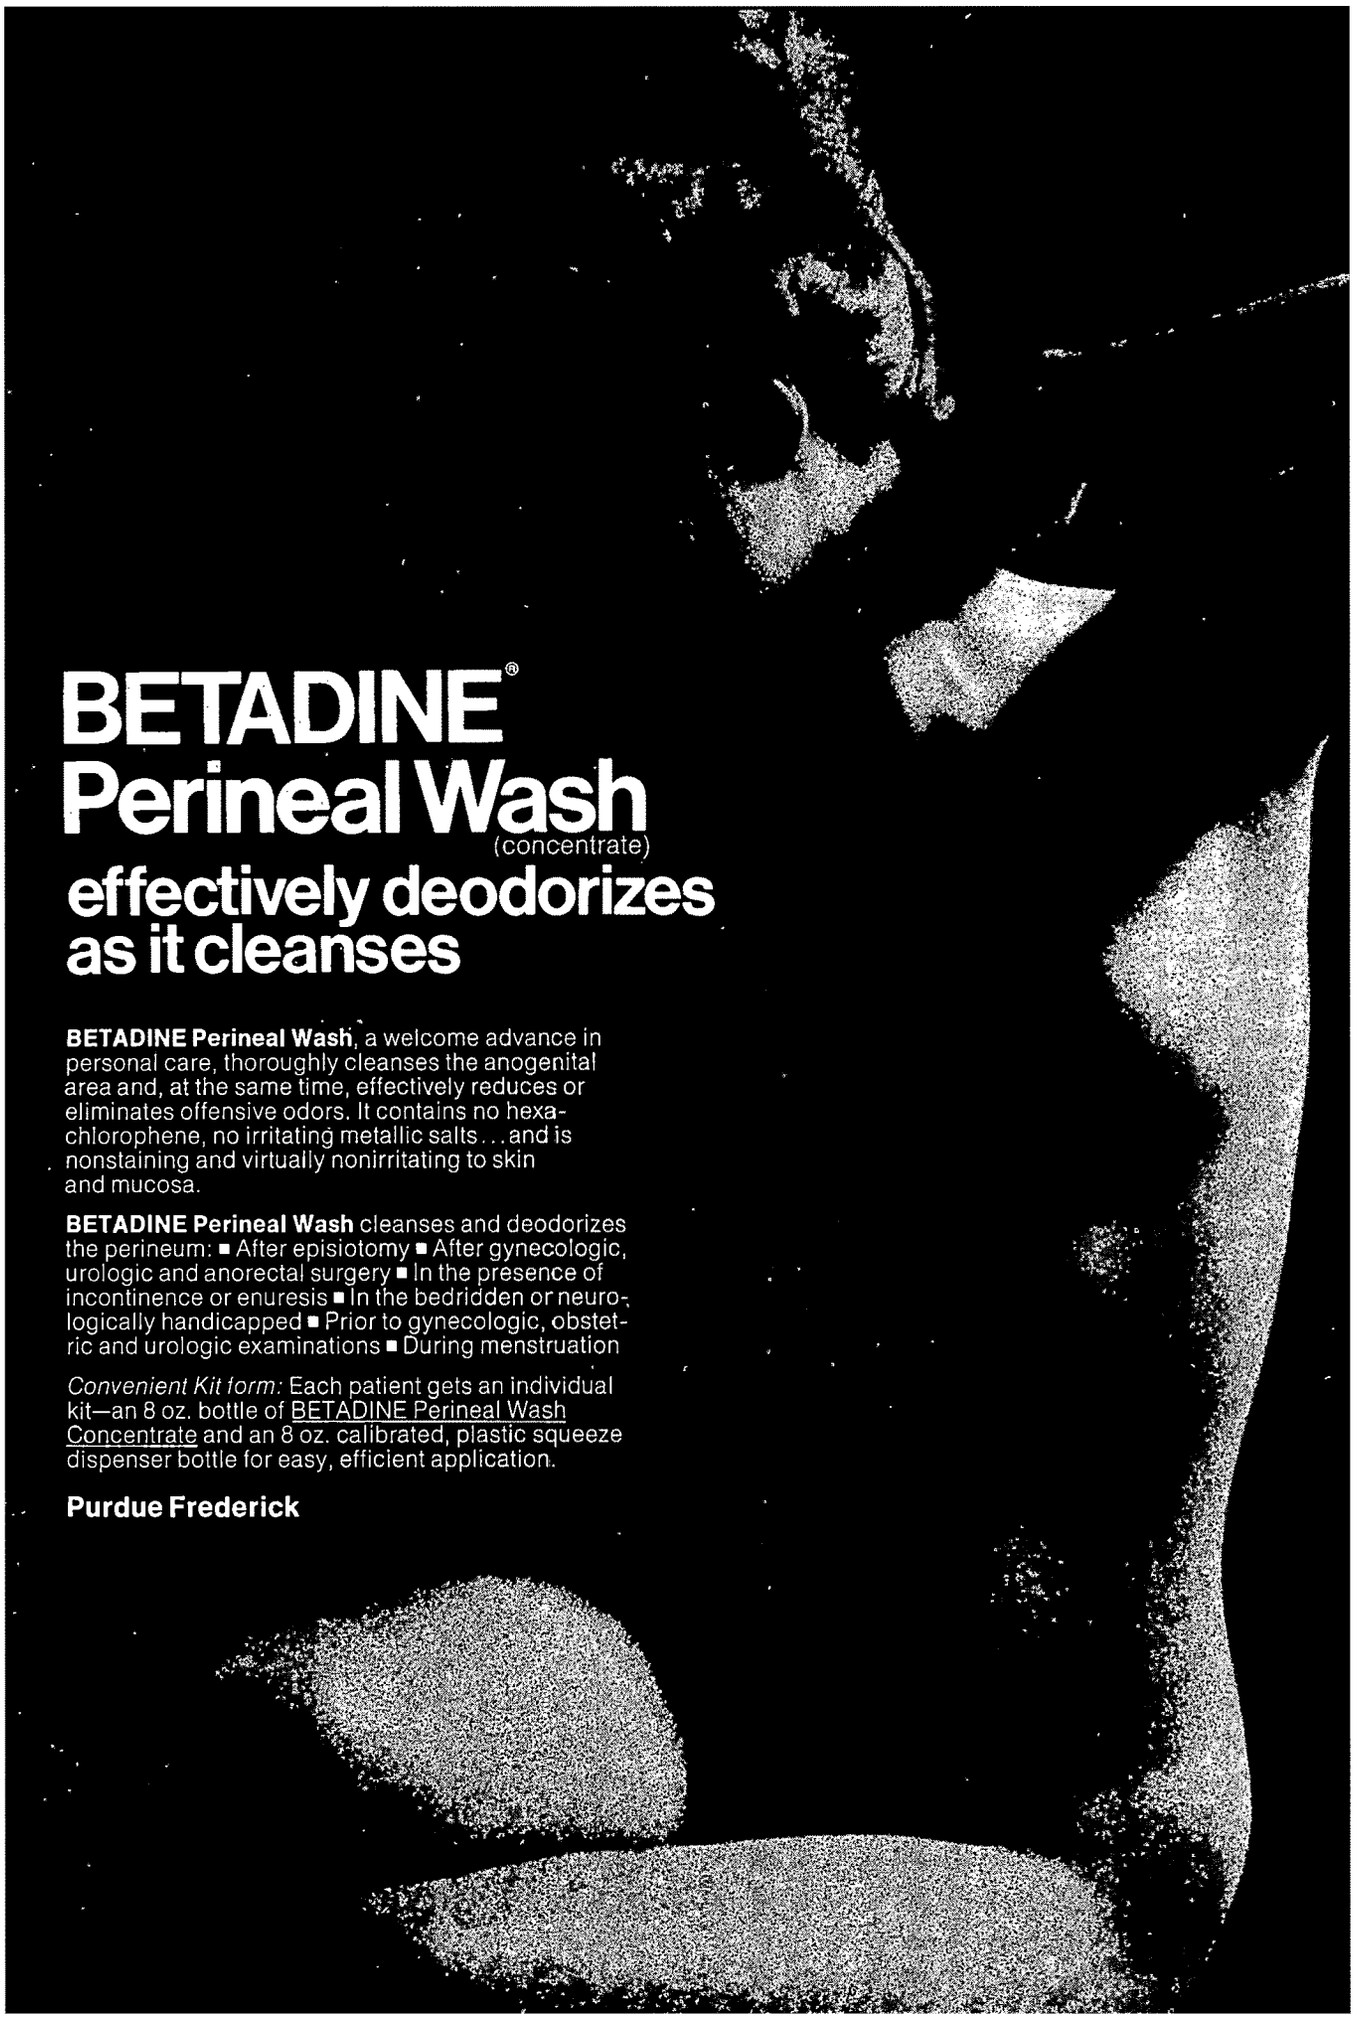
A retrospective evaluation of the conditions which at different times and in different places prompted the abandonment of conservative therapy and the report to surgery is obviously preposterous and will not be pursued. Even in Case 2, where hypothyroidism was proved 9 years after surgery, the assumption that thyroid dysfunction caused the polycystic ovarian disease seems unjustified, as the patient had regular menses for 3 years following operation. It may be relevant, however, to note that, with the exception of Case 7, none of those patients had hirsutism, a prominent sign in the Stein-Leventhal syndrome.

The common features in the present series are extensive periovarian and peritubal adhesions. A stormy postoperative course easily explains their presence in Case 1. All other cases were asymptomatic.

Similar cases have been reported occasionally in the literature. Stein,[5] when reoperating six women for suspected recurrence of the polycystic ovarian disease, found dense peri-ovarian adhesions to omentum and/or bowel in four of them. Kistner[6] was impressed

with the number of patients having recurrent amenorrhea or oligoovulation subsequent to wedge resection in whom extensive peritubal adhesions were demonstrated by culdoscopy. Cohen[7] studied a number of women who had relatively regular, apparently ovulatory cycles after ovarian resection, but remained infertile, and found endoscopic evidence of ovarian adhesions extensive enough to prevent ovulation. Goldzieher[1] assumed that surgical factors may partly explain why fertility is corrected by wedge resection less often than the menstrual rhythm. The increasing use of gynecologic endoscopy, and particularly of laparoscopy, is now proving the important role of pelvic peritoneal adhesions in limiting the success of wedge resection.[7]

The present series of cases shows that the surgical procedure alone may be responsible for the persistence of infertility through a mechanical factor which makes pregnancy virtually impossible. Adequate reconstructive surgery becomes a precondition to successful fertilization in those cases where ovarian resection cured anovulation, and to successful fertilization following induction of ovulation by clomiphene or other agents in those cases where ovarian surgery failed to correct anovulation. This policy has been applied in four of the six cases where reconstructive surgery was possible, with gratifying results.



While it is impossible to establish at present the frequency of periovarian and peritubal adhesions following ovarian resection, it may be safely assumed that they constitute one of the important causes of failure of the surgical procedure to achieve its ends. Laparoscopy is therefore mandatory in the investigation of the unsuccesful results of bilateral ovarian resection. The observation of reversible or irreversible damage wrought by the surgical procedure indirectly supports the plea of Kistner[8] to relegate the surgical approach to a minor position in patients with Stein-Leventhal syndrome. It stresses the importance of meticulous technique in the performance of conservative ovarian surgery during the reproductive age. Patients with pelvic adhesions, impairing ovarian and tubal function, should be offered the benefit of reconstructive surgery.

Fourth Annual Conference on Perinatal Medicine

The Fourth Annual Conference on Perinatal Medicine will be held March 25 and 26, 1976, at Callaway Gardens, Pine Mountain, Georgia. For further information, please contact: Micki L. Souma, M.D., and Louis Levy, M.D., Perinatology Department, The Medical Center, Columbus, Georgia 31901.

BETADINE® Perineal Wash (concentrate) effectively deodorizes as it cleanses

BETADINE Perineal Wash, a welcome advance in personal care, thoroughly cleanses the anogenital area and, at the same time, effectively reduces or eliminates offensive odors. It contains no hexachlorophene, no irritating metallic salts... and is nonstaining and virtually nonirritating to skin and mucosa.

BETADINE Perineal Wash cleanses and deodorizes the perineum: ■ After episiotomy ■ After gynecologic, urologic and anorectal surgery ■ In the presence of incontinence or enuresis ■ In the bedridden or neurologically handicapped ■ Prior to gynecologic, obstetric and urologic examinations ■ During menstruation

Convenient Kit form: Each patient gets an individual kit—an 8 oz. bottle of BETADINE Perineal Wash Concentrate and an 8 oz. calibrated, plastic squeeze dispenser bottle for easy, efficient application.

Purdue Frederick

How these Abbott hematinics meet your pregnant patients' needs

- Each product contains the recommended*800 mcg. of Folic Acid for pregnancy.
- Each product contains 525 mg. of Ferrous Sulfate in controlled-release form to minimize gastric upset—an important consideration in pregnancy.
- Dosage for each product is once-a-day—helps to assure that the busy or forgetful patient complies with your regimen.

*Federal Register, 38:20737, Aug. 2, 1973.

Fero-Folic-500® ℞

Controlled-Release Iron

525 mg. of Ferrous Sulfate (equivalent to 105 mg. elemental iron)

Plus Enhanced Iron Absorption

500 mg. Ascorbic Acid (as sodium ascorbate)

Plus 800 mcg. of Folic Acid

Indications: For the treatment of iron deficiency and prevention of concomitant folic acid deficiency in non-pregnant adults. Also indicated in pregnancy for the prevention and treatment of iron deficiency and to supply a maintenance dosage of folic acid. **Contra-indications:** Pernicious anemia. **Warnings:** Folic acid alone is improper therapy in the treatment of pernicious anemia and other megaloblastic anemias where vitamin B_{12} is deficient. **Precaution:** Where anemia exists, its nature should be established and underlying causes determined. Fero-Folic-500 contains 800 mcg. of folic acid per tablet. Folic acid especially in doses above 1.0 mg. daily may obscure pernicious anemia, in that hematologic remission may occur while neurological manifestations remain progressive. **Adverse Reactions:** The likelihood of gastric intolerance is remote. If such should occur the tablet may be taken after a meal. Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

Gradumet—Controlled-release dose form, Abbott. 503085

Iberet-Folic-500® ℞

Controlled-Release Iron

525 mg. of Ferrous Sulfate (equivalent to 105 mg. elemental iron)

Plus Enhanced Iron Absorption

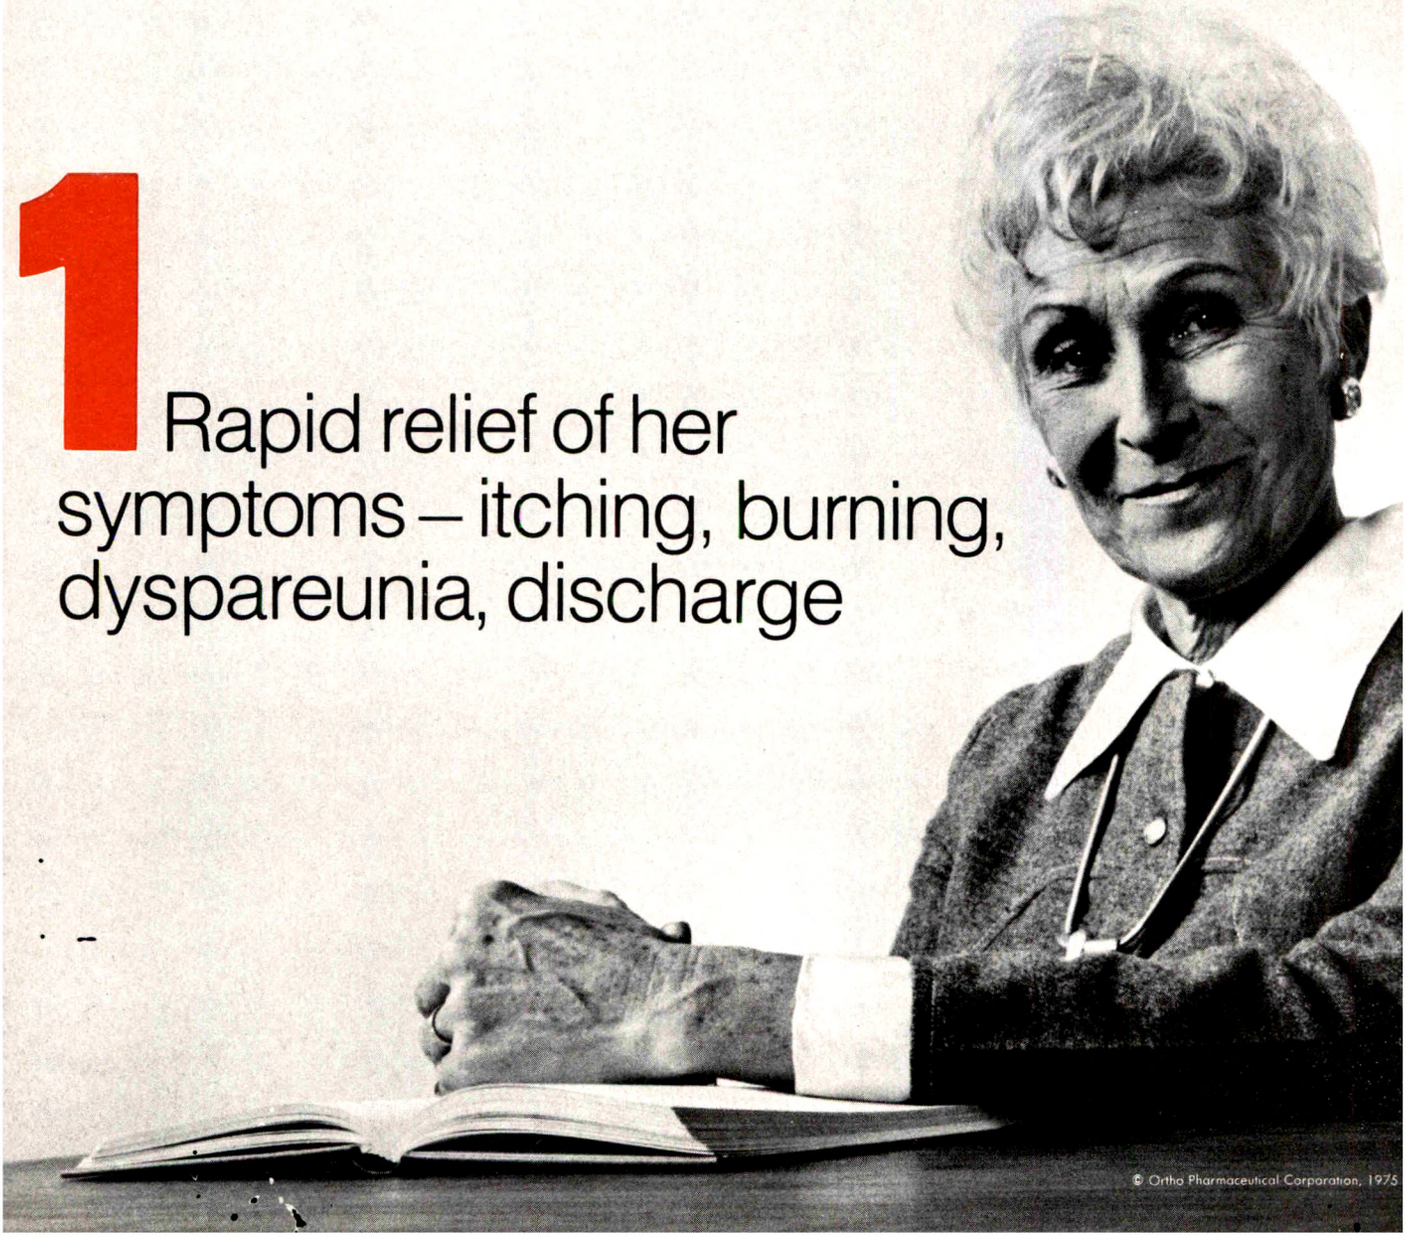
500 mg. Ascorbic Acid (as sodium ascorbate)

Plus the B-Complex

Niacinamide	30 mg.
Calcium Pantothenate	10 mg.
Vitamin B_1 (Thiamine Mononitrate)	6 mg.
Vitamin B_2 (Riboflavin)	6 mg.
Vitamin B_6 (Pyridoxine Hydrochloride)	5 mg.
Vitamin B_{12} (Cyanocobalamin)	25 mcg.

Plus 800 mcg. Folic Acid

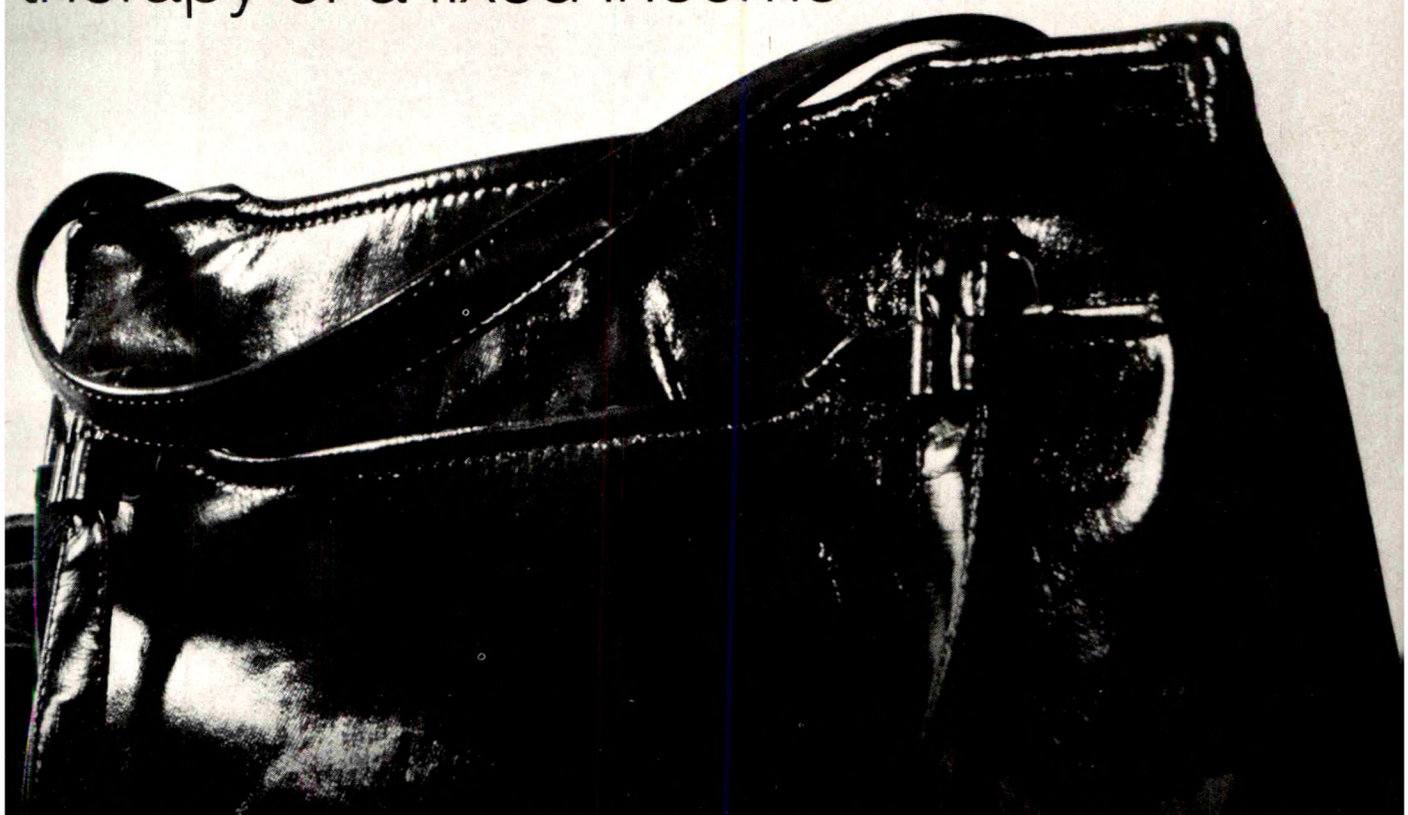
Indications: In non-pregnant adults, for the treatment of iron deficiency and prevention of concomitant folic acid deficiency where there is an associated deficient intake or increased need for the B-complex vitamins. Also indicated in pregnancy for the prevention and treatment of iron deficiency where there is a concomitant deficient intake or increased need for B-complex vitamins (including folic acid). **Contraindication:** Pernicious anemia. **Warnings:** Folic acid alone is improper therapy in the treatment of pernicious anemia and other megaloblastic anemias where vitamin B_{12} is deficient. **Precaution:** Where anemia exists, its nature should be established and underlying causes determined. Iberet-Folic-500 contains 800 mcg. of folic acid per tablet. Folic acid especially in doses above 1.0 mg. daily may obscure pernicious anemia, in that hematologic remission may occur while neurological manifestations remain progressive. **Adverse Reactions:** The likelihood of gastric intolerance is remote. If such should occur, the tablet may be taken after a meal. Allergic sensitization has been reported following both oral and parenteral administration of folic acid.



ABBOTT

Two reasons your atrophic vaginitis patient will really appreciate ORTHO Dienestrol Cream:

TRADEMARK



(dienestrol 0.01%)

1 Rapid relief of her symptoms – itching, burning, dyspareunia, discharge

© Ortho Pharmaceutical Corporation, 1975

2 Provides economical relief of her symptoms that's easy on her pocketbook…an important consideration if she's on long-term maintenance therapy or a fixed income

Indications: Dienestrol Cream is indicated for the treatment of postmenopausal and senile vulvovaginitis, atrophic vaginitis, pruritus vulvae caused by atrophic changes in the vulval epithelium, dyspareunia associated with atrophic vaginal epithelium, and for use prior to plastic pelvic surgery in menopausal cases. *Contraindications:* Malignancies or precarcinomatous lesions of the vagina or vulva. A statistically significant association has been reported between maternal ingestion during pregnancy of diethylstilbestrol and the occurrence of vaginal carcinoma in the offspring. The use of

geners is contraindicated in pregnancy. *Warning:* Vaginal adenosis has been reported in 30% to 90% of postpubertal girls and young women whose mothers received diethylstilbestrol or a closely related congener during pregnancy. This condition was found most frequently in those cases where DES had been given in early pregnancy (first 12 weeks). The significance of this finding with respect to potential for development of vaginal adenocarcinoma is unknown. Periodic examination of such patients is recommended. *Precautions:* In pruritus vulvae due to infectious conditions, the organism

a specific agent. *Dosage:* One or two applicatorsful per day for one or two weeks, then gradually reduced to one-half initial dosage for a similar period. A maintenance dosage of one applicatorful, one to three times a week may be used after restoration of the vaginal mucosa has been achieved. *Supplied:* Available in 2.75 oz. (78 g) tubes with or without ORTHO* Measured-Dose Applicator.

You can change probe tips without changing handle or supply line with our cryosurgical instrument

The OHIO 850. Allows you to use any of the gynecology probes in the treatment of uterine cervix disorders. Because probe tips designed for these diseases are interchangeable.

And if you're in a clinic practice, the instrument can be shared with other specialists. Because it's easy to move from one exam room to another. And OHIO provides probes for most currently used cryosurgical procedures. So compact it won't crowd your exam room. Simple to operate. And you use economical, readily available medical nitrous oxide as your refrigerant. Cool the tip to -85°C in seconds. The more sophisticated OHIO Model 880 is ideal for hospital use or in a large group practice.

For more information, fill out the coupon below and mail it today.

Case of successful excision of the cervix uteri in a scirrhous state

JOHN B. STRACHAN
American Journal of the Medical Sciences, vol. 5, pp. 307-309, 1829

308 Strachan's *Case of Excision of the Cervix Uteri.*

frequently. The debility had continued to such an extent as to confine her to bed, and there was only a slight amendment of her general health, although the loss of blood had not lately been excessive. There was considerable irritation, and frequency of the pulse, which led the reporter to propose an examination to ascertain the state of the uterus, which resulted in discovering extensive scirrhus of the cervix uteri with additional fungous growth. His friend, Dr. John B. Strachan, attended in consultation on the next visit, when amputation was determined on, after a candid statement had been made to the patient. She was brought to Petersburg on the 4th of September.

About 1 o'clock, P. M. September 9th, 1829, Dr. John B. Strachan, whose skill, dexterity, and intrepidity, as a surgeon, are well known in Virginia, proceeded to perform the operation. The patient was placed on a narrow table, which was covered with blankets, her head sufficiently elevated by pillows, and her legs flexed, separated, and well supported by assistants. The operator then introduced his left hand, and seized the diseased part of the uterus, which, without the aid of hooks, was easily drawn down nearly as low as the os externum. The state of extreme relaxation of the parts, facilitated, in a great degree, this part of the operation. At this stage we ascertained the extent of the scirrhus, and Dr. S. with a scalpel readily extirpated the cervix, and about one-third of the body of the uterus. A curved bistoury was tried, but proved greatly inferior to the common scalpel. During the operation a large artery was cut, but the hæmorrhage lasted only a very short time. The hand was again introduced, and satisfied us that the knife had not penetrated any of the adjoining cavities. Common lint was applied to the parts, and the patient removed to bed. It should here be remarked that there was no occasion for the styptic lint and washer which had been prepared in the event of the hæmorrhage being excessive. Immediately after the operation severe uterine pains, resembling labour pains, came on, which at once arrested the hæmorrhage, and were so very violent as to require repeated doses of fifty drops of laudanum before any relief could be procured. A lukewarm infusion of chamomile flowers was directed to be injected in the vagina every six or eight hours. The parts extirpated, on examination, presented all the characters of the hard fibrous texture which usually precede cancerous affections. The fungous growth exhibited a raw, uneven, and rugged appearance at its anterior extremity.

10*th*.—The patient more composed, but complaining still of uterine pains, and a sense of soreness in the lower part of her belly, which, however, was not attended with any distention. Pulse feeble

Prior to the advent of cellular pathology, the classification of cervical malignancy was hopelessly confused. Treatment of this condition consisted of purging, venesection, leeches applied to the cervix, and other equally ineffective remedies. Amputation of the cervix gained some popularity as it occasionally met with success. Strachan, of Virginia, first successfully amputated the cervix in America. The patient, age 33, had been treated intermittently for 9 months for vaginal bleeding. Following operation (see figure) the patient developed severe pelvic pain and apparently infection, attended by temperature and rapid pulse. However, within five weeks, the wound was healed and the patient returned home.

CURRENT DEVELOPMENTS

Vaginal agenesis

VINCENT J. CAPRARO, M.D., F.A.C.O.G.
MARCOS B. GALLEGO, M.D.
Buffalo, New York

Vaginal agenesis is not rare. Many ingenious procedures have been devised for its correction; some are simple, and some are complicated. Not enough emphasis has been placed on the emotional aspects when patients with this problem are treated. Proper timing of the operation and selection of the best procedure are discussed. We feel the procedure of choice is the simplest, least dangerous one which will give good results in the individual patient. Rather than using the same routine procedure in each patient, we fitted the treatment to each patient. Our experience, particularly with the simple vulvovaginoplasty technique, is given. Postoperative support and encouragement are needed to have a successful outcome.

VAGINAL AGENESIS was first described in 1572 by Realdus Columbus.[1, 2] It is said to occur once in 4,000 to 5,000 women.[1, 3, 4]

Through the years, numerous ingenious techniques have been devised to treat this anomaly. Perhaps not enough emphasis has been given to the patient and her emotional status.

Material and methods

This report covers our experience, attitudes, and management techniques as they have evolved with the last 50 patients referred to this service for the creation of a neovagina. The distribution of patients (Table I) is as would be expected in a pediatric and adolescent gynecology service, i.e., there is a larger proportion of patients with intersex problems than seen in the usual gynecology service.

Some of these patients at this writing have had definitive treatment; others are waiting until we feel the proper time has arrived. While these youngsters are growing up, they are not simply waiting in a vacuum. We see the children and their families regularly for counseling and emotional support.

From the Department of Gynecology-Obstetrics, School of Medicine, State University of New York at Buffalo, and the Division of Pediatric-Adolescent Gynecology, Buffalo Children's Hospital.

Reprint requests: Dr. Vincent J. Capraro, 130 Hodge Ave., Buffalo, New York 14222.

The patient: emotional aspects and time of operation

Most important in the preoperative evaluation is assessment of the patient's emotional status and, indeed, that of the family also. Most patients can be properly handled by the gynecologist without need for psychiatric referral.

We stress the positive with emphasis on the normal—normal breasts, normal hormone production, normal pituitary, normal ovaries, normal sex hair, etc. We point out that the patient *can* marry and *can* have normal sexual relations with normal orgasm. She *can* have children. She will adopt her children, as will one of six married couples.

These patients, while not needing psychiatric care, do need emotional support, guidance, assurance, and tender loving care from the gynecologist. This, we feel very strongly, is part and parcel of the management of

Table I. Vaginal agenesis: distribution of 50 patients

Classification	*No. of patients*
Genetically normal female, vaginal agenesis only	13
Genetically normal female, vaginal agenesis with other congenital anomalies	17
Intersex patients, 4 with testicular feminization syndrome and 10 male hermaphrodites	20
Total	50

the patient with vaginal agenesis. To be simply a technician is not enough. One must be a keen technician and also a sensitive physician to help the patient over the emotional hurdles. It is also necessary that other members of the family be informed of the situation and what to expect.

It has been our observation that the patient with vaginal agenesis does not feel that she is a whole woman. She will not compete for dates with her peers for the eligible men in the community. She feels that she cannot develop an honest close relationship with a man.

Since she lacks the organ (vagina) which will permit her to be a complete woman, she feels she is deceiving the men she dates. Therefore, she avoids the conflict by not dating. In discussing this with behavioral scientists, we have learned that they have made similar observations.

We perform the operation when the patient feels that she wants the neovagina and when we are convinced that she will cooperate with the use of dilators postoperatively. If she is not ready to cooperate, the operation is doomed to failure because of atresia of the new vaginal canal. Operation should not be performed before the patient reaches full body size because the artificial vagina will not grow with the patient.

Some advocate that a definitive operation should be performed shortly before the patient is to be married. We prefer not to postpone the operation until shortly before marriage because at times the results are poor. If infection takes place or if constriction occurs, it may be necessary to postpone the wedding. This is an emotional catastrophe for the couple and a social catastrophe for the families.

In these 50 patients, there were one failure and one poor result because of inaccurate evaluation of the emotional status of the patient preoperatively. One patient had the McIndoe operation performed by a competent gynecologist in another city. We saw her one year later with no evident vaginal canal and much scar tissue. She had simply not cooperated postoperatively with the use of dilators because she "didn't feel like it." In her case, we performed a second operation with a large bowel transplant which will not obliterate if the patient does not cooperate.

Another of our patients who was 17 years old had a less than satisfactory result following the McIndoe operation because she would cooperate on an "off and on" basis. The vagina is not of adequate depth, and there is much scar tissue in the vault.

Which patients need vaginoplasty?

Patients with congenital vaginal agenesis will fall into one of the following categories: (1) the subject who is genetically female and normal except for vaginal agenesis (with or without a functioning uterus); (2) the subject who is genetically female with vaginal agenesis (with or without a functioning uterus) and other anomalies in the skeletal system, urinary tract, or bowel, etc.; (3) the intersex patient—the true hermaphrodite or the male hermaphrodite of either the masculinizing or feminizing type.

Other patients needing vaginal construction are those not having a functioning vagina secondary to cancer therapy—either surgical or radiation.

In addition, a new group of patients, the transsexuals, in some cases need vaginoplasty.

Diagnosis of vaginal agenesis

In the absence of functioning endometrial tissue, the most common complaint is primary amenorrhea, and most of our patients present in their teens with this complaint. Those seen later will also complain of inability to have satisfactory coitus.

If the patient has a functioning uterus, she will probably present at menarche with an acute picture of hematometra with pain and mass in the lower abdomen. If the upper portion of the vagina is present, she will also have hematocolpos.

The diagnosis of vaginal agenesis is extremely simple and can be made by examination of the patient. The usual findings are those of a normal vulva with normal labia majora, labia minora, urethra, and clitoris. There may be a shallow dimple measuring 1 or 2 cm. but no additional vaginal canal. This dimple represents the attempt of the urogenital sinus to form the lower vagina. Agenesis of the upper four fifths of the vagina results from failure of normal Müllerian duct development.

After examination of the vulva, rectal examination will usually confirm that there is no palpable uterus or cervix in most cases.

The classic vaginal agenesis patient with the so-called Rokitansky-Küster-Hauser Syndrome has no functioning uterus. Instead there are bilateral noncanalized muscular (myometrial) buds, normal tubes, normal round ligaments, and normal ovaries.

The rest of the physical examination usually shows normal breast development and normal sex hair, i.e., normal secondary sexual characteristics.

There are a number of conditions which may appear to be congenital absence of the vagina. These include adhesions of the labia minora,[5] the imperforate hymen, the microperforate hymen,[6] and labioscrotal fusion as seen in the adrenogenital syndrome and other forms of intersexuality.

If the hymen is imperforate, it may be noted to bulge shortly after birth from mucocolpos[7, 8] or at puberty from hematocolpos.

In the delivery room, if there is any question, it is easy to ascertain the presence of a vagina by inserting a lubricated catheter into the vaginal canal. This is not done routinely. Another simple way of confirming the presence of a vagina—at least the lower portion of the vagina—is to grasp the labia on both sides between the thumb and index finger and to gently pull the labia away from the patient toward the examiner while simultaneously spreading them laterally.[9]

This will expose and stretch the hymenal opening, and through it one can see the lower vaginal canal and mucosa. To be positive that there are an upper vagina and cervix, one must resort to vaginoscopy. This need be done only in a few selected cases.

The extent of the preoperative evaluation

After a thorough history and physical examination, two procedures are indicated. One is an intravenous pyelogram. A high percentage of patients with vaginal agenesis also have urinary tract anomalies such as absence of one kidney, horseshoe kidney, pelvic kidney, or duplicate collecting systems. Our studies have shown that 50 per cent of our patients with vaginal agenesis have a urinary tract anomaly.

Although not routinely done by us, spinal x-rays may reveal vertebral anomalies.[10–12]

A buccal smear or perferably chromosome studies are indicated to prove a normal female genetic status, that is sex chromatin positive and 46,XX chromosome pattern.[13–15]

Exploratory laparotomy or laparoscopy is not necessary in a genetically normal female subject if there is nothing to suggest a functioning uterus.

Before a definitive operation, the gynecologist must assure himself that the patient will cooperate with the use of vaginal dilators and molds postoperatively, or the result may be failure. This is the single most important aspect of the preoperative evaluation of the patient with vaginal agenesis.

Techniques currently in vogue

A number of ingenious procedures have been devised to treat this problem. Each has its advantages and disadvantages. One must evaluate each patient individually and use the simplest technique which will give good results in the particular patient involved. In other words, the procedure is chosen that best suits the individual patient.

The Frank nonoperative technique (Fig. 1). This depends on the use of dilators to make a channel by pressure between the bladder and rectum. In some highly motivated patients, this works well.[16] Indeed, cases are reported of formation of a neovagina by coitus alone.[17] Our experience has been that success is more likely in those patients who have a vaginal dimple of 3 or 4 cm. Without an appreciable dimple, the results with the Frank nonoperative technique are not good in our patients.

The Wharton technique (Fig. 2). A new vaginal space is dissected between the bladder and the rectum. A mold is placed into this space, and epithelialization should take place. This epithelialization takes a long period of time, and frequently there is considerable scarring high in the vault.

The McIndoe procedure[18] (Fig. 2). This is begun as in the Wharton operation. A split-thickness skin graft is taken from the buttock or thigh, placed over a stent, and inserted into the neovaginal canal to serve as a lining. This operation takes considerable time to perform and a long period of hospitalization. There is considerable risk of injury to bladder and rectum. Sometimes there is poor take of the graft, especially if infection takes place. Dilators must be used faithfully until regular coitus occurs, or the neovagina will constrict and become obliterated.

Procedures with the use of the bowel.[19-21] Other procedures involve transplantation of segments of small or large bowel. We feel that these bowel transplants are contraindicated except where other procedures have failed. It does not seem appropriate to increase the risk with bowel surgery until other simple methods have failed.

Procedure with the use of peritoneum. A technique has been described in which a neovagina is created and then lined with peritoneum.[22] With simpler vulvovaginoplasty procedures now available, it appears an unnecessary risk to enter the peritoneal cavity.

Transplant of vagina.[23] This has been reported from mother to daughter in Greece. It seems unneces-

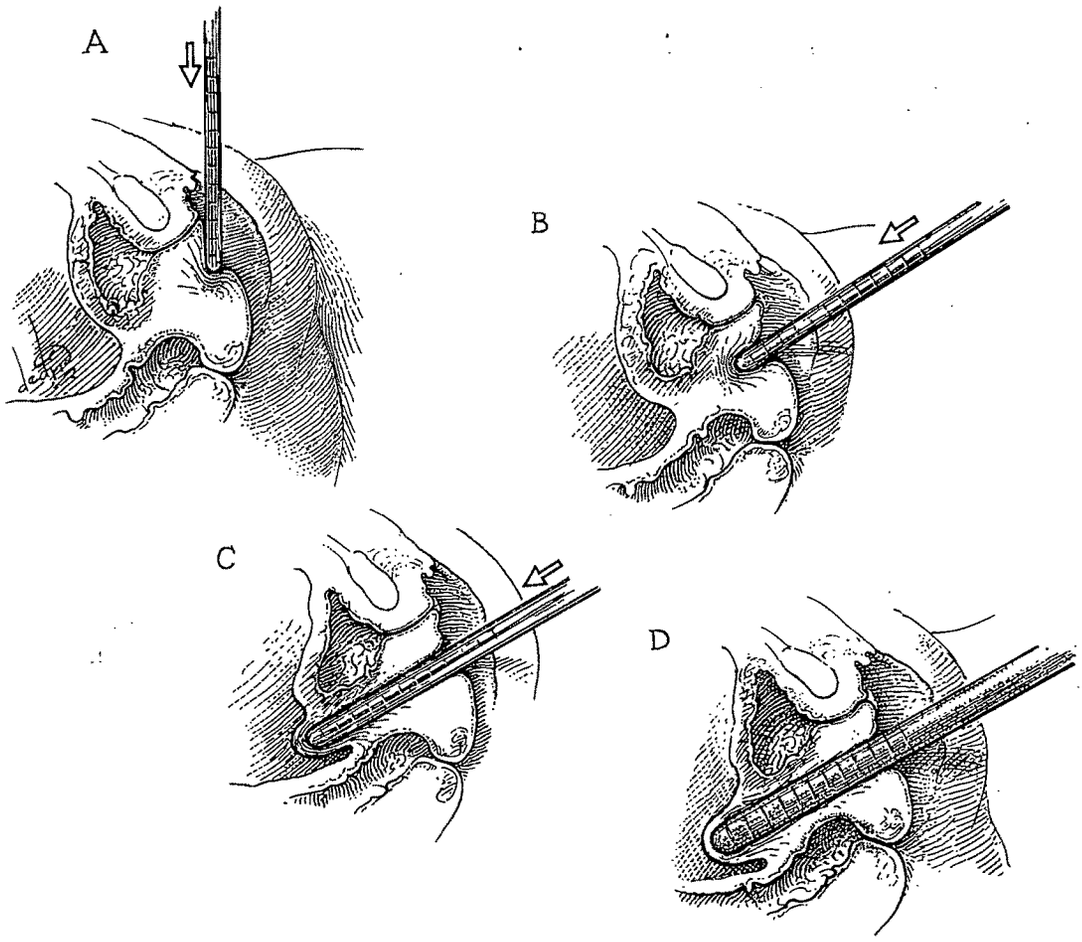

Fig. 1. Frank nonoperative technique of creating an artificial vagina. Dilators of increasing caliber are used to create an artificial channel by means of pressure. Note that in *A* the smallest dilator is directed posteriorly in order to avoid the urethra. After a short channel has been created, the dilators are then directed cephalad *(B, C,* and *D)* with longer and larger dilators. (Reprinted from the author's Chapter 39, Volume II, *Gynecology and Obstetrics,* by permission of the Medical Department, Harper & Row, Publishers, Inc., Hagerstown, Maryland.)

sary to place the patient at risk from immunosuppressive drugs when there are simpler and less risky alternative procedures available for vaginal reconstruction.

The Williams[24] vulvovaginoplasty technique. This involves use of the tissues of the labia. We first learned of this procedure in 1967 from Professor C. J. Dewhurst of London. Professor Williams[24] had first reported this in 1964 in patients where vaginectomy had been performed for malignancy. Our modification of this technique is described in Figs. 3 to 7.

The Buffalo modification of the Williams vulvovaginoplasty.

Our modification[25, 26] includes the following:

1. The incision begins at the level of the urethra or below. This permits free egress of urine and avoids the "cesspool" effect of stagnant urine trapped in the neovagina as might occur in the original technique.

2. The visual appearance of vulva is more "normal." The new "perineum" does not cover the urethra, and the normal anatomy of the upper labia minora and clitoris is preserved.

3. The "touch picture" of the vulva is more "normal" for the reasons already given.

4. With the more median placement of our incision, the hair-bearing skin of the labia majora is not part of the wall of the neovagina.

Why does this operation work?

In our experience, the Frank nonoperative technique is successful only where the patient has some vaginal canal (3 to 4 cm.) to begin with. The neovagina

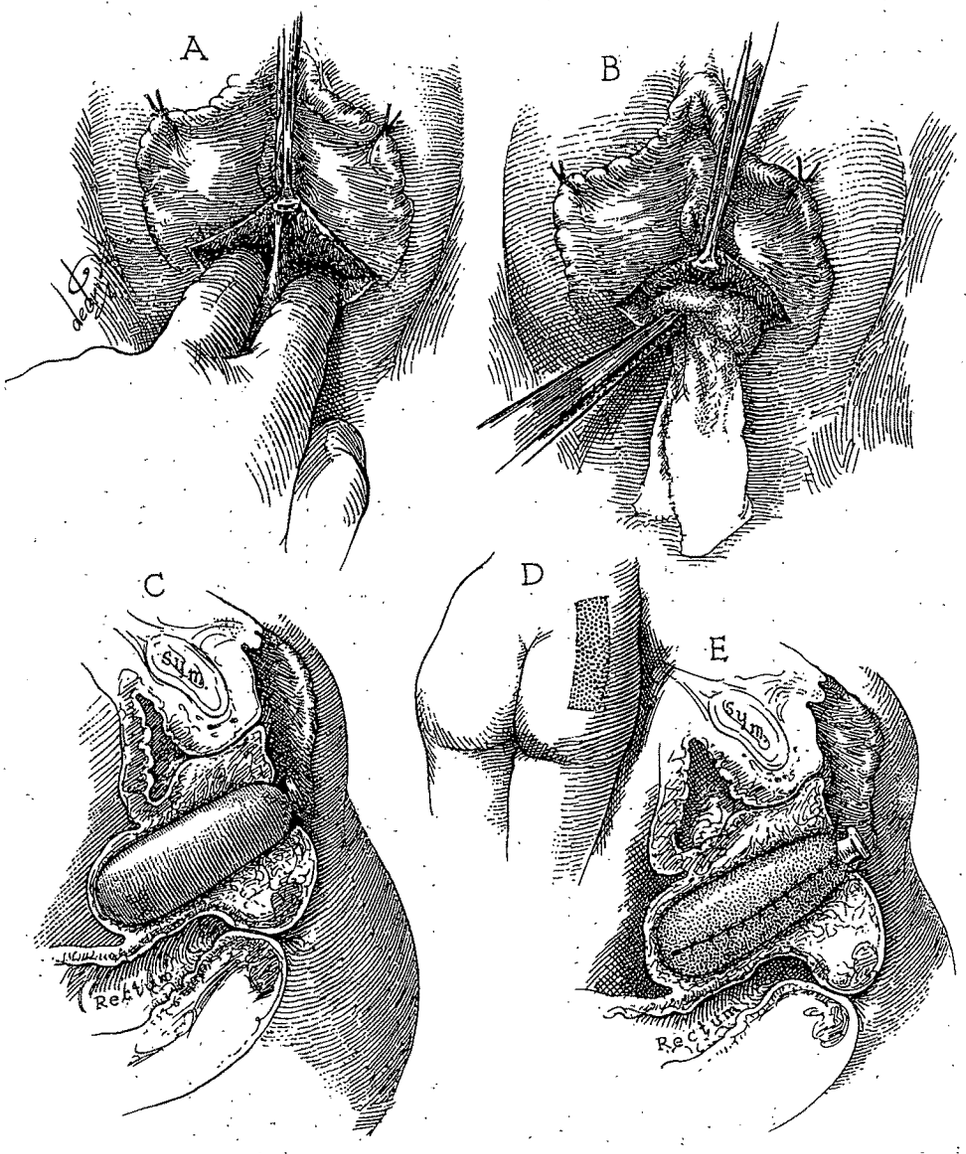

Fig. 2. Wharton technique and McIndoe technique of vaginoplasty. In both of these operative techniques, an artificial channel is developed between the bladder and rectum. *A,* Dissection is more easily carried out on both sides of the midline in loose adventitia-type tissue by blunt finger dissection. The adherent fibrous midline tissue, which is probably noncanalized Müllerian duct remnants, is then cut off with the scissors. *B,* Repeated packing of the canal with wet gauze aids in enlarging the cavity and in controlling fine capillary bleeding. *C,* Insertion of a vaginal mold completes the Wharton operation. The vaginal mold keeps the canal patent while spontaneous epithelialization occurs slowly. *D* and *E,* Completion of the McIndoe operation. *D,* The donor site for a split-skin graft. It is taken from the buttock so that it may be covered in a bathing suit and also because the patient cannot easily see it to be constantly reminded of her defect. *E,* A mold covered with a split-skin graft placed in the new vaginal canal for immediate epithelialization completes the McIndoe vaginoplasty. (Reprinted from the author's Chapter 39, Volume II, *Gynecology and Obstetrics,* by permission of the Medical Department, Harper & Row, Publishers, Inc., Hagerstown, Maryland.)

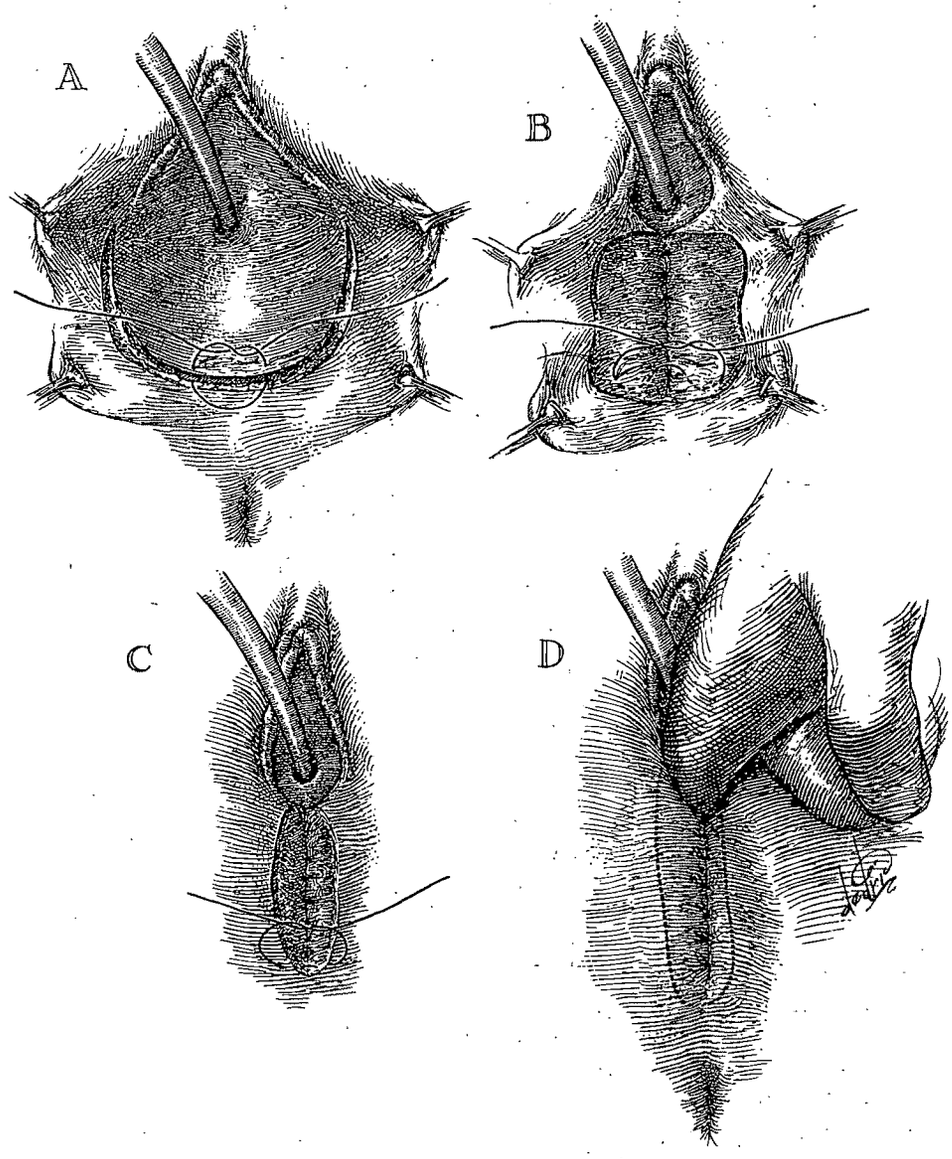

Fig. 3. *A,* The vulvar tissues are put under tension by four properly placed Allis clamps. A U-shaped incision in the skin of the medial aspects of the labia majora begins at the level of the urethra or lower, about 4 cm. lateral to the urethra. The closure of the first layer of skin begins posteriorly and proceeds anteriorly. Interrupted sutures of 3-0 chromic catgut on an atraumatic needle are tied so that the knots are placed in the new vaginal cavity rather than buried in the tissue. *B,* Closure of the second skin layer brings the subcutaneous tissue together in the midline with interrupted 3-0 catgut sutures. *C,* Closure of the third layer approximates skin and subcutaneous tissue with interrupted 3-0 or 4-0 chromic catgut sutures. *D,* The index finger is easily admitted into the neovagina. Axis of the neovagina is perpendicular to the floor immediately after operation. (Reprinted from the author's Chapter 39, Volume II, *Gynecology and Obstetrics,* by permission of the Medical Department, Harper & Row, Publishers, Inc., Hagerstown, Maryland.)

obtained by our method is smaller in caliber and depth than one obtained with the Williams method but has less distortion of "perineal tissues." The patient can easily lengthen and dilate the neovagina and change its axis by using test tubes (Figs. 5, 6, and 7) and later by active coitus. In this operation we construct a small neovagina "outward." Although this resembles a "kangaroo pouch," it does give the patient something to work with in order to develop the neovagina "inward." Normal depth, caliber, and axis (Fig. 6) have been easily achieved with dilators (Fig. 7) first and then coitus by 100 per cent of our patients.

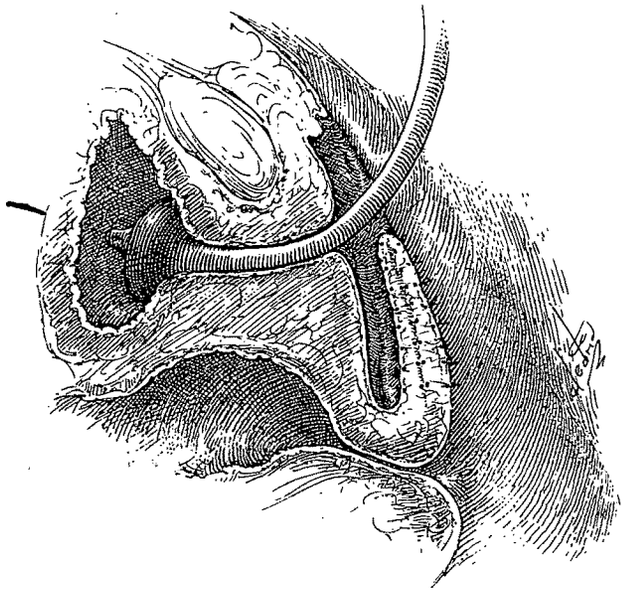

Fig. 4. Sagittal view shows direction of neovagina immediately after operation. Patients have not had any difficulty voiding. (Reprinted from the author's Chapter 39, Volume II, *Gynecology and Obstetrics,* by permission of the Medical Department, Harper & Row, Publishers, Inc., Hagerstown, Maryland.)

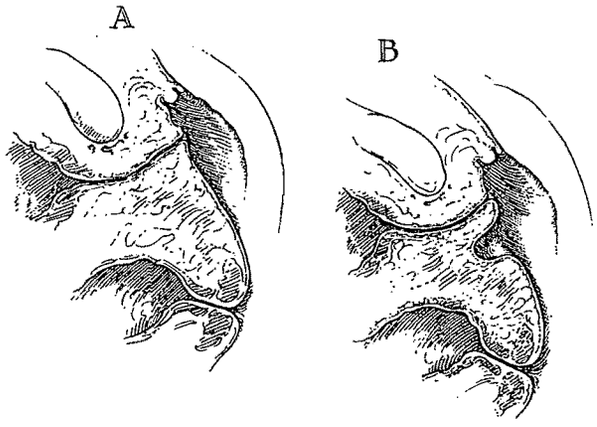

Fig. 5, *A* and *B*. *A,* Patient with no vaginal dimple. Frank nonoperative technique usually fails. *B,* Patient with vaginal "dimple" of at least 3 or 4 cm. is more likely to have good results with Frank nonoperative technique.

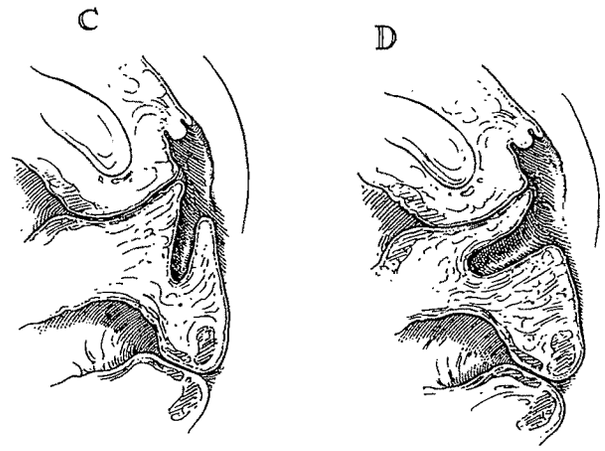

Fig. 5, *C* and *D*. *C,* Neovagina constructed "outward" with vulvovaginoplasty technique. This gives the patient something to work with. *D,* Neovagina of normal depth, caliber, and axis after use of dilators and then coitus.

Advantages of vulvovaginoplasty

The advantages of this vulvovaginoplasty technique for creating a neovagina are numerous:

1. The time of operation is reduced to minutes rather than hours—30 minutes average time for vulvovaginoplasty compared to 2½ hours for the McIndoe procedure.

2. The time of hospitalization is drastically reduced from weeks to days.

3. The risk of injuries to the urethra, bladder, or rectum is almost nil as compared to that with the other procedures.

4. The blood loss is minimal—only a few milliliters.

5. Eliminating all evidence and reminders of the anomaly is important in these young patients. With our procedure, there no visible abdominal scar (which occurs with bowel procedures) and no scarred skin donor site (which occurs with the McIndoe procedure).

6. There is no need for additional anesthesia to remove or change the vaginal mold as in the other operations.

7. It is possible to use the neovagina within a few weeks for coitus rather than having to wait months.

8. If the patient does not use the dilators, the neovagina will not constrict down as it does in the skin graft technique. It will remain patent because it is lined with normal mucosa. Dilatation at a future date will reconstitute its desired size.

9. Another important advantage of this procedure is that the patient does not have an artificial vagina. She has a neovagina which is made from her own vulvar tissues and not from a graft taken from the buttock. This psychological boost to the patient's ego and self-image is an important aspect.

Postoperative management with vulvovaginoplasty

An indwelling silicone rubber Foley catheter is inserted at operation and is removed in four or five

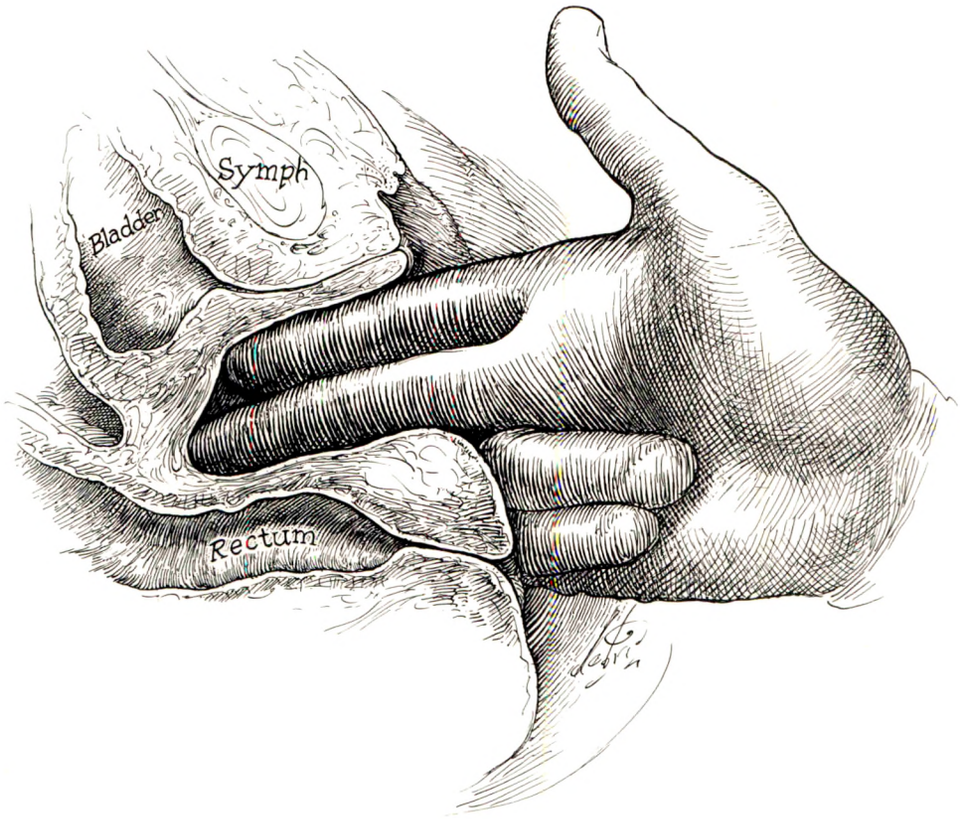

Fig. 6. Sagittal view after use of graded dilators and after sexual intercourse. The axis, depth, and caliber of the neovagina are found to be normal on digital vaginal examination.

days. Prophylactic postoperative antibiotics are given. Perineal care consists of soap and water washing plus use of a dry heat lamp. On the fourth or fifth day, we instruct the patient in the use of graded dilators, after which she is discharged. An important aspect of this procedure is close supervision of the patient to be sure she is using the dilators correctly and regularly.

Within a few weeks, the neovagina shows a normal axis and is of adequate depth and caliber (Fig. 6).

Results with the various techniques

Table II shows the techniques used in managing our last 50 patients with vaginal agenesis. Our results are listed below.

Frank nonoperative technique. Of the nine patients in whom the Frank nonoperative technique was used, all nine had adequate follow-up. Eight showed a good anatomic result, and in one the vaginal canal was not deep enough. Seven of the patients had coitus, which six stated was satisfactory and one stated was unsatisfactory. Three of the patients at this point have not had coitus.

Table II. Vaginal agenesis: Management of 50 patients

Type of procedure	*Operation performed*	*Operation contemplated at proper age*
Frank nonoperative	9	0
Wharton	3	0
McIndoe	7	10
Bowel transplant	2	0
Vulvovaginoplasty	13	2
To be determined	–	4
Total	34	16

Wharton technique. Of the three patients in whom this technique was used, two had adequate follow-up. One showed a good anatomic result, and one showed a poor anatomic result. Both of the patients who were followed had coitus, and both stated it was satisfactory.

McIndoe technique. All seven patients on whom the McIndoe operation was performed had adequate follow-up. The anatomic results were judged to be good in six of the patients and not satisfactory in one

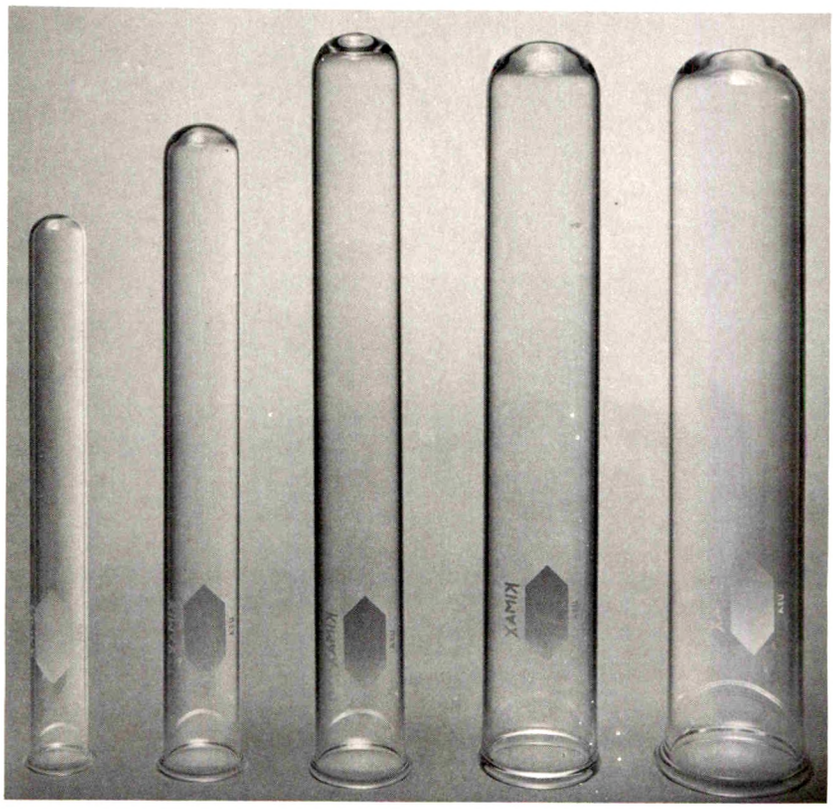

Fig. 7. Graded test tubes (outside diameter 1.8 to 3.7 cm.) used postoperatively as dilators by patient.

patient. Six of these patients reported having had coitus, and it was satisfactory in all six. One of the patients to this date has not had coitus.

Bowel transplant technique. The bowel transplant technique was used in two patients, both of whom had adequate follow-up. The anatomic result was good in both patients. Both patients have experienced coitus, which was described as satisfactory in one and not satisfactory in the other who complained of dyspareunia. This was corrected by the use of dilators.

Vulvovaginoplasty technique. Of the 13 patients in whom our modified vulvovaginoplasty technique was carried out, 12 had adequate follow-up. In 11 of these patients, the anatomic result was judged good on pelvic examination. In one patient the anatomic result was good insofar as depth and caliber of vagina. However, there was a slight breakdown in the lower portion of the sling which resulted from a local infection. Although we judged this a poor anatomic result, this patient has married and is having satisfactory coitus. Eight of the patients with this vulvovaginoplasty technique have experienced coitus, and all eight described this as satisfactory. Four of the patients with follow-up have not had coitus at the time of this writing.

The postoperative psychological status was good in all of the patients treated except for the two described previously.

Comment

An important aspect of management of the patient needing construction of a neovagina is recognition of the emotional problems involved. The timing of the operation is dependent on the patient's reaching full body size and on her willingness to cooperate postoperatively to prevent atresia of the neovagina.

At the present time, our choice of procedure depends on the anatomic findings. If the patient has an adequate "vaginal dimple" of 3 to 4 cm., the Frank nonoperative technique is tried first and generally succeeds. If it does not succeed, we then choose an operative method.

If the vulva appears normal with "good" labia, the vulvovaginoplasty as modified by us is our first choice. In the past four years, in genetically female subjects with normal labia, we have used this procedure exclusively.

If the vulvar anatomy is such that the labial structure is not present, as in some patients with intersex problems, we will choose the McIndoe operation with the use of a split-skin graft.

If any of these methods fail, we will then resort to a bowel transplant procedure. In other words, we use the simplest procedures first and reserve the more complicated and hazardous methods for when the other methods fail.

Roster of American obstetrical and gynecological societies*

(Appears annually in the January 1 issue)

American Gynecological Society. (1876) *President,* Gordon W. Douglas. *Secretary,* J. George Moore, Dept. Ob-Gyn, UCLA School of Medicine, Los Angeles, Calif. 90024. Meetings, restricted.

The American Association of Obstetricians and Gynecologists. (1888) *President,* Keith Russell. *Secretary,* George W. Mitchell, Jr., 171 Harrison Ave., Boston, Mass. 02111. Meeting (Mid-year), April 15-17, 1976. Meeting (Annual), Sept. 9-11, 1976.

The Central Association of Obstetricians and Gynecologists. (1929) *President,* Raymond H. Kaufman. *Secretary,* David G. Anderson, Women's Hospital, University of Michigan Medical Center, Ann Arbor, Mich. 48104. Meetings, Oct. 14-16, 1976.

The South Atlantic Association of Obstetricians and Gynecologists. (1938) *President,* O. Hunter Jones. *Secretary,* William H. Kirkley, 2000 S. Andrews Ave., Ft. Lauderdale, Fla. 33316. Meetings, Jan. 24-29, 1976.

Pacific Coast Obstetrical and Gynecological Society. (1931) *President,* Carl Goetsch. *Secretary,* Leon J. Shulman, 2200 Santa Monica Blvd., Santa Monica, Calif. 90404. Meetings, Nov. 7-13, 1976.

Akron Obstetrical and Gynecological Society. (1934)

Atlanta Obstetrical and Gynecological Society. (1953) *President,* Thomas A. Harris. *Secretary,* Hugo S. Moreno, 2739 Felton Dr., East Point, Ga. 30344. Meetings, Jan. 6, March 5, and May 7, 1976.

Bronx Gynecological and Obstetrical Society. (1924)

Brooklyn Gynecological Society, Inc. (1890) *President,* Aldo C. Scorza. *Secretary,* Norman Ames Posner, 4802- 10th Ave., Brooklyn, N. Y. 11219. Meeting,

Buffalo Gynecologic and Obstetric Society. (1945) *President,* David H. Nichols, *Secretary,* M. M. Hreshchyshyn, 100 High St., Buffalo, N. Y. 14203. Meetings, second Tuesday, Sept.-April, 1976.

*Changes, omissions, and corrections must be received by the publisher two months in advance (by November 1) for the Roster. Please address the Journal Editing Department, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63141. The number after the Society's name is the year of founding. For further information, address the respective secretaries.

The American College of Obstetricians and Gynecologists. (1951) *President,* Roy T. Parker. *Secretary,* Martin L. Stone, New York Medical College, 1249 Fifth Ave., New York, N. Y. 10029. Meetings, May 10-13, 1976.

Section on Obstetrics and Gynecology, American Medical Association. (1859) *President,* John R. McCain. *Secretary,* Van R. Jenkins, Larkin Professional Building, 2505 Larkin Road, Lexington, Ky. 40503. Meeting, annual.

Society of Obstetricians and Gynaecologists of Canada. (1945) *President,* Lise Fortier. *Secretary,* John C. G. Whetham, 367 Lytton Blvd., Toronto, Ontario M5N 1R9. Meeting, June 8-12, 1976.

American Board of Obstetrics and Gynecology, Inc. (1930) *President,* J. George Moore. *Secretary,* Clyde L. Randall, 200 West Cold Spring Lane, Baltimore, Md. 21210. Meetings, June 22-23 and Nov. 5-12, 1976.

Chicago Gynecological Society. (1878) *President,* Lester D. Odell. *Secretary,* Robert E. Lane, 333 East Superior St., Chicago, Ill. 60611. Meetings, third Friday, except Dec., July, Aug., and Sept.

Cincinnati Obstetrical and Gynecological Society. (1876) *President,* Paul Haas. *Secretary,* Harold Johnstone, Bethesda Hospital, Oak & Reading Rd., Cincinnati, Ohio 45206. Meetings, third Thursday, each month.

Cleveland Society of Obstetricians & Gynecologists. (1947)

The Colorado Gynecological and Obstetrical Society.

Columbus Obstetric-Gynecologic Society. (1944)

Connecticut Society of American Board Obstetricians and Gynecologists, Inc. (1952) *President,* Peter Goodhue. *Secretary,* Philip C. Dennen, 134 Grandview Ave., Suite 203, Waterbury, Conn. 06708. Meetings, May and Dec.

Dallas-Fort Worth Obstetric and Gynecologic Society. (1933) *President,* Robert B. Brunken. *Secretary,* E. E. Harrison, 202-B, Lake Highlands Village, Dallas, Texas 75218. Meetings, third Tuesday, April and Oct.

Dayton Obstetrical and Gynecological Society. (1932)

Georgia State Obstetrical and Gynecological Society. (1951) *President,* John S. Inman. *Secretary,* Armand Hendee, 69 Butler St., S.E., Atlanta, Ga. 30703. Meetings, March and Dec., 1976.

Honolulu Obstetrical and Gynecological Society. (1947) *President,* Gail Li. *Secretary,* Theodore Tseu, 1523 Kalakaua Ave., Honolulu, Hawaii 96814. Meetings, variable date.

Idaho Obstetrical and Gynecological Society. (1955) *President,* Max D. Gudmundsen. *Secretary,* Dean T. Watkins, 148 E. Jefferson, Boise, Idaho 83702. Meeting, spring 1976.

Indiana Obstetrical and Gynecological Society. (1947) *President,* Charles R. Echt. *Secretary,* David E. Copher, 3266 N. Meridian #404, Indianapolis, Ind. 46208. Meetings, three times yearly.

Iowa Obstetrical and Gynecological Society. (1946) *President,* John G. Napier. *Secretary,* Robert M. Kretzschmar, University Hospitals, Iowa City, Iowa Meetings, Dec. 10-11, 1975.

Jackson Gynecic Society. President, Thomas E. Holden. Secretary-Treasurer, Fred Ingram, Department of Obstetrics and Gynecology, University of Mississippi Medical Center, 2500 N. State St., Jackson, Mississippi 39216. Meetings, fourth Monday of each month, excluding June, Aug., and Dec.

Kansas City Gynecological Society. (1932) *President,* William T. Griffin. *Secretary,* Thomas L. Stribling, 3036 Gillham Road, Kansas City, Mo. 64108. Meetings, Jan. 15, March 18, and May 20, 1976.

The Kentucky Obstetrical and Gynecological Society. (1948) *President,* Mervel V. Hanes. *Secretary-Treasurer,* Hugh P. Adkins, 303 Medical Towers North, Louisville, Ky. 40402. Meetings, spring and fall.

Louisville Obstetrical and Gynecological Society *President,* J. Patrick Sutherland. *Secretary,* Charles R. Oberst, 215 Medical Towers North, Louisville, Ky. 40202.

Los Angeles Obstetrical and Gynecological Society, Inc. (1914) *President,* Lester T. Hilbard. *Secretary,* James C. Caillouette, 5410 Wilshire Blvd., Suite 600, Los Angeles, Calif. 90036. Meetings, second Tuesday, Jan. 13, March 9, and May 18, 1976.

Memphis and Shelby County Obstetrical and Gynecologic Society. *President,* Martha Loving. *Secretary,* Jesse C. Woodall, Jr., 220 S. Claybrook, Suite 401, Memphis, Tenn. 38104. Meetings, second Tuesday of each month, excluding June, July, and Aug.

Miami Obstetrical and Gynecological Society. (1946) *President,* Howard A. Novell. *Secretary,* Arthur I. Rudolph, 7400 N. Kendall Dr., Suite 410, Miami, Fla. 33056. Meetings, second Thursday, Nov., Jan., March, and May.

Michigan Society of Obstetricans and Gynecologists. (1924) *President,* Hermann A. Ziel, Jr. *Secretary,* Robert G. Walkowiak, 28 W. Adams, Detroit, Mich. 48226. Meetings, Jan. 3, Feb. 12, March 9, April 4, and May 15, 1976.

Milwaukee Gynecological Society. (1951) *President,* David V. Foley. *Executive Secretary,* Robert Herzog, 2825 N. Mayfair Rd., Milwaukee, Wis. 53222. Meetings, Feb. 9, March 8, April 12, Oct. 5, and Nov. 2, 1976.

Mississippi Obstetrical and Gynecological Society. (1947) *President,* Calvin T. Hull. *Secretary,* Lewis D. Lipscomb, 500 G. E. Woodrow Wilson, Jackson, Miss. 39216. Meeting, May 5, 1976.

Montana Obstetrical and Gynecological Society. (1948) *President,* Ed Schumaker. *Secretary,* Gordon K. Phillips, 1220 Central Ave., Great Falls, Mont. 59401. Meetings, unscheduled.

Nassau Obstetrical and Gynecological Society. (1944) *President,* James N. Nicklas. *Secretary,* J. Conrad Greenwald, 179 Community Dr., Great Neck, N. Y. 11020. Meetings, Mar. 1 and April 26, 1976.

Nebraska State Obstetric and Gynecological Society. (1955) *President,* Marvin Dietrich. *Secretary,* Dennis D. Beavers, 8552 Cass St., Omaha, Neb. 68114. Meetings, Dec. 4-6.

New Jersey Obstetrical and Gynecological Society. (1947) *President,* Robert Haines. *Secretary,* James Thompson, 2424 Morris Ave., Union, N. J. 07083. Meeting, annual.

The New Orleans Gynecological and Obstetrical Society. (1947)

The New York Obstetrical Society. (1863) *President,* James Nelson. *Secreatry,* E. Thomas Steadman, 449 E. 68 St., New York, N. Y. 10021. Meetings, second Tuesday, Oct. through May, 1976.

North Dakota Society of Obstetrics and Gynecology. (1938) *President,* Joseph Adducci. *Secretary,* Robert P. Bushell, 737 Broadway, Fargo, N. D. 58102. Meeting, Sept. 10-11, 1976.

Northern California Obstetrics and Gynecologic Society. (1953) *President,* John Evrigenis. *Secretary,* John J. Sullivan, Campus Commons Medical Plaza, 1 Scripps Drive. Suite 305, Sacramento, Calif. 95825. Meetings, third Wednesday.

Obstetrical and Gynecological Assembly of Southern California. (1945) *General Chairman,* James E. Davis. *Secretary,* Bruce B. Rolf, 5410 Wilshire Blvd., Suite 600, Los Angeles, Calif. 90036. Meetings, Feb. 9-13, 1976.

Obstetrical Society of Boston. *President,* Charles L. Easterday. *Secretary,* Edward H. Copenhaver, 605 Commonwealth Avenue, Boston, Mass. 02215. Meetings, Jan. 19, Feb. 9, March 15, April 19, Oct. 18, and Nov. 15.

The Obstetrical Society of Philadelphia. (1868) *President,* John J. Mikuta. *Secretary,* Kaighn Smith, Suite 433, Lankenau Medical Building, Philadelphia, Pa. 19151. Meetings, first Thursday, each month, except Jan.

Oklahoma City Obstetrical and Gynecological Society. (1940)

Omaha Obstetrical-Gynecological Society. (1946) *President,* William Orr. *Secretary,* Joseph Scott, Dept. Ob-Gyn, University of Nebraska Medical Center, Omaha, Neb. 68132. Meetings, Jan., Mar., May, Sept., and Nov.

Orange County Obstetrical & Gynecological Society. (1958)

Pediatric Section of the County of Kings and the Academy of Medicine. *President,* Shirley M. Lippsett. *Secretary,* A. Zachary Apfel, 105-23 Ave., Brooklyn, N. Y. Meetings, Jan. 14, Feb. 18, and April 17, 1976.

Peninsula Gynecologic Society. (1954) *President,* Frederick R. Schlichting. *Secretary,* Arthur M. Brown, 596 Carroll St., Sunnyvale, Calif. 94086. Meetings, Feb., May, Sept., and Nov.

Philadelphia Obstetrical Society.

Phoenix Obstetrical and Gynecological Society. *President,* Norman Brown. *Secretary,* Franklin Loffer, 2021 N. Central Ave., Phoenix, Ariz. 85004. Meetings, Jan., March, May, Sept., and Nov.

Queens Gynecological Society. (1948) *President,* Patrick J. Concannon. *Secretary,* John S. Rienzo, c/o Queens Gynecological Society, 112-25 Queens Blvd., Forest Hills, Queens. Meetings, Feb. 11 and May 12, 1976.

Riverside-San Bernardino Obstetrical and Gynecological Society. (1957) *President,* William G. McCormick. *Secretary,* Jerome Niswonger, Loma Linda University Medical Center, Dept. Ob-Gyn, Room 3004, Loma Linda, Calif. 92354. Meetings, Jan. 21, Mar. 10, and May 19, 1976.

Rochester Academy of Medicine, Obstetrics and Gynecology Section. (1939) *President,* Henry Thiede. *Secretary,* Marvin Amstey, Highland Hospital, Rochester, N. Y. 14620. Meetings, quarterly.

St. Louis Gynecological Society. (1922) *President,* Denis Cavanagh. *Secretary,* Joe E. Belew, 3839 Lindell Blvd., St. Louis, Mo. 63108. Meetings, Feb. 12 and April 8, 1976.

San Antonio Obstetrical and Gynecological Society. (1963) *President,* Paul Weinberg. *Secretary,* Wendell Schorlemer, 318 Medical Professional Bldg., San Antonio, Texas 78212. Meetings, third Wednesday, Jan., March, May, July, Sept., and Nov.

San Diego Gynecological Society. (1937) *President,* Roger Miesfield. *Secretary,* Richard Philpott, 3240 Main St., Lemon Grove, Calif. 92045. Meetings, third Thursday, June, July, and Aug.

San Francisco Gynecological Society. (1929) *President,* Eugene C. Sandberg. *Secretary-Treasurer,* Robert W. Hoag, 2915 Telegraph Avenue, Berkeley, Calif. 94705. Meetings, second Tuesday, each month, except Dec. of each academic year.

Shufelt Society of Santa Clara County. (1947) *President* Harlan S. Parks, *Secretary,* Vincent F. Nola, 2081 Forest Ave., San Jose, Calif. 95128. Meetings, Jan. 15, Mar. 18, May 20, July 15, Sept. 16, and Nov. 18, 1976.

Society for Gynecological Investigation. *President,* Robert B. Jaffe. *Secretary,* Thomas H. Kirschbaum, Dept. of OB-GYN, Michigan State Univ., E. Lansing, Mich. 48824. Meeting, March 24-26, 1976.

South Dakota Society of Obstetrics and Gynecology. (1952) *President,* Milton G. Mutch, Jr. *Secretary,* Thomas L. Looby, 1200 S. Euclid, Sioux Falls, S. D. 57105. Meeting, annual.

Suffolk County Obstetrical and Gynecological Society. *President,* Jack Lipman. *Secretary,* Melvin Berlin, 111 Carleton Ave., Islip Terrace, N. Y. 11752. Meetings: second Tuesday, Sept., Nov., Feb., and May.

The Texas Association of Obstetricans and Gynecologists. (1931) *President,* William J. McGanity. *Secretary,* William H. Nash, Suite 304, 7711 Louis Pasteur Drive, San Antonio, Texas 78229. Meetings, Mar. 11-13, 1976.

Toledo Society of Obstetricians and Gynecologists. *President,* Carl Armstrong. *Secretary,* L. R. Kavanagh, 1614 S. Byrne Rd., Toledo, Ohio 43614. Meetings, Feb. and May, 1976.

Tri-Counties Obstetrical and Gynecological Society. (1959) *President,* Lowell McLellan. *Secretary,* Larry R. Moncur, 317 W. Pueblo St., Santa Barbara, Calif. 93105. Meetings, bi-monthly.

Utah Obstetrical and Gynecological Society. (1948) *President,* James Warenski. *Secretary,* Robert McMaster, 3905 Harrison Blvd., #308, Ogden, Utah 84403. Meetings, quarterly.

Virginia Obstetrical and Gynecological Society. (1936) *President,* Mason C. Andrews. *Secretary,* Lucien W. Roberts, P.O. Box 10, South Boston, Va. 24592. Meetings, spring and fall.

Washington Gynecological Society. (1933) *President,* Harzen S. Shea. *Secretary,* Charles E. Townsend, 4740 Bradley Blvd., Chevy Chase, Md. 20015. Meetings, Jan. 4, March 10, and April 14, 1976.

Westchester Obstetrical and Gynecological Society. (1937)

West Virginia Obstetrical and Gynecological Society. (1935) *President,* Robert P. Pulliam. *Secretary,* T. Keith Edwards, Bluefield Sanitarium, Bluefield, West Virginia 24701. Meeting, October 8-9, 1976.

Wisconsin Society of Obstetrics and Gynecology. *President,* William J. O'Leary, Jr. *Secretary,* C. Weir Horswill, 2630 Amhurst Rd., Middleton, Wisc. 53562. Meeting, early Sept., 1976 dates to be arranged.

ITEMS

Symposium on Diabetes and Other Endocrine Disorders During Pregnancy and in the Newborn Infant

A two-day Symposium on Diabetes and Other Endocrine Disorders During Pregnancy and in the Newborn Infant will be held at the New York Hilton Hotel in New York City, April 1-2, 1976. Sponsored by The National Foundation–March of Dimes, the symposium program will be presented by Cornell University Medical Center.

Dr. Maria I. New, Professor of Pediatrics, Cornell University Medical Center, and Dr. Robert H. Fiser, Jr., Professor and Chairman of the Department of Pediatrics, University of Arkansas Medical Sciences Campus, will serve as co-chairmen of the conference.

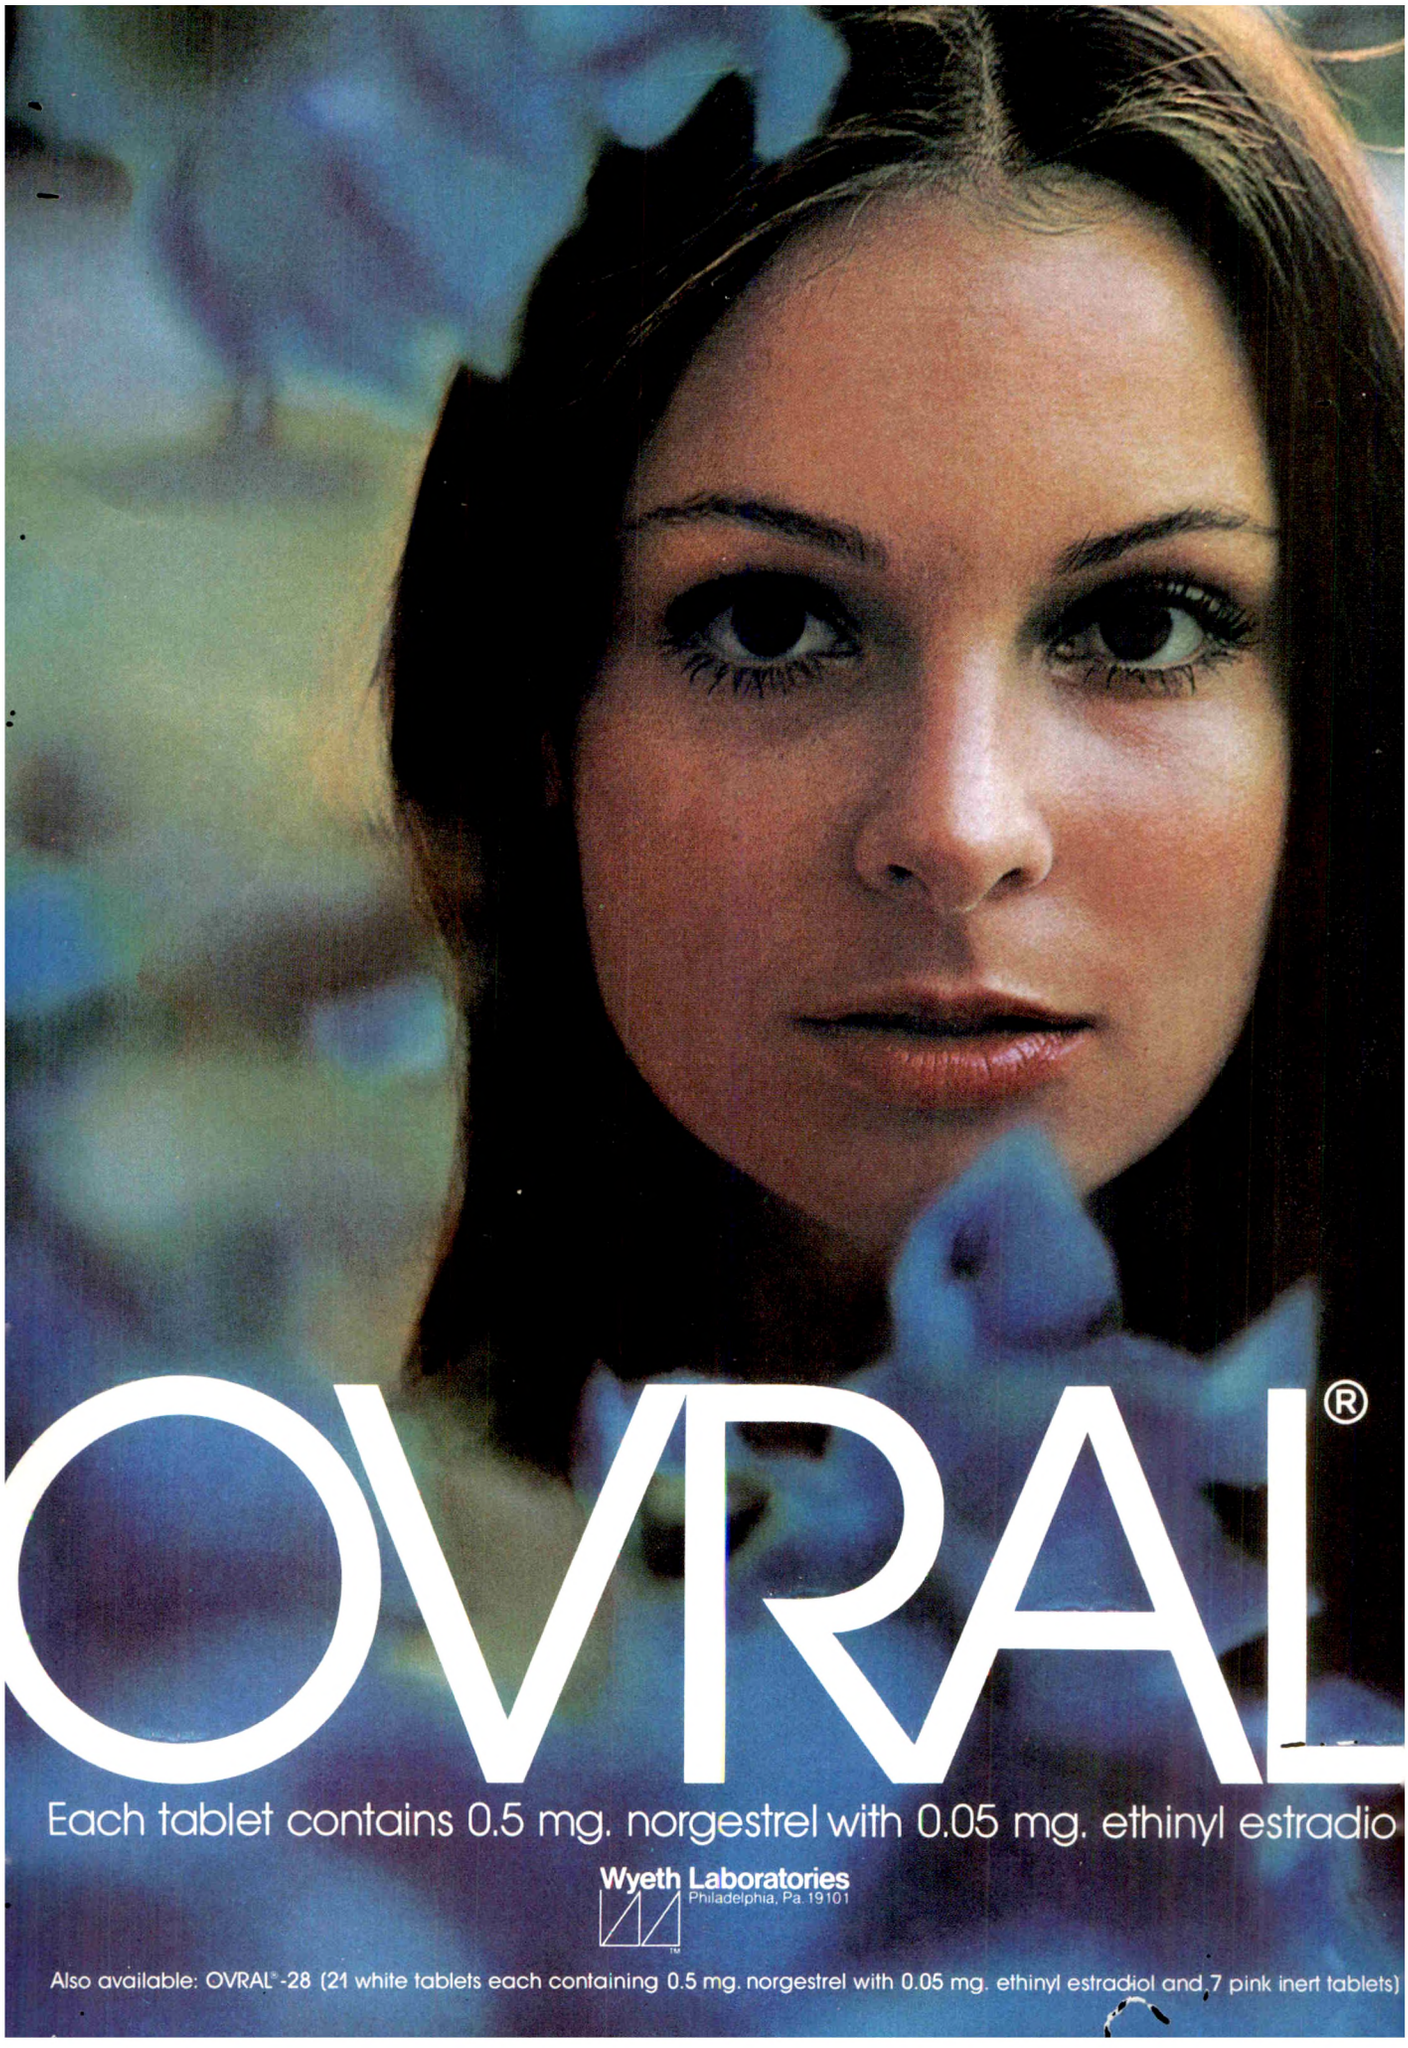
The purpose of this two-day symposium is to aid in understanding the perinatal physiology of diabetes and other hormonal disorders. Specific attention will be given to the effect on the fetus and the newborn infant of hormones administered to the mother during pregnancy. Guidelines for the therapeutic use of hormones and the management of the diabetic during pregnancy will be discussed.

The specific topics to be discussed are: (1) Diabetes and Carbohydrate Regulation of the Fetus and Newborn, (2) Gonadotrophins and Growth Factors, (3) Steroid Hormones During Pregnancy and in the Newborn, and (4) Thyroid and Parathyroid Hormones.

For further information, contact: The National Foundation–March of Dimes, 622 Third Ave., New York, New York 10017. Telephone: (212) 682-6430.

XIIIth Société Médicale Internationale d'Endoscopie et de Radiocinéma International Congress

The XIIIth Société Médicale Internationale d'Endoscopie et de Radiocinéma (S.M.I.E.R.) International Congress will take place in Lyons, France, May 6-8, 1976. Professor Pierre Mounier-Kuhn will preside. The Congress will be presented in liaison with the meeting of the French Language Broncho-Esophagology Society (President, Professor J. Gaillard). The theme will be, "The Contribution of Endoscopy, Radiology, Cinematography and Thermography Toward Early Diagnosis of Cancer." Official languages include French and English, with simultaneous translation. The Secretary-General–Treasurer is: Professeur Agrégé J. P. Haguenauer, O.R.L. Clinic, Hôpital de la Croix-Rousse, 69317 Lyon Cedex 1, France. The Agency is: LYCOTOUR, Maison de Lyon, Place Bellecour, B.P. 254 Lyon R.P., 69223 Lyon Cedex 1, France.



Postgraduate Course in Gynecologic Oncology

This course is a two and a half day program, designed to acquaint the practicing gynecologist, radiologist, pathologist, or medical oncologist with recent advances and current concepts in the diagnosis and management of gynecologic cancer. In addition to formal presentations by a distinguished faculty, ample time for informal question and answer periods has been provided to encourage maximal discussion between the faculty and participants.

Program directors are Philip J. DiSaia, M.D., and Roger K. Freeman, M.D. The guest faculty includes John McLean Morris, M.D., Felix N. Rutledge, M.D., and Robert E. Scully, M.D.

The program will be presented by the Women's Hospital Medical Center, Long Beach, California, January 16-18, 1976, in the Memorial Hospital Medical Center of Long Beach–University of California, Irvine Center for Health Education, 2801 Atlantic Ave., Long Beach, California. Registration fee is $200.00 ($100.00 for residents). This continuing medical education activity is acceptable for 15 hours of category 1 credit toward the Physicians' Recognition Award of the AMA.

Further information may be obtained from the Executive Secretary, Center for Health Education, 2801 Atlantic Ave., Long Beach, California 90801. Telephone: (213) 595-3823.

OVRAL®
Each tablet contains 0.5 mg. norgestrel with 0.05 mg. ethinyl estradio
Wyeth Laboratories
Philadelphia, Pa. 19101
Also available: OVRAL®-28 (21 white tablets each containing 0.5 mg. norgestrel with 0.05 mg. ethinyl estradiol and 7 pink inert tablets)

Articles to appear in early issues

Pregnancy with bilateral ruptured benign cystic teratomas
Usha Mehra, M.D., Timothy O'Connor, M.B., B.Ch., Frank Ostapowicz, M.D., F.A.C.O.G., and Denis Cavanagh, M.D., F.A.C.O.G.
St. Louis, Missouri

Periovulatory changes in ovarian temperature in ewes

PERSONALIZED LIBRARY CASES

Keep your personal copies of AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY in these specially designed library file cases. Two files hold an entire year's issues. Designed to keep your journal copies near at hand in your office, library, or home.

Your case is heavy bookbinder's board in a rich red Kivar cover. Files are scuff-resistant and washable.

Lettering is stamped in gold leaf and the cases make a fit companion for the most costly binding.

Files are reasonably priced—only $4.25 each, postpaid (3 for $12., 6 for $22.). Add $1.00 postage per case for orders outside U. S. Satisfaction unconditionally guaranteed or your money back! Use the coupon for prompt shipment.

CURRENT DEVELOPMENTS IN INFECTIOUS DISEASE IN OBSTETRICS-GYNECOLOGY

Will be presented by
UNIVERSITY OF SOUTHERN CALIFORNIA
SCHOOL OF MEDICINE-POSTGRADUATE DIVISION
and
THE INFECTIOUS DISEASE SOCIETY OF
OBSTETRICS & GYNECOLOGY
in
LOS ANGELES, CALIFORNIA
February 24, 25 and 26, 1976
Presentation and Workshops in:

Genital Infections, Anaerobic Infections, Antibotic Use in Gynecology, TORCH Syndrome, Maternal-Fetal Factors in Infection During Pregnancy, Controversy In Obstetrics including The Treatment of Premature Rupture of Membranes and Prophylactic Antibiotics in Obstetrics.

FACULTY

Ian Craft, England; Hans Hirsch, Germany; Davis Charles, Memorial Hospital, Newfoundland, Canada; Rudolph Galask, University of Iowa; William Ledger, University of Southern California; Philip Mead, University of Vermont; Gilles Monif, University of Florida; Richard Schwarz, University of Pennsylvania, plus other distinguished faculty from Obstetrics & Gynecology, Pediatrics, Internal Medicine and Surgery.

Tuition—$200—Enrollment limited to first 300 registrants.
To enroll, or for further information, write: Associate Dean, Postgraduate Medical Education, 2025 Zonal Avenue, Los Angeles, CA 90033, Phone (213) 226-2051 or 2052.

Please enroll me (check enclosed)_____

Please send further information_____
(There will be a $10 service fee on all refunds) No refunds after course begins.

Happy homecoming for the new mother-

For continued relief of postepisiotomy discomfort, send her home from the hospital with DERMOPLAST® Aerosol

What DERMOPLAST starts doing to relieve postepisiotomy discomfort in the hospital, it can keep doing at home—to help make the new mother's first days with her baby as enjoyable as they should be. DERMOPLAST permeates the suture line without affecting sutures, and relieves itching that accompanies tissue regeneration and hair regrowth.

It will not dry or macerate the skin, and is easily removed with soap and water. DERMOPLAST is easy to apply—sprays from any angle. Available in three sizes, including convenient 3-oz. size that is especially designed for self-administration by the patient.

DERMOPLAST Aerosol Spray contains: Benzocaine, w/w 4.5%; benzethonium chloride, w/w 0.1%; menthol, w/w 0.5%; oxyquinoline benzoate, w/w 1.2%; and methylparaben, w/w 2.0%. Inactive ingredients, vegetable oils and propellant. Also contains 1.9% isopropyl alcohol.

For additional indications, full directions for use, and warnings, see label copy on DERMOPLAST Aerosol Spray can.

When women outlive their ovaries...

Here, illustration shows artist's interpretation of cross section of brain symbolizing impulse transmissions from hypothalamic area to the pituitary and other neurohormonal target organs.

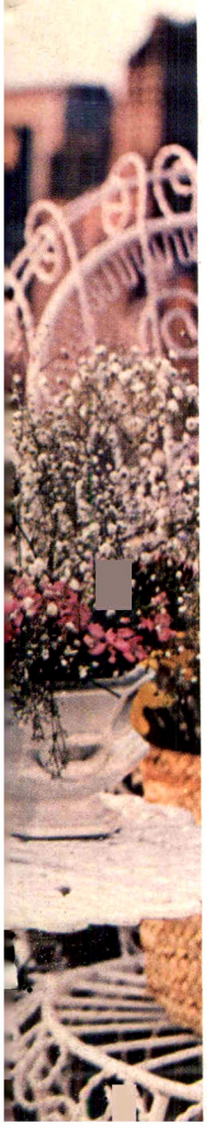
"There we were—my husband at the peak of his career—busy, successful...but no time for me. With that and all my other problems, I'd lie awake night after night, more depressed every day. This wasn't a 'change,' it was a catastrophe."

UNIVERSITY COLLEGE OF MEDICINE
LIBRARY

Because some emotional symptoms may simply coincide with the menopause, it is essential to distinguish them from those symptoms which are related to estrogen deficiency–and to begin appropriate therapy.

It's axiomatic that the menopause carries its own burden of physical and emotional problems, some related to ovarian decline, some not.

The first step in identifying the source of emotional symptoms is to obtain a thorough history; emotional problems of recent origin are more likely to be related to estrogen deficiency than those of long standing.



Then, to distinguish those symptoms that will respond to estrogen replacement therapy from those that may require other approaches to treatment, institute a *therapeutic trial* with PREMARIN.

In many cases, prolonged use of tranquilizers will not be necessary; patients taking PREMARIN alone often report relief of emotional symptoms when these are due to estrogen deficiency...and an improved sense of well-being.

Thus, the benefits of PREMARIN in such patients are threefold: it can help relieve symptoms related to estrogen deficiency; help treat the underlying cause; and finally, help identify symptoms unrelated to estrogen deficiency.

"I was always so irritable... snapping at the children... almost anything could annoy me. I knew I was doing it, but I just couldn't seem to stop myself."

For the emotional symptoms of the menopause related to estrogen deficiency

PREMARIN®

(CONJUGATED ESTROGENS TABLETS, U.S.P.)

CONTAINS NATURAL ESTROGENS EXCLUSIVELY

See last page of advertisement for prescribing information.

BRIEF SUMMARY
(For full prescribing information, see package circular.)
PREMARIN® Brand of
CONJUGATED ESTROGENS TABLETS, U.S.P.

Actions: Estrogens are responsible for development and maintenance of the female reproductive system and secondary sex characteristics. They cause the growth and development of the vagina, uterus, and fallopian tubes, and enlargement of the breasts. Indirectly, they contribute to the shaping of the skeleton, maintenance of tone and elasticity of urogenital structures, changes in the epiphyses of the long bones that allow for pubertal growth spurt and termination, growth of axillary and pubic hair, and pigmentation of the nipples and genitals. Estrogens are also involved in psychologic and emotional aspects of feminine behavior. As estrogen levels increase during the menstrual cycle, there is a sense of vigor and well-being, and in the menopausal period estrogens aid in relieving nervous symptoms (*e.g.* anxiety, depression and irritability) due to estrogen deficiency. Decline of estrogenic activity at the end of the menstrual cycle can bring on menstruation, although the cessation of progesterone secretion is the most important factor in the mature ovulatory cycle. However, in the pre- or non-ovulatory cycle, estrogen is the primary determinant in the onset of menstruation. Estrogens do not induce ovulation.

Estrogens affect calcium and phosphorus metabolism, and are involved in maintenance of normal bone structure. In prolonged estrogen deficiency states, administration of estrogen acts to prevent associated bone degenerative changes.

Estrogens appear to be responsible for the relatively greater amount of alpha-lipoprotein and correspondingly lower amount of beta-lipoprotein found in premenopausal women as compared with men.

Estrogens affect the release of pituitary gonadotropins and may also deplete the gonadotropic content of the pituitary.

Indications: Based on a review of PREMARIN Tablets by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications for use as follows:
Effective: As replacement therapy for naturally occurring or surgically induced estrogen deficiency states associated with: the climacteric, including the menopausal syndrome and postmenopause; senile vaginitis and kraurosis vulvae, with or without pruritus.
"Probably" effective: For estrogen deficiency-induced osteoporosis, and only when used in conjunction with other important therapeutic measures such as diet, calcium, physiotherapy, and good general health-promoting measures. Final classification of this indication requires further investigation.

Contraindications: Short acting estrogens are contraindicated in patients with (1) markedly impaired liver function; (2) known or suspected carcinoma of the breast, except those cases of progressing disease not amenable to surgery or irradiation occurring in women who are at least 5 years postmenopausal; (3) known or suspected estrogen-dependent neoplasia, such as carcinoma of the endometrium; (4) thromboembolic disorders, thrombophlebitis, cerebral embolism, or in patients with a past history of these conditions; (5) undiagnosed abnormal genital bleeding.

Warnings: Estrogen therapy should not be given to women with recurrent chronic mastitis or abnormal mammograms except, if in the opinion of the physician, it is warranted despite the possibility of aggravation of the mastitis or stimulation of undiagnosed estrogen-dependent neoplasia.

The physician should be alert to the earliest manifestations of thrombotic disorders (thrombophlebitis, retinal thrombosis, cerebral embolism and pulmonary embolism). If these occur or are suspected, estrogen therapy should be discontinued immediately.

Estrogens may be excreted in the mother's milk and an estrogenic effect upon the infant has been described. The long range effect on the nursing infant cannot be determined at this time.

Hypercalcemia may occur in as many as 15 percent of breast cancer patients with metastases, and this usually indicates progression of bone metastases. This occurrence depends neither on dose nor on immobilization. In the presence of progression of the cancer or hypercalcemia, estrogen administration should be stopped.

A statistically significant association has been reported between maternal ingestion of diethylstilbestrol during pregnancy and the occurrence of vaginal carcinoma in the offspring. This occurred with the use of diethylstilbestrol for the treatment of threatened abortion or high risk pregnancies. Whether or not such an association is applicable to all estrogens is not known at this time. In view of this finding, however, the use of any estrogen in pregnancy is not recommended.

Failure to control abnormal uterine bleeding or unexpected recurrence is an indication for curettage.

Precautions: As with all short acting estrogens, the following precautions should be observed:

A complete pretreatment physical examination should be performed with special reference to pelvic and breast examinations.

To avoid prolonged stimulation of the endometrium and breasts in climacteric or hypogonadal women, estrogens should be administered cyclically (3 week regimen with 1 week rest period—withdrawal bleeding may occur during rest period).

Because of individual variation in endogenous estrogen production, relative overdosage may occur which could cause undesirable effects such as abnormal or excessive uterine bleeding, mastodynia and edema.

Because of salt and water retention associated with estrogenic anabolic activity, estrogens should be used with caution in patients with epilepsy, migraine, asthma, cardiac, or renal disease.

If unexplained or excessive vaginal bleeding should occur, reexamination should be made for organic pathology.

Estrogen usage may cause preexisting fibromyomata to increase in size; therefore, patients should be examined at regular intervals while receiving estrogenic therapy.

The pathologist should be advised of estrogen therapy when relevant specimens are submitted.

Because of their effects on epiphyseal closure, estrogens should be used judiciously in young patients in whom bone growth is incomplete.

Prolonged high dosages of estrogens will inhibit anterior pituitary functions. This should be borne in mind when treating patients in whom fertility is desired.

The age of the patient constitutes no absolute limiting factor, although treatment with estrogens may mask the onset of the climacteric.

Certain liver and endocrine function tests may be affected by exogenous estrogen administration. If test results are abnormal in a patient taking estrogen, they should be repeated after estrogen has been withdrawn for one cycle.

Adverse Reactions: The following adverse reactions have been reported associated with short acting estrogen administration:
nausea, vomiting, anorexia
gastrointestinal symptoms such as abdominal cramps and bloating
breakthrough bleeding, spotting, unusually heavy withdrawal bleeding (See DOSAGE AND ADMINISTRATION)
breast tenderness and enlargement
reactivation of endometriosis
possible diminution of lactation when given immediately postpartum
loss of libido and gynecomastia in males
edema
aggravation of migraine headaches
change in body weight (increase, decrease)
headache
allergic rash
hepatic cutaneous porphyria becoming manifest

Dosage and Administration: PREMARIN should be administered cyclically (3 weeks of daily estrogen and 1 week off) for all indications except selected cases of carcinoma and prevention of postpartum breast engorgement.

Menopausal Syndrome—1.25 mg. daily, cyclically. Adjust dosage upward or downward according to severity of symptoms and response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

If the patient has not menstruated within the last two months or more, cyclic administration is started arbitrarily. If the patient is menstruating, cyclic administration is started on day 5 of bleeding. If breakthrough bleeding (bleeding or spotting during estrogen therapy) occurs, increase estrogen dosage as needed to stop bleeding. In the following cycle, employ the dosage level used to stop breakthrough bleeding in the previous cycle. In subsequent cycles, the estrogen dosage is gradually reduced to the lowest level which will maintain the patient symptom-free.

Postmenopause—as a protective measure against estrogen deficiency-induced degenerative changes (*e.g.* osteoporosis, atrophic vaginitis, kraurosis vulvae)—0.3 mg. to 1.25 mg. daily and cyclically. Adjust dosage to lowest effective level.

Osteoporosis (to retard progression)—usual dosage 1.25 mg. daily and cyclically.

Senile Vaginitis, Kraurosis Vulvae with or without Pruritus—0.3 mg. to 1.25 mg. or more daily, depending upon the tissue response of the individual patient. Administer cyclically.

How Supplied: PREMARIN (Conjugated Estrogens Tablets, U.S.P.)
No. 865—Each *purple* tablet contains 2.5 mg., in bottles of 100 and 1,000.
No. 866—Each *yellow* tablet contains 1.25 mg., in bottles of 100 and 1,000. Also in unit dose package of 100.
No. 867—Each *red* tablet contains 0.625 mg., in bottles of 100 and 1,000. Also in unit dose package of 100.
No. 868—Each *green* tablet contains 0.3 mg., in bottles of 100 and 1,000.

When Women outlive their Ovaries...

PREMARIN®
(CONJUGATED ESTROGENS TABLETS, U.S.P.)
contains natural estrogens exclusively

Thief.

When baby takes more iron than mother can afford to give, *iron deficiency anemia of pregnancy* is a likely consequence.

Stolen iron can be replaced with a single formulation.

Tabron.

Throughout pregnancy and the postpartum period, one Tabron tablet per day can usually fill her iron requirements. Tabron can also supply her with folic acid, a fecal softener, vitamin B_{12}, ascorbic acid, and other vitamins she's likely to need.

FILMSEAL®

Tabron®

a comprehensive hematinic... restores the iron and more

Each Tabron Filmseal represents: 304.2 mg ferrous fumarate (represents 100 mg of elemental iron); 500 mg ascorbic acid; 6 mg thiamine mononitrate; 6 mg riboflavin; 5 mg pyridoxine hydrochloride; 25 mcg cyanocobalamin, crystalline; 1 mg folic acid; 30 mg niacinamide; 10 mg calcium pantothenate; 30 I U vitamin E (*dl*-alpha tocopheryl acetate); 50 mg dioctyl sodium sulfosuccinate.

Caution: Folic acid may obscure pernicious anemia; the peripheral blood picture may revert to normal while neurological manifestations remain progressive.

PARKE-DAVIS

The causes of vaginitis are multiple

You can depend on AVC... therapy that combats major vaginal pathogens and provides rapid symptomatic relief.*

***Indications:** Based on a review of AVC by the National Academy of Sciences–National Research Council and/or other information, FDA has classified the indications as follows:

"Probably" effective: For the relief of symptoms of vulvovaginitis where isolation of the specific organism responsible (usually *Trichomonas vaginalis, Candida albicans,* or *Hemophilus vaginalis)* is not possible.

NOTE: When the offending organism is known, treatment with a specific agent known to be active against that microorganism is preferred.

"Possibly" effective: For the treatment of trichomoniasis, vulvovaginal candidiasis, and vaginitis due to *Hemophilus vaginalis* or other susceptible bacteria.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Known sensitivity to sulfonamides.

Precautions/Adverse Reactions: The usual precautions for topical and systemic sulfonamides should be observed because of the possibility of absorption. Burning, increased local discomfort, skin rash or other manifestations of sulfonamide toxicity are reasons to discontinue treatment.

Dosage: 1 applicatorful (about 6 g.) or 1 suppository intravaginally once or twice daily.

Supplied: Cream–4 ounce tube with applicator.
Suppositories–Box of 16 with inserter.

In the past 17 years, URISTIX® Reagent Strips—10-second dip-and-read test for detection of urinary glucose and protein—has emerged as a test-of-choice among physicians who see obstetric patients.

These two tests, performed during each prenatal office visit, have proved useful as "early warning" indicators:

☐ *the glucose:* reflects stress reactions, gestational or latent diabetes... monitors existing diabetes

☐ *the protein:* provides early sign of hypertension, toxemia, renal vascular dysfunction

Now...screening with more meaning

Recent literature suggests that there is a need to expand routine prenatal screening to include a test for asymptomatic bacteriuria.[1] Early detection of bacteriuria at any time during pregnancy may significantly reduce the incidence of overt UTI and subsequent renal involvement.[1-3]

Especially for your obstetric patients, Ames Company is introducing a more meaningful screen: N-URISTIX

☐ comprehensive prenatal screen utilizing the URISTIX protein and glucose indicators—PLUS...

☐ 30-second, dip-and-read test for urinary nitrite, an indicator of significant bacteriuria (10^5 organisms/ml or more)

new **N-Uristix**™ Reagent Strips

Test for Urine Nitrite, Glucose, and Protein

In routine and resistant vaginal moniliasis...

MONISTAT CREAM
TRADEMARK

(MICONAZOLE NITRATE 2%)

effective when used once daily, h.s., for 14 days†

high cure rates in the pregnant,††
the non-pregnant, women on antibiotic therapy,
women previously treated with other
antifungal agents

negative cultures usually maintained 30 days
or more post-therapy

†usually works in one course of therapy
with a simple once-daily h.s. dosage for 14 days

soothing, non-staining cream
also may be used on external vulva

††Monistat Cream may be used in the second and third trimesters. However, in the first trimester, it should be used only when the physician considers it essential to the patient's welfare.

Description MONISTAT (miconazole nitrate 2%) is a water-miscible, white cream containing as the active ingredient, 2% miconazole nitrate, 1-[2,4-Dichloro-β-(2,4-dichlorobenzyloxy) phenethyl] imidazole nitrate.

Actions MONISTAT Cream exhibits fungicidal activity *in vitro* against species of the genus *Candida*. The pharmacologic mode of action is unknown.

Indications MONISTAT Cream is indicated for the local treatment of vulvovaginal candidiasis (moniliasis).

As MONISTAT Cream is effective only for candidal vulvovaginitis, the diagnosis should be confirmed by KOH smears and/or cultures. Other pathogens commonly associated with vulvovaginitis (*Trichomonas* and *Haemophilus vaginalis*) should be ruled out by appropriate laboratory methods.

MONISTAT is effective in both pregnant and non-pregnant women, as well as in women taking oral contraceptives. (See PRECAUTIONS.)

Contraindication Patients known to be hypersensitive to this drug.

Precautions *General:* Discontinue drug if sensitization or irritation is reported during use. *Laboratory Tests:* If there is a lack of response to MONISTAT, appropriate microbiological studies should be repeated to confirm the diagnosis and rule out other pathogens. *Pregnancy:* MONISTAT Cream was used in 209 pregnant patients. Follow-up reports now available in 117 of these patients reveal no adverse effects or complications attributable to MONISTAT therapy in infants born to these women. Since MONISTAT Cream is absorbed in small amounts from the human vagina, it should be used in the first trimester of pregnancy only when the physician considers it essential to the welfare of the patient.

Adverse Reactions Thirty-nine (7.4%) of the 528 patients treated with MONISTAT reported complaints during therapy that were possibly drug-related. Most complaints were reported during the first week of therapy. Vulvovaginal burning, itching or irritation occurred in 6.6%, while other complaints such as vaginal burning, pelvic cramps, hives, skin rash and headache occurred rarely (each less than 0.2% patient incidence). The therapy-related dropout rate was 0.9%.

Dosage and Administration One applicatorful is administered intravaginally once daily at bedtime for 14 days. Course of therapy may be repeated after other pathogens have been ruled out by appropriate smears and cultures.

Supplied MONISTAT Cream is available in 3 oz. (85 g) tubes with Ortho* Measured Dose Applicator.

MONISTAT (Miconazole Nitrate 2%) is a development of Ortho Pharmaceutical Corporation and Janssen Pharmaceutica, Belgium.

True human estrogen replacement

Hormonin

(estriol, estradiol, estrone)

***BRIEF SUMMARY:** See package insert for full prescribing information.*

CHOOSE FROM TWO CONVENIENT ORAL FORMS:

***HORMONIN NO. 1** (half strength)*	***HORMONIN NO. 2** (full strength)*
Each Tablet Contains:	*Each Tablet Contains:*
ESTRIOL 0.135 mg.	*ESTRIOL 0.27 mg.*
ESTRADIOL 0.3 mg.	*ESTRADIOL 0.6 mg.*
ESTRONE 0.7 mg.	*ESTRONE 1.4 mg.*

***INDICATIONS:** Replacement therapy for naturally occurring or surgically induced estrogen deficient states, including the menopause syndrome and post-menopausal conditions.*

***CONTRAINDICATIONS:** Women having familial or personal history of mammary or genital cancer.*

***PRECAUTIONS:** Estrogen should not be administered to women with recurrent mastitis or abnormal mammograms except in instances where the physician feels that treatment is warranted despite the possibility of aggravation of the mastitis or stimulation of undiagnosed estrogen dependent neoplasia.*

The physician should be alert to the earliest manifestation of thrombotic disorders. Should this problem occur, discontinue estrogen therapy immediately. The long range effect of estrogen on nursing infants has not been established.

Hypercalcemia may occur in as many as 15 percent of breast cancer patients with metastases, and this usually indicates progression of bone metastases. This occurrence depends neither on dose nor on immobilization. In the presence of progression of the cancer of hypercalcemia, estrogen administration should be discontinued. The use of any estrogen in pregnancy is not recommended.

A complete pretreatment physical examination should be performed with special reference to the pelvis and breast. To avoid continuous stimulation of the uterus and breast, cyclic therapy is recommended (3 weeks on medication and 1 week off). Withdrawal bleeding may occur during the one week off medication. If unexplained or excessive vaginal bleeding occurs, the physician should check for the organic pathology.

Pre-existing fibromyomata may increase in size while using estrogen. For this reason, patients should be examined at regular intervals. Treatment with estrogen may mask the onset of the climacteric. Certain liver and endocrine function tests may be affected by exogenous estrogen administration.

***DOSAGE:** Orally, for the relief of menopausal symptoms, HORMONIN NO. 1, 1 or 2 tablets daily according to severity of symptoms; HORMONIN NO. 2, 1 tablet daily. The initial dosage may be decreased to establish maintenance dosage. To avoid possible continuous stimulation of the breast and uterus, cyclic therapy may be employed. In severe cases, initial therapy may be supplemented with parenteral estrogens.*

Announcing

Senokot® S Tablets

(standardized senna concentrate and dioctyl sodium sulfosuccinate)

a unique natural laxative plus a classic stool softener

Provides a unique natural laxative—standardized senna concentrate... virtually colon-specific ...effectiveness documented in numerous published studies comprising thousands of patients.

Provides a classic stool softener—DSS... complementing the laxative action by softening the stool for smoother and easier passage.

Comfortable, predictable evacuation... a bedtime dose of SENOKOT S Tablets usually induces comfortable evacuation the next morning, allowing uninterrupted sleep. SENOKOT S Tablets aid in rehabilitation of the constipated patient by facilitating regular elimination.

Indications: SENOKOT S Tablets offer welcome relief in functional constipation when combined neuroperistaltic stimulation plus stool softening is indicated, especially for: the aged; postpartum and postoperative patients; drug-induced constipation; cardiovascular patients and those with hemorrhoids. **Dosage** (preferably at bedtime): Adults: Initial Dosage: 2 tablets (max. dose—4 tablets b.i.d.). Children (above 60 lb.): 1 tablet (max. dose—2 tablets b.i.d.). To meet individual requirements, dosage may be decreased or increased by 1 tablet (up to maximum) until the most effective dose is established. **Supplied:** Bottles of 30 and 60 tablets.

better beginnings thanks to better monitoring...

Honoring its commitment to better fetal, neonatal and maternal care, Roche Medical Electronics introduces a new fetal monitor with dramatically expanded capabilities.

The Fetasonde® 2104 is capable of continuous fetal and/or maternal monitoring throughout labor and delivery. The improved counting circuits and displays of the Fetasonde 2104 provide more meaningful data, for a broader range of patients than ever before.[1]

Only Fetasonde 2104 combines outstanding accuracy, flexibility and ease of use with these important technological advantages:

- Choice of indirect or direct fetal heart rate monitoring.
- Unique multi-crystal cloverleaf transducer.
- Ultrasonic ranging for accurate counting.
- Beat-to-beat heart rate and ECG recording for mother, fetus or neonate, for examination of short term variability patterns and arrythmias.
- Full clinical range of fetal heart rate counting in both direct and indirect modes.
- Unique credence and poor-signal verification logic, increases data reliability.
- Automatic Arteriosonde® 1216 maternal blood pressure monitoring and permanent record with the 2104.

ROCHE ... improving patient care through technology.

Roche offers reliable, high performance instruments for obstetrics, pediatrics, cardiology, surgery and intensive care. The stringent standards we apply to the development, manufacture and clinical testing of all Roche instruments assure you of providing your patients with the very best care.

For advanced application consultation, system planning, operational training or service, Roche is ready to supply immediate professional and skilled assistance.

ROCHE people and products... on call or in attendance, around the clock, seven days a week.

Instructions to authors

Submission of contributions. Manuscripts should in general be sent to a particular Editor according to the following plan: If it is from the southeastern quadrant of the United States or from Canada, or if it has been presented before one of the official sponsoring societies, to Dr. Brewer; if from the northeastern quadrant (including Ohio), or if it is a Clinical Opinion or a Letter to the Editors, to Dr. Zuspan; if from the north central states, any of the United States west of the Mississippi, Hawaii, Alaska, or abroad, Dr. Quilligan.

All articles published in this Journal must be contributed to it exclusively. Articles previously published in another language are not acceptable.

It is assumed by the Editors that articles emanating from a particular institution are submitted with the approval of the requisite authority, **including all matters pertaining to human studies.** Articles dealing with human experimentation cannot be accepted unless the experiment was approved by the author's local Human Experimentation Committee.

Statements and opinions expressed in the articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or publisher and the Editor(s) and publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the publisher guarantee, warrant, or endorse any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

Manuscripts. Manuscripts should be typewritten on one side of the paper only, with double spacing and liberal margins. The original and one copy of the manuscript are required. References should be placed at the end of the article and should conform to the style of the Cumulated Index Medicus, viz., name of author, article title, name of periodical, volume, page, and year. Authors are encouraged to limit references to *16, except* for Communications in Brief, limited to *2,* Current Investigation and Clinical Opinion, limited to *6,* and Current Developments for which there is *no* limit. Illustrations accompanying manuscripts should be numbered, provided with suitable legends, and marked lightly on the back with the author's name. Authors should indicate on the manuscript the approximate position of tables and text figures.

Tables should be typed on separate sheets of paper, not in the text, with one table to a page. They should be numbered in sequence and each must be referred to at an appropriate point in the text. Captions of the tables should be brief, yet indicate clearly the purpose or content of each table. Rows and columns in the table should precisely define the nature of the data in each. Abbreviations in tables should be used as little as possible and if abbreviations are used they should be explained in a footnote to the table.

An abstract of 50 to 150 words, to be published as an introduction, should accompany each manuscript and should be typed on a separate sheet of paper.

A footnote should be included which gives the name and complete mailing address of the person to whom reprint requests and correspondence should be sent.

A Guide to Writing for the American Journal of Obstetrics and Gynecology may be obtained from the Publisher on request.

Illustrations. A reasonable number of halftone illustrations will be reproduced free of cost to the author, but special arrangements must be made with the Editors for color plates, elaborate tables, or extra illustrations. Original drawings or graphs should be drawn with black India ink. Typewritten or freehand lettering is not acceptable. All lettering must be done professionally. Do not send original art work, x-ray films, or ECG tracings. Glossy print photographs are preferred, for good black and white contrast is essential.

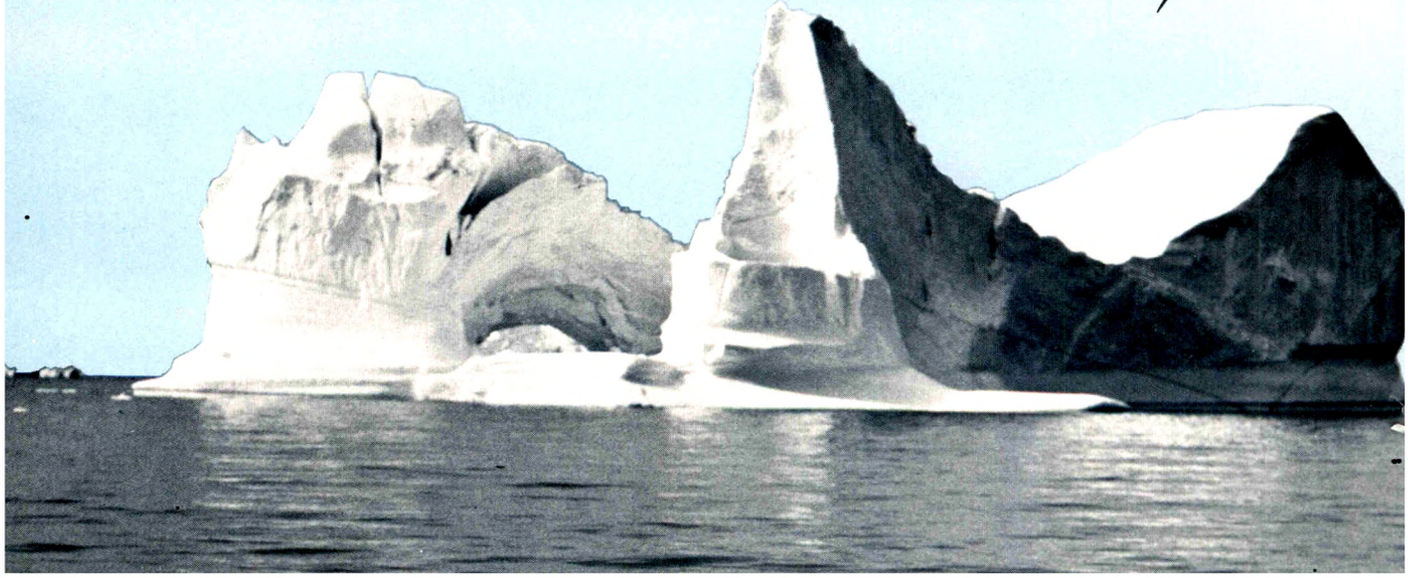
Announcements. Announcements of meetings must be received by Dr. Brewer at least 2½ months prior to the time of the meeting. Such announcements should concern major meetings and other significant activities. Announcements of symposia or seminars for which fees are charged are not published in the scientific pages of the Journal but may be submitted for paid advertisements, if desired.

Letters to the Editors: A brief Letter to the Editors commenting upon some article which has appeared in the Journal will be considered for publication. The writer of the original article will have an opportunity to reply to unfavorable comments. A brief case presentation of special interest in the form of a Letter to the Editors will also be considered for publication. All such letters should be sent to Dr. Zuspan.

Books. Books received will be listed in the Journal. They should be sent to Dr. Gerbie.

Reprints. Reprints of articles must be ordered from the Publishers, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63141, who will send their schedule of prices. Individual reprints of an article must be obtained through the author.

PUT PATIENT DISCOMFORT ON ICE



Cryosurgery with Dynatech Instruments is fast, safe, simple — and highly effective in the treatment of hemorrhoids, cervicitis, cervical erosion, condylomata, cysts, polyps, verrucae and other superficial skin lesions. This type of treatment is odorless, smokeless and virtually painless, causing little or no trauma, bleeding or scarring.

Dynatech provides a wide range of interchangeable probes. . . a choice of models. . . handsome styling to enhance the professional appearance of any office. Meticulous engineering of every component, along with strict quality control during each step of manufacture, makes Dynatech cryosurgical instruments so reliable that they alone carry a full 18-month warranty.

*(*Postal Union of the Americas and Spain)*

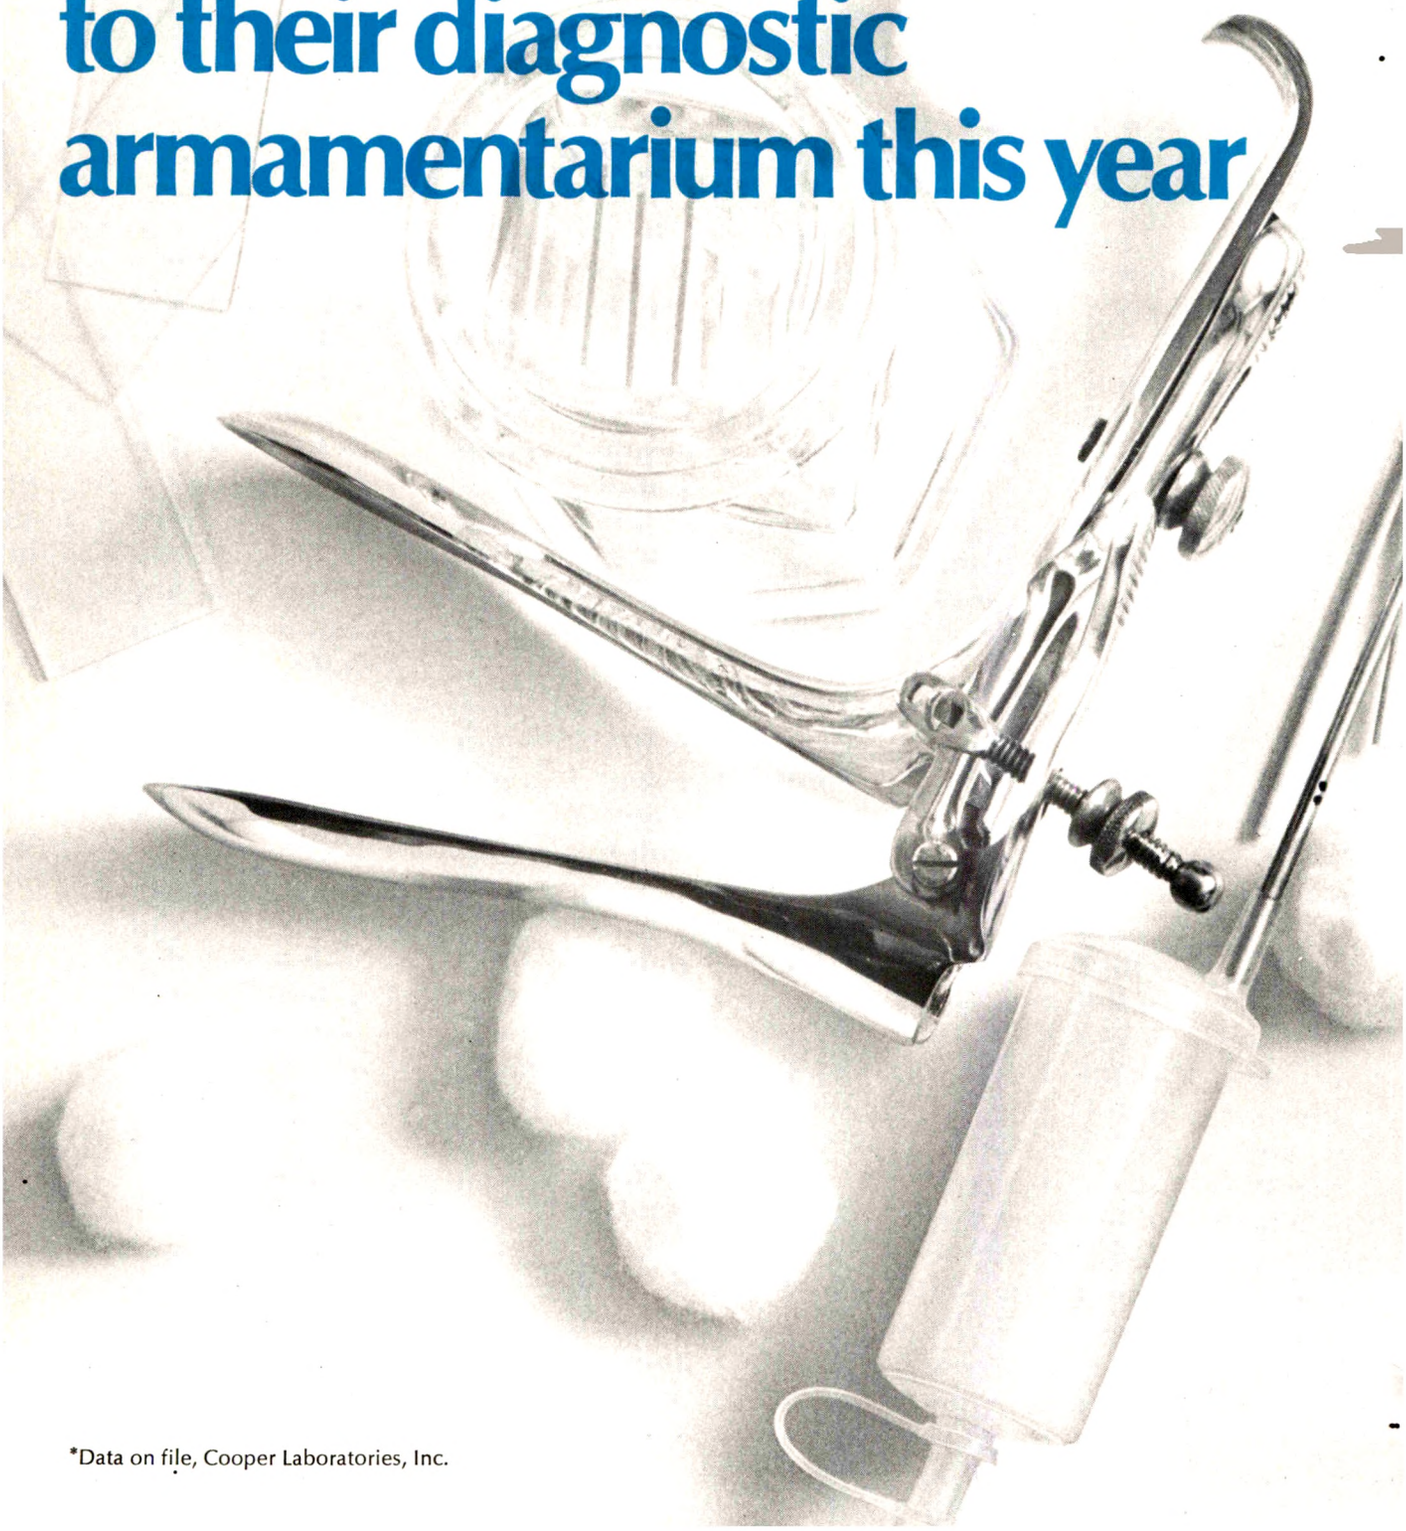
Single copies are $3.50 postpaid. Remittances should be made by check, draft, or post office or express money order, payable to this Journal.

**Institutional (multiple-reader) subscriptions are available to public and private libraries, schools, hospitals, and clinics; city, county, state, provincial, and national government bureaus and departments; and all commercial and private institutions and organizations.

†Personal subscriptions and all student-rate subscriptions must be in the names of, billed to, and paid by individuals. All student-rate requests must indicate training status and name of institution.

Publication order. The semimonthly issues of this Journal form three volumes per year; the index is in the last issue of the volume—in the April 15, August 15, and December 15 issues.

Change of address notice. Six weeks' notice is required to effect a change of address. Kindly give the exact name under which a subscription is entered, the name of this Journal, and the full form of both old and new addresses, including the ZIP code number.



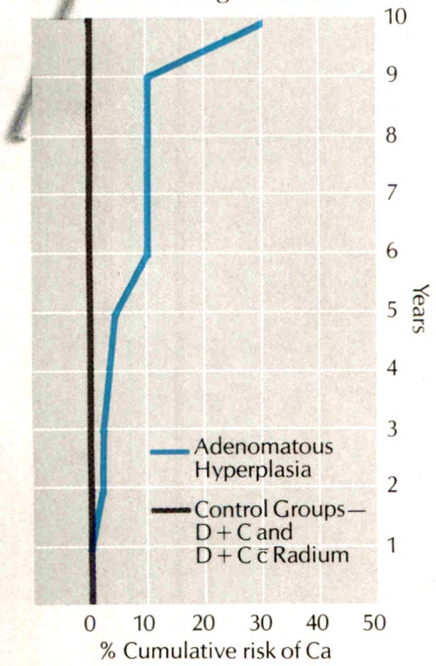
Advertisements. Forms close 25th of second previous month for the 1st of month issue; 15th of preceding month for the 15th of month issue. Advertising rates and page sizes will be given on application. Neither the Editor(s) nor the publisher guarantee, warrant, or endorse any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

Bound volumes. Publishers' Authorized Bindery Service, 4440 West Roosevelt Road, Chicago, Illinois 60624, will quote prices for binding complete volumes in permanent buckram.

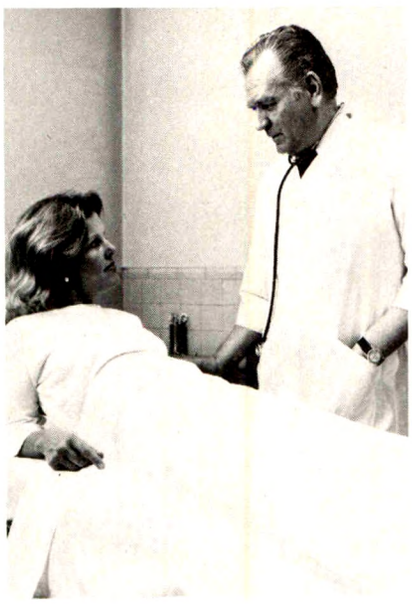
Published semimonthly

Subscriptions may begin at any time.

More than 2000* practices, clinics, and hospitals added the Vabra® Aspirator to their diagnostic armamentarium this year



*Data on file, Cooper Laboratories, Inc.



Detection of premalignant endometrial lesions

Endometrial carcinoma—its incidence is increasing, its control is dependent on early detection of the premalignant stage. Specifically, control is dependent on early detection of adenomatous hyperplasia, encountered most frequently in perimenopausal women with dysfunctional bleeding, and for some time now recognized as a high-risk factor for later invasive malignancies (see chart).

Probability of Ca of corpus after adenomatous hyperplasia[1]
At the end of the seventh year, the percentage of Ca in the Hyperplasia Group is statistically different from the percentage of Ca in the Control Groups at the .01 level of significance.

The Papanicolaou smear yields a cytologic sample, frequently unreliable in diagnosing adenomatous hyperplasia. However, until recently, the only way of obtaining a reliable histologic diagnosis was by dilatation and curettage—a hospital procedure which obviously cannot be part of a routine gynecological checkup. As a result, all too frequently, diagnosis of endometrial carcinoma came only when the survival rate was already compromised.

Routine in-office/OPD histologic screening

Today the gynecologist can add the Vabra Aspirator to his routine diagnostic procedures. It is a sterile, disposable vacuum curette which permits rapid,[2] *routine* in-office/OPD histologic screening for endometrial carcinoma and its precursors. The Vabra technique is reliable and accurate—investigators report diagnostic correlations ranging from 90 to 100 per cent between aspiration and conventional D&C.[2,5,6] The procedure has been found to be safe,[3,4,6] and tolerance of the procedure by patients is good to excellent.[2] Return to normal activities is rapid.[2]

No anesthetic risk, no costly hospitalization

The benefits of Vabra aspiration to patients are obvious—low cost, no anesthetic risk, no psychological trauma of hospitalization. Future lay-acceptance of the procedure as a standard part of a routine gynecological checkup is destined to be high.

To obtain additional information on the Vabra Aspirator, write to:
Cooper Laboratories, Inc.
Parsippany, New Jersey 07054
Att: Vabra Professional Services Department

Description: The Vabra Aspirator is a sterile, disposable unit consisting of a stainless steel aspiration cannula and a collecting chamber. Proximally on the cannula are two pressure-control holes of 1.5 mm. diameter. The aspiration cannula has a diameter of 3 mm. and is slightly curved at the end. It has a cut-out opening of 1.5 mm. x 16 mm. a few mm. from the distal end. The aspirate is collected in a plastic container, fitted with a fine mesh to prevent the aspirate from being withdrawn while the vacuum pump is in operation.

Indications: Uterine curettage—diagnostic.

Caution: Do not resterilize or reuse this unit. Federal law restricts sale of this device to order of a physician.

Supply: Each Vabra Aspirator is packaged in a box containing the sterile unit in an envelope. Full instructions for use are supplied with each unit.

Vabra® Aspirator

For early diagnosis of endometrial carcinoma

Cooper Laboratories, Inc.
Wayne, New Jersey 07470

904-19/COS-147

Nearly everybody believed that a very low dose oral contraceptive automatically meant a high incidence of breakthrough bleeding.

11,085 cycles later...

LO/OVRAL®

averaged only 3.9% breakthrough bleeding in total cycles.

Combination oral contraceptive—low estrogen and low progestogen.

Unsurpassed contraceptive effectiveness.

Extremely low incidence of minor side effects.*

Ready acceptance.

Convenient dosage in easy-to-use Pilpak® dispenser.

Low dose oral contraceptive—no other combination is more effective

Despite the fact that LO/OVRAL contains only 0.3 mg. norgestrel and 0.03 mg. ethinyl estradiol, contraceptive effectiveness is comparable to that of higher-dosage combinations. In clinical trials with LO/OVRAL encompassing 1,287 patients for a total of 11,085 cycles, only one pregnancy was reported. By Pearl's formula, this is a pregnancy rate of 0.12 per 100 woman-years' usage.

Minor side effects—even breakthrough bleeding—have been remarkably infrequent

In clinical trials the incidence of breakthrough bleeding in the initial cycle was only nine percent. And even that low incidence decreased to an average of only 3.9 percent as cycles progressed.

Incidence of Breakthrough Bleeding in Premarketing Clinical Trials

Cycle	1	3	6	12	Total Cycles 11,085
Breakthrough Bleeding	9.0%	3.5%	2.7%	2.6%	3.9%

Acceptance has been excellent

The low incidence of minor side effects has resulted in ready acceptance of LO/OVRAL by the great majority of patients. Patient complaints have been infrequent. Only eight percent of women participating in clinical trials discontinued LO/OVRAL because of common side effects.

Steroidal balance and norgestrel make the difference

Although total steroids in LO/OVRAL are reduced by 40 percent, the time-proved progestogen-estrogen ratio of OVRAL** is retained. This, together with norgestrel's distinctive qualities, is largely responsible for the patient comfort and acceptance experienced to date. Unlike other progestogens in current use, norgestrel is non-estrogenic, is apparently not converted to estrogen *in vivo* and closely resembles natural progesterone in its progestogenic activity.

Simple to take

The dosage regimen with LO/OVRAL is convenient and easy to follow: 3 weeks on, 1 week off. The attractive, uncomplicated Pilpak® dispenser helps patients follow the right dosage schedule.

*Serious as well as minor adverse reactions have been reported following the use of all oral contraceptives. The physician should remain alert to their earliest manifestations and in the event of serious adverse reactions should avoid any oral contraceptives. *Special note, contraindications, warnings, precautions and adverse reactions* in the accompanying IN BRIEF should be carefully considered.

**OVRAL® each tablet contains 0.5 mg. norgestrel with 0.05 mg. ethinyl estradiol, Wyeth.

Important information on next page.

Wyeth Laboratories
Philadelphia, Pa 19101

LO/OVRAL®

each tablet contains 0.3 mg. norgestrel with 0.03 mg. ethinyl estradiol, Wyeth

Low dose oral contraceptive.

IN BRIEF:

SPECIAL NOTE: Oral contraceptives have been marketed in the United States since 1960. Reported pregnancy rates vary from product to product. The effectiveness of the sequential products appears to be somewhat lower than that of the combination products. Both types provide almost completely effective contraception.

An increased risk of thrombotic, thromboembolic and cerebral-vascular disease associated with the use of hormonal contraceptives has been shown in studies conducted in both Great Britain and the United States. Other risks, such as those of elevated blood pressure and reduced tolerance to carbohydrates, have been reported, and appropriate tests should be conducted to monitor these during oral-contraceptive therapy. Liver disease has also been reported, and the physician should be alert to its earliest manifestations.

Long-term administration of both natural and synthetic estrogens in subprimate animal species in multiples of the human dose increases the frequency for some animal carcinomas. These data cannot be transposed directly to man. The possible carcinogenicity due to the estrogens can neither be affirmed nor refuted at this time. Close clinical surveillance of all women taking oral contraceptives must be continued.

INDICATIONS: For oral contraception.

CONTRAINDICATIONS: 1. Thrombophlebitis, thromboembolic disorders, cerebral-vascular disease, or a past history of these conditions; 2. Markedly impaired liver function; 3. Known or suspected carcinoma of the breast; 4. Known or suspected estrogen-dependent neoplasia; 5. Undiagnosed abnormal genital bleeding; 6. Known or suspected pregnancy.

WARNINGS: 1. The physician should be alert to the earliest manifestations of thrombotic and thromboembolic disorders, thrombophlebitis, cerebrovascular disorders including hemorrhage, pulmonary embolism and retinal thrombosis. Should any of these occur or be suspected, the drug should be discontinued immediately.

Retrospective studies of morbidity and mortality in Great Britain and studies of morbidity in the United States have shown a statistically significant association between thrombophlebitis, pulmonary embolism and cerebral-vascular disease, occlusive or hemorrhagic, and the use of oral contraceptives. There have been three principal studies in Great Britain[1-3] leading to these conclusions and three[4-7] in this country. The estimate of the relative risk of thromboembolism in the study by Vessey and Doll[3] was about sevenfold, while the United States studies found relative risks of 4.4 to 11, meaning that the users are several times as likely to undergo thromboembolic disease without evident cause as non-users.

In May, 1974, the Royal College of General Practitioners in England[8] issued an interim report of its continuing large-scale prospective study comparing a user group to a non-user group. This study in its interim analysis states: "A statistically significant higher rate of reporting of cerebrovascular accidents in Takers is evident, but the numbers are too small to justify an estimation of the degree of risk." The study also reported a higher incidence of superficial and deep vein thrombosis in users as compared to non-users.

The Sartwell study[4] indicated that the risk did not persist after discontinuation of administration. Both the Sartwell and the Royal College study indicated that the degree of risk was not associated with duration of treatment.

In a collaborative American study[5,6] of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the relative risk of thrombotic stroke was 4.1 to 9.5 times greater in users than in non-users. A comparable estimate for hemorrhagic stroke was 2.0.

None of the American studies was designed to evaluate a difference between products. However, the Sartwell study[4] suggested that there might be an increased risk of thromboembolic disease in users of sequential products.

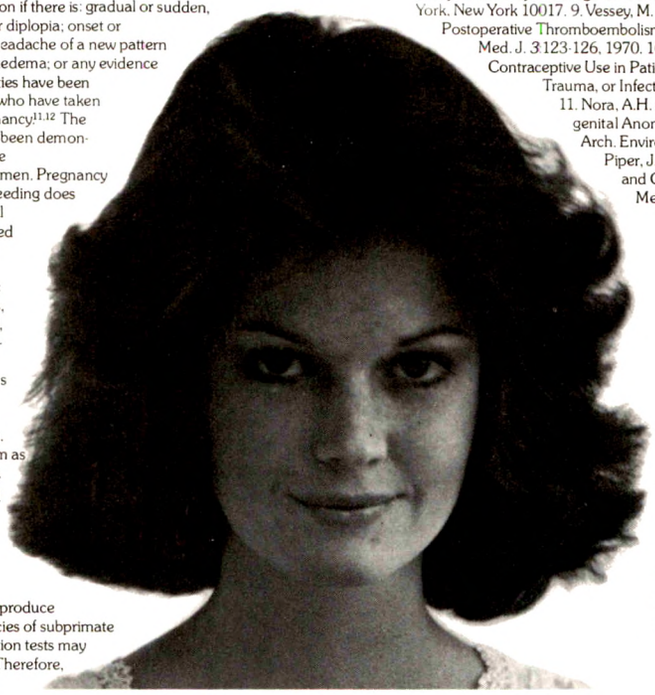
Other retrospective studies[9,10] have reported an increased risk of post-surgery thromboembolic complications in oral-contraceptive users. It has been recommended that therapy be discontinued at least one month prior to elective surgery.

2. Discontinue oral-contraceptive medication if there is: gradual or sudden, partial or complete loss of vision; proptosis or diplopia; onset or aggravation of migraine or development of headache of a new pattern which is recurrent, persistent or severe; papilledema; or any evidence of retinal-vascular lesions. 3. Fetal abnormalities have been reported to occur in the offspring of women who have taken progestogens and/or estrogens during pregnancy[11,12] The safety of LO/OVRAL® in pregnancy has not been demonstrated. Pregnancy should be ruled out before initiating or continuing the contraceptive regimen. Pregnancy should always be considered if withdrawal bleeding does not occur. 4. A small fraction of the hormonal agent in oral contraceptives has been identified in the milk of mothers receiving these drugs. The long-range effect to the nursing infant cannot be determined at this time. 5. Hepatic lesions (adenomas, hepatomas, hamartomas, regenerating nodules, etc.), occasionally fatal, have been reported in women on oral contraceptives. Such lesions may present as an abdominal mass or with the signs and symptoms of an acute abdomen. These lesions should be considered if the patient has abdominal pain or evidence of intra-abdominal bleeding. Such lesions have been reported in short-term as well as long-term users of oral contraceptives.

PRECAUTIONS: 1. A thorough history and physical examination should be performed before prescribing oral contraceptives and periodically during their administration and should include special reference to breasts and pelvic organs including Papanicolaou smears, since estrogens have been known to produce tumors, some of them malignant, in five species of subprimate animals. 2. Endocrine and possibly liver-function tests may be affected by treatment with LO/OVRAL® Therefore, if such tests are abnormal in a patient taking LO/OVRAL® it is recommended that they be repeated after the drug has been withdrawn for two months. 3. Under the influence of estrogen-progestogen preparations, pre-existing uterine fibromyomata may increase in size. 4. Because these agents may cause some degree of fluid retention, conditions which might be influenced by this factor, such as epilepsy, migraine, asthma, cardiac or renal dysfunction, require careful observation. 5. In breakthrough bleeding, and in all cases of irregular bleeding per vaginam, nonfunctional causes should be borne in mind. In undiagnosed bleeding per vaginam, adequate diagnostic measures are indicated. 6. Patients with a history of psychic depression should be carefully observed and the drug discontinued if the depression recurs to a serious degree. 7. Any possible influence of prolonged LO/OVRAL® therapy on pituitary, ovarian, adrenal, hepatic or uterine function awaits further study. 8. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. The mechanism of this decrease is obscure. For this reason, diabetic patients should be carefully observed while receiving LO/OVRAL® therapy. 9. The age of the patient constitutes no absolute limiting factor, although treatment with LO/OVRAL® may mask the onset of the climacteric. 10. The pathologist should be advised of LO/OVRAL® therapy when relevant specimens are submitted. 11. Susceptible women may experience an increase in blood pressure following administration of contraceptive steroids. 12. Cholestatic jaundice has been reported in users of oral contraceptives. If this occurs, LO/OVRAL® should be discontinued. This condition is more likely to occur in patients who have experienced cholestatic jaundice of pregnancy. Patients with a history of cholestatic jaundice of pregnancy should be carefully observed during LO/OVRAL® therapy.

ADVERSE REACTIONS OBSERVED IN PATIENTS RECEIVING ORAL CONTRACEPTIVES: A statistically significant association has been demonstrated between use of oral contraceptives and the following serious adverse reactions: thrombophlebitis, pulmonary embolism, cerebral thrombosis and hemorrhage, gall bladder disease.

Although available evidence is suggestive of an association, such a relationship has been neither confirmed nor refuted for the following serious adverse reactions: neuro-ocular lesions, e.g., retinal thrombosis, optic neuritis and hepatic lesions with or without intra-abdominal bleeding.



The following adverse reactions are known to occur in patients receiving oral contraceptives: nausea, vomiting, gastrointestinal symptoms (such as abdominal cramps and bloating), breakthrough bleeding, spotting, change in menstrual flow, amenorrhea during and after treatment, edema, chloasma or melasma, which may persist, breast changes: tenderness, enlargement and secretion, change in weight (increase or decrease), changes in cervical erosion and cervical secretions, suppression of lactation when given immediately post-partum, cholestatic jaundice, migraine, rash (allergic), rise in blood pressure in susceptible individuals, mental depression.

Although the following adverse reactions have been reported in users of oral contraceptives, an association has been neither confirmed nor refuted: anovulation post treatment, which tends to occur more frequently in women with a history of menstrual disorders, premenstrual-like syndrome, changes in libido, changes in appetite, cystitis-like syndrome, headache, intolerance to contact lenses, nervousness, dizziness, fatigue, backache, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, itching and vaginitis.

The following laboratory results may be altered by the use of oral contraceptives: hepatic function; increased sulfobromophthalein retention and other tests; coagulation tests; increase in prothrombin, Factors VII, VIII, IX and X; decrease in antithrombin III; increase in platelet aggregability; thyroid function: increase in PBI, and butanol extractable protein-bound iodine and decrease in T^3 uptake values; metyrapone test; and pregnanediol determination.

NOTE: For more specific details on LO/OVRAL, refer to package insert.

CLINICAL OPINION

This section reports opinion on the handling of clinical situations, i.e., the clinical diagnosis and management of certain disease entities. Papers should range from eight to twenty typed pages, including illustrations, tables, and figures which clarify the author's management. References are limited to six citations. Mail to Frederick P. Zuspan, M.D., Editor.

Management of the hyperextended fetal head

E. DAW

Dundee, Scotland

Hyperextension of the fetal head in utero is readily detectable by roentgenography and ultrasound scan. Management is determined by presentation of the fetus. There are three types of presentations: face presentation, star-gazing breech presentation, and the flying fetus presentation. Undiagnosed hyperextension of the fetal head is frequently associated with cervical cord injury.

HYPEREXTENSION of the fetal head in utero gives rise to characteristic roentgenographic and ultrasound scan appearances, and the management of the individual case will depend initially upon this diagnosis and subsequently depending upon several other factors. The presentation of the fetus is important in this condition: If the head is presenting, the appearances are those of "face" presentation; if the breech is presenting, the appearances are those of a "star-gazing" breech presentation; if the fetus is lying transversely, the appearance is that of the "flying fetus" presentation. These three presentations are illustrated graphically in Figs. 1 to 3. In this paper I wish to review and discuss recent changes in management of these conditions.

Reprint requests: Dr. E. Daw, Lecturer, Department of Obstetrics and Gynaecology, Ninewells Hospital, The University of Dundee, Dundee DD2 1UD, Scotland.

Classification

Face presentation (Fig. 1) may be further subdivided into mentolateral, mentoposterior, and mentoanterior presentations, depending upon the relationship of the chin of the fetus to the pelvic inlet. As the head is not relative to the pelvis with a star-gazing breech presentation (Fig. 2), no subdivision of this group is made, and the breech presentation is classified as usual, depending upon whether the legs are extended or flexed. Hyperextension of the fetal head with the flying fetus (Fig. 3) is associated with extension of the fetal arms and spine and partial extension of the fetal legs. This attitude of the fetus is quite characteristic and obviously different from "transverse lie" of the fetus with

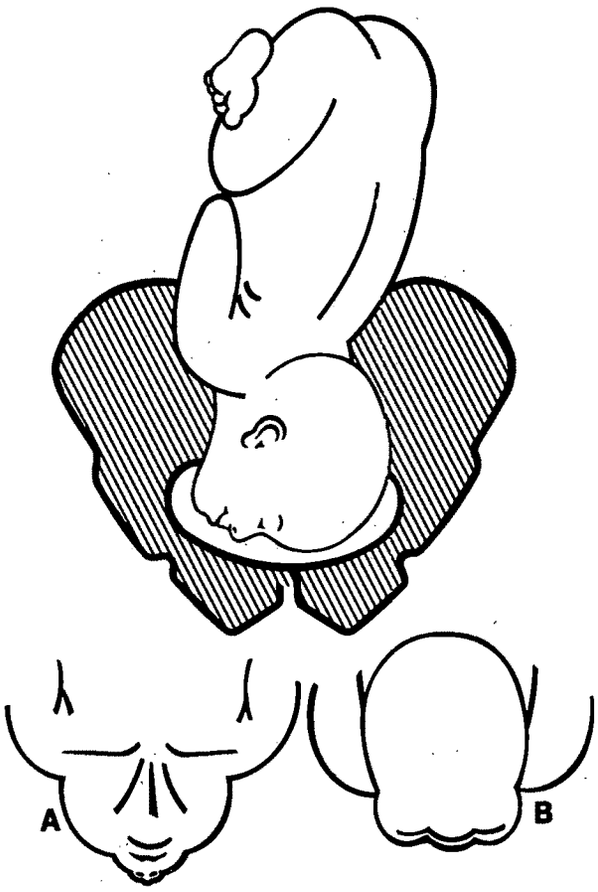

Fig. 1. Face presentation (mentolateral) with mentoanterior *(A)* and mentoposterior *(B)* variations.

generalized flexion of the fetus and the back either upward or downward.

Incidence

Face presentation has the commonest incidence, occurring approximately in one of every 500 hospital cases. The star-gazing breech and the flying fetus presentations occur so infrequently that one cannot give an accurate incidence.

Complications

The relationship between intrauterine hyperextension of the fetal head and subsequent cervical cord injury during vaginal breech delivery is now established.[3] The usual site of injury is the lower cervical region, and the injury frequently escapes notice because of no associated bony damage. The three clinically recognizable groups of injury are: (1) either stillbirth or sudden death of the infant soon after delivery; (2) survival of the infant for a short period, in shock, with respiratory depression and secondary changes in the lungs similar to those with hyaline membrane disease; (3) survival of the infant with

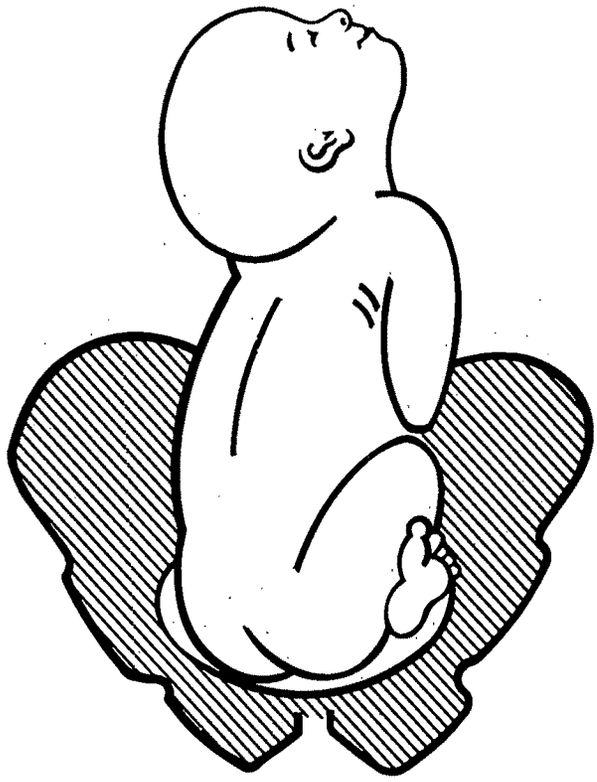

Fig. 2. Star-gazing breech presentation.

transient or permanent paralysis and spasticity. Bhagwanani and associates[1] thought that even with the use of average traction the sudden extreme flexion of the head and cervical spine, which is so much a part of vaginal breech delivery, was sufficient to damage the vulnerable spinal cord. The resulting flexion injury is similar to the rotational injury occasionally seen with forceps delivery.[6] The lesions are similar macroscopically and microscopically with no obvious bony injury, but the rotational injury is usually at a higher level (at the level of the second cervical vertebra). A recent review of the literature[3] shows the degree of protection afforded the infant in the star-gazing breech presentation when delivery is effected by cesarean section.

Diagnosis

Hyperextension of the fetal head is often not diagnosed until labor has commenced; however, in many cases, some abnormality was suspected during the antenatal period but this was not followed up by radiography or ultrasound scan. A high presenting part or a persistent abnormality, such as a transverse lie on abdominal palpation, merits further investigation such as ultrasound scan or x-ray in the later weeks of pregnancy. During labor, transverse lie or a persistently high presenting part on abdominal examination also merits such investigation.

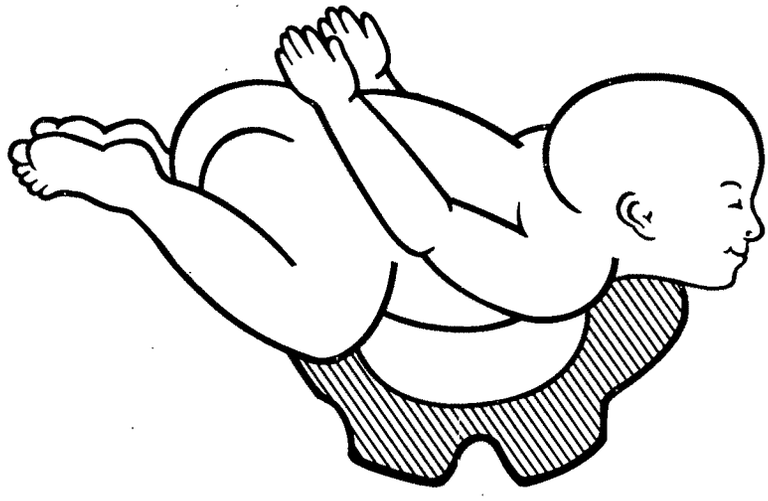

Fig. 3. Flying fetus presentation.

On vaginal examination in the later weeks of pregnancy the high presenting part may not be reached, but classically, with a patient in labor, the forewaters are sausage-shaped with the presenting part high and indistinct.

Ultrasound scan has an advantage over radiography in that neck tumors may be detected, but, as Bhagwanani and associates[1] concluded, "Radiologic evidence of hyperextension of the fetal head . . . after labor is established seems to be an indication for cesarean section unless there is gross fetal deformity. The remote possibility of an abnormality that is radiologically undetectable should not discourage an obstetrician."

Management of delivery

As *face presentation* is more common than the other two, most units will have a policy for dealing with this condition; therefore, I will only list some principles of management of delivery.

1. Exclusion of fetal abnormality, particularly anencephaly, by x-ray or ultrasound scan is of paramount importance. If the fetus appears normal, primary face presentation may be left alone until labor starts.

2. Once labor starts, if the face presentation persists and if pelvic contraction is suspected or if the fetus is unduly large, or if there is a suspicion of placenta previa or any other condition putting the fetus "at risk," cesarean section delivery is indicated.

3. In the remaining cases of face presentation, the position of the chin as the head descends into the pelvis then becomes important; as a rule, mentoposterior face presentation undoubtedly indicates cesarean section.

4. In areas where the perinatal mortality rate is low because there are facilities for rapid intervention, *heroic* obstetric interference, with its high potential injury to the fetus, is avoidable. However, manipulative procedures such as Thorn's maneuver, or internal version and breech extraction may be necessary where facilities for rapid intervention are not available.

In the absence of evidence of gross fetal abnormality, the *flying fetus* presentation is best managed by elective cesarean section. Prolapse of the cord during labor is an obvious complication in this condition, but, should full dilatation of the cervix occur, the problem of reaching the extended lower limbs for internal version is also real.

Most recent reports and reviews have shown that after labor is established in the absence of evidence of gross fetal abnormality the *star-gazing breech* presentation is best managed by elective cesarean section. Taylor[7] has pointed out that the safest method for delivery of the term infant presenting as a breech is by cesarean section; this is true for the infant in a star-gazing breech presentation even before term.

GYNECOLOGY

A comparison between gonadotropin radioimmunoassays with the use of 48 hour and six-day incubation methods

THOMAS S. KOSASA, M.D., C.M.
IRWIN E. THOMPSON, M.D.
WILLIAM B. BYER, B.A.
MELVIN L. TAYMOR, M.D.
Boston, Massachusetts

A double-antibody radioimmunoassay for human follicle-stimulating hormone (FSH) and human luteinizing hormone (LH) which can be carried to completion in 48 hours was compared with the conventional six-day double-antibody radioimmunoassay. The bound-over total (B/T) dose response curves for the 48 hour assay were comparable in slope and dose range with the six-day assay and the four per cent average within-assay and the nine per cent between-assay coefficients of variation for the 48 hour assay were comparable with the variation observed in the conventional six-day assay. Maximum variation among identical serum samples assayed in both systems was 15.3 per cent so that quantitative results obtained with either assay system were comparable.

IN THE MOST commonly used double-antibody radioimmunoassay method, an immunoprecipitating serum or second antibody to precipitate soluble antigen-antibody complexes is used. This technique is stable, sensitive, precise, and offers reliability and reproducibility.[1] It is known that a period of incubation of sufficient length is required to ensure that the reaction reaches equilibrium. This has been shown to be a matter of days, and not hours, to ensure completion.[1] Results can be obtained more rapidly but only at the expense of using considerably higher concentrations of antibody to bind labeled hormone, thus compromising sensitivity.[1] This appears to be true if the complete reaction is carried out at four degrees C.

Recently a radioimmunoassay with the use of the double-antibody technique has been reported which requires only 36 to 48 hours for completion.[2, 3] This method was first described for the human chorionic gonadotropin–B (HCG-B) subunit assay but has also been used successfully for several years for human follicle-stimulating hormone (FSH) and human luteinizing hormone (LH).[4]

Because of the consistently sensitive and reproducible results obtained with a HCG-B subunit assay, it was decided that the shorter incubation methodology for FSH and LH assays should be used. A prospective study was initiated with half of the assays with the use of the 48 hour incubation method, and half with the use of the six-day incubation.

Material and methods

Hormone preparations.

Human chorionic gonadotropin. Highly purified HCG was obtained from Serono Pharmaceuticals (Rome, Italy). This purified HCG had a biological activity of 12,000 to 18,000 I.U. per milligram and a radioimmunologic activity of 6,000 to 7,000 I.U. per milligram Second International Reference Preparation of HCG.

Anti-HCG antiserum was generated in rabbits and was found to be sufficiently specific for HLH for purposes of radioimmunoassay.

Human follicle-stimulating hormone. Purified pituitary FSH (LER-1366) for purposes of iodination was provided by the National Pituitary Agency through the Hormone Distribution Officer, National Institute of Arthritis and Metabolic Disease.

Anti-FSH Batch No. 3 was obtained through the courtesy of the National Pituitary Agency.

The standard curve for each assay was made up from a commercial preparation of human menopausal gonadotropin* (HMG) previously assayed against the Second International Reference Preparation of Human Menopausal Gonadotropin and consisted of eight serial dilutions from 5 mI.U. per milliliter to 640 mI.U. per milliliter.

Iodination. The iodination procedure utilized has been described previously.[3] Fresh columns were always prepared on the day of iodination. A 5 × 0.5 cm. column bed of Biogel P-10 (Bio Rad Labs, Richmond, California) was prepared by washing three to four times with 0.01M phosphate-buffered saline (PBS), followed by 1.5 ml. of two per cent bovine serum albumin (Sylvana Co., Milburn, New Jersey). A final washing with two columns of 0.01M PBS was done before the column was ready for the iodinated mixture. All iodinations were carried out at room temperature.

Human chorionic gonadotropin. Two millicuries of low–specific activity $Na^{125}I$ (Amersham/Searle, Chicago, Illinois) was added to 4 μg of highly purified HCG dissolved in 0.025 ml. of 0.4M Na phosphate buffer pH 7.5. Chloramine-T (0.01 ml. of a 25 mg. per 10 ml. solution of 0.01M PBS) was added to the hormone. Sodium metabisulfite (0.025 ml. of a 25 mg. per 10 ml. solution of 0.01M PBS) was used to stop the reaction after two minutes. After ten seconds of mixing the mixture was added to the column and collected in 0.5 ml. aliquots. To the peak tube was added 0.05 ml. of two per cent bovine serum albumin in 0.01M PBS and 0.5 ml. of 0.01M PBS. The iodinated hormone was stored at 4 degrees C. Specific activities for HCG ranged from 140 to 240 μc per microgram.

Human follicle-stimulating hormone. Low–specific activity $Na^{125}I$, one millicurie was added to 2 μg of FSH (LER-1366) dissolved in 0.025 ml. of 0.4M Na phosphate buffer. Chloramine-T and sodium metabisulfite were used in the same concentrations described for HCG except the reaction mixture was stopped after 20 seconds. Specific activities for FSH ranged from 130 to 224 μc per microgram.

Radioimmunoassay. The following reagents, added to a 10 × 75 mm. disposable glass tube to make a final volume of 1 ml., were used in the radioimmunoassay for LH: (1) buffer containing 0.01M PBS and one per cent egg whites; (2) 0.2 ml. of serum to be assayed or 0.2 ml. of standard in buffer; (3) 0.2 ml. of anti-HCG antisera (1:100,000 final tube dilution) in 0.05 M ethylenediamine tetra-acetic acid (EDTA), 0.01M sodium phosphate, 0.14M sodium chloride, pH 7.0, and 1:400 normal rabbit serum; (4) 0.1 ml. of ^{125}I-HCG containing 0.1 μg of hormone with counts ranging from 14,000 to 24,000 c.p.m. depending on the specific activity, (5) 0.2 ml. of sheep anti-rabbit gamma globulin (RGG).

The reagents used in the radioimmunoassay for FSH were the same as those used in the assay for LH except that 0.2 ml. of anti-FSH antisera (1:15,000 final tube dilution Batch No. 3 NPA) and 0.1 ml. of ^{125}I-FSH (13,000 to 22,000 c.p.m.) were used.

Standard curves for all the assays contained the appropriate amount of antigenic hormone in one per cent egg white buffer but contained no serum or plasma.

Procedure.

48 Hour assay. Antisera, iodinated hormone, buffer, and the serum to be assayed were incubated in a 37 degree C. water bath for two hours. After removal from the water bath the samples were incubated at four degrees C. for 22 hours. Second antibody (sheep antirabbit gamma globulin) was added and the mixture incubated at four degrees C. for an additional 24 hours to achieve separation of bound antibody from free labeled hormone. Tubes were centrifuged at 3,000 r.p.m. for 20 minutes on a Sorval RC-2 centrifuge, and the supernatant was aspirated by suction. The precipitate was counted in an automatic well-type gamma counting system (Searle Analytic, Chicago, Illinois).

Six-day assay. The method used for this study was based on the procedure as described by Midgely and Jaffe.[5, 6] Antisera, buffer, and the serum to be assayed were incubated at four degrees C. for 24 hours. Iodinated hormone was added and the mixture

*Pergonal, Serono Laboratories, Boston, Massachusetts.

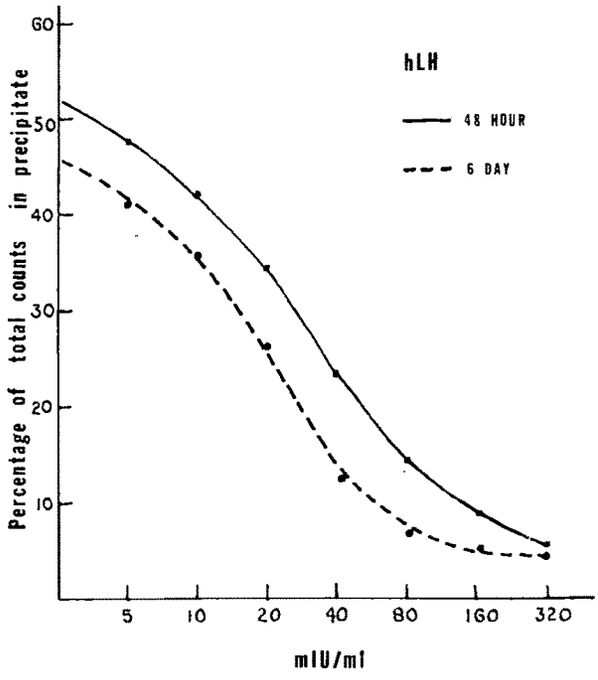

Fig. 1. Comparison of standard curves for LH with the use of a 48 hour versus a six-day incubation methodology. First antibody was used at 1:100,000 final tube dilution for both systems.

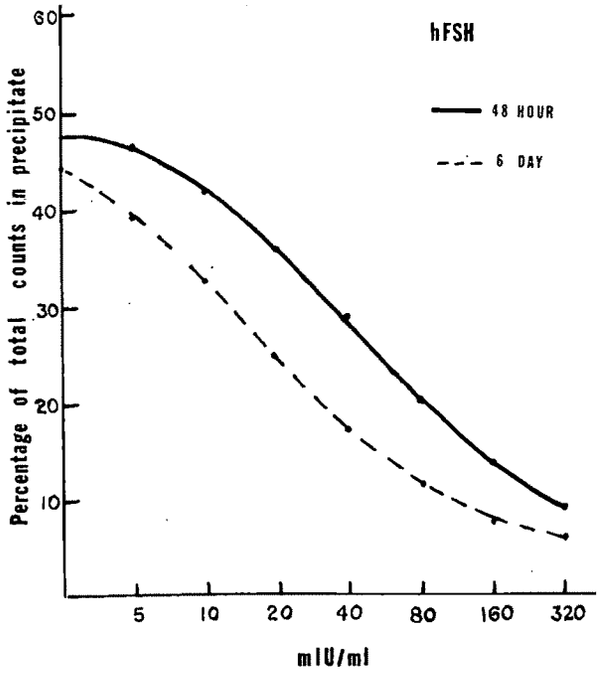

Fig. 2. Comparison of standard curves for FSH with the use of a 48 hour versus a six-day incubation methodology. First antibody was used at 1:15,000 final tube dilution for both systems.

incubated at four degrees C. for 24 hours. Second antibody was then added and incubation carried out at four degrees C. for 96 hours. Tubes were then centrifuged, aspirated, and counted by use of the procedure described for the 48 hour assay.

In both the 48 hour assay and the six-day assay, the assay tubes were identical with respect to antibody dilution, buffer solutions, and iodinated hormone.

Analysis of radioimmunoassay results. All radioimmunoassay data were analyzed by a computer program (Lee, E. Y., and Kosasa, T. S., in preparation). Analysis began with the percentage binding being expressed as: Y = B (Counts bound in the presence of labeled and unlabeled ligand) − background counts, divided by B_0 (Counts bound in the presence of labeled ligand alone) − background counts. The relation between Y and the log (dose) for the standard curve was analyzed through two different approaches. The first was the linear regression of logit (Y) on the log dose and the second was a curvilinear fitting of Y as a quartic polynomial of the log (dose). The standard error of fitting was then calculated for each approach and the program automatically used the approach which was associated with the least amount of error. An inverse transformation was performed on the surviving functional relation to obtain log (dose) as a function of Y. Unknown samples were then claculated from this standard curve and the results expressed in milli-international units per milliliter.

Results

In a six-month period over 2,000 assay tubes for FSH and 2,000 assay tubes for LH were determined with the use of a 48 hour incubation method. During the same time period a comparable number of assay tubes were determined for FSH and LH with the use of the six-day incubation method. A consistent finding in both the FSH and LH assays was the higher binding of tracer antigen observed with the same dilution of antisera in the 48 hour assay. The bound counts in the LH zero standard tubes B_0 (amount bound in the absence of unlabeled antigen) in the 48 hour assays were 4.2 to 8.6 per cent higher than the zero standard tubes in the comparison six-day assays. The zero standard tubes in the 48 hour FSH assays were two to 12.2 per cent higher than those in the comparison of six-day assays (Figs. 1 and 2).

The within-assay coefficient of variation for the 48 hour assay was four per cent and the between-assay coefficient of variation nine per cent as compared with three per cent within assay and seven per cent between assay for the six-day assay.

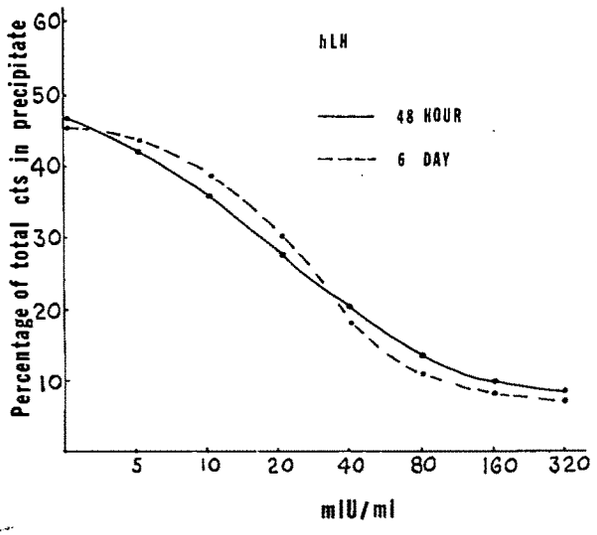

Fig. 3. Comparison of standard curves for LH with the use of a 48 hour versus a six-day incubation methodology. First antibody was used at 1:150,000 for the 48 hour assay and 1:100,000 for the six-day assay.

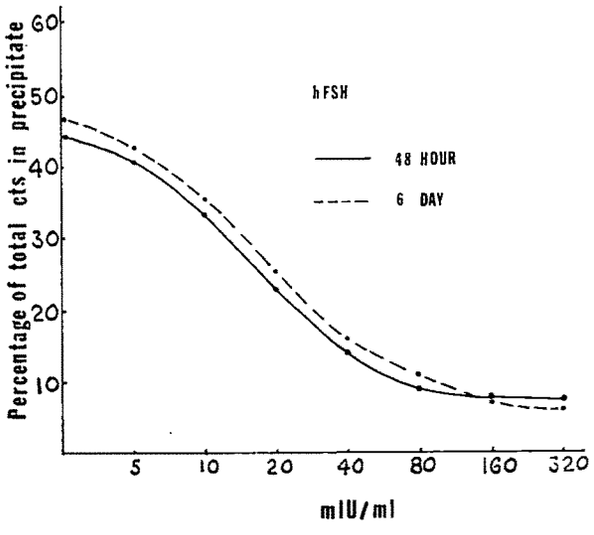

Fig. 4. Comparison of standard curves for FSH with the use of a 48 hour versus a six-day incubation methodology. First antibody was used at 1:20,000 for the 48 hour assay and 1:15,000 for the six-day assay.

Eight identical serum samples from a post-menopausal pool were included in every assay to compare any quantitative differences between the 48 hour and six-day incubation methods. The average of the pool for LH was 90.6 mI.U. per milliliter and that for FSH was 112.6 mI.U. per milliliter. Differences among these samples in the 48 hour and six-day assay systems were 2.9 mI.U. per milliliter to 12.2 mI.U. per milliliter in ten consecutive assays for LH and 1.0 to 11.4 mI.U. per milliliter in ten consecutive assays for FSH.

Comment

Although it is known that some antibodies lose effectiveness when incubated at 37 degrees C., none of the antibodies used in this study appeared to be affected when incubated at this temperature. Commercial anti-HCG and anti-FSH (Calbiochem, La Jolla, California) appeared to work equally as well in both the 48 hour and six-day assays.

The parallelism between the standard curves employing the 48 hour and six-day incubation method for FSH and LH appear to indicate similar immunologic behavior for the two systems. This parallelism has been observed in a radioimmunoassay which carries out the complete reaction at 37 degrees C.[7] The slight increase in binding of the standard curves with the use of the 48 hour incubation method suggests that the first antibody could be used at a slightly greater dilution with a subsequent improvement in sensitivity when measuring sera with low levels of hormone. By use of a final anti-HCG dilution of 1:150,000 in the 48 hour assay and comparing it to the six-day assay with a dilution of 1:100,000, the standard curves are virtually indistinguishable (Fig. 3). Similar results have been shown when the anti-FSH has been reduced to a final dilution of 1:20,000 in the 48 hour assay (Fig. 4).

In this comparison study anti-RGG from our own sheep was used diluted 1:8 in PBS buffer. It was found that anti-RGG from commercial sources could be used at greater dilutions (Serono Pharmaceuticals, Rome, Italy, 1:25, and Antibodies Incorporated, Davis, California 1:32). When these commercial sources of anti-RGG were used, the precipitates in the B_0 and standard tubes were almost nonexistent in the 48 hour assay. As a result there was a frequent loss in precipitated counts from aspiration errors. In order to create an adequate precipitate to facilitate aspiration when anti-RGG from these sources was utilized, 0.1 ml. of normal sheep serum was added to the background, B_0, and standard tubes. Presently the assay tubes for the 48 hour incubation method are centrifuged at 5,000 r.p.m. for seven minutes without any appreciable differences in results.

It has been shown that identical serum samples may have differences in the quantitative results when measured by different laboratories with the use of the same standard, antisera, and incubation methods. Even greater differences in the quantitative results have been shown when the methodologies are altered.[8] Identical serum samples assayed in both the 48 hour

and six-day assays showed quantitative differences but were within an acceptable range of variation. Although the maximum coefficient of variation of 13.6 per cent for LH and 15.3 per cent for FSH between the two assay systems was greater than the maximum between-assay variation of 12 per cent for the 48 hour assay and 10.2 per cent for the six-day assay, it appeared reasonable considering the differences in methodology. The within-assay and between-assay coefficients of variation for both the 48 hour and six-day assay were comparable to the variation for the double antibody radioimmunoassay system reported by others.[9-12].

From this study it has been shown that quantitative results obtained in the 48 hour assay were comparable with those obtained in the six-day assay. The added advantage of providing a result in 48 hours rather than one week makes this assay well suited for a clinically oriented laboratory.

The authors are grateful for the technical assistance provided by Linda A. Levesque, Stephen Kirsch, William Donn Rogosin, and Susan Griffin.

The Copper T 220C: A new long-acting copper intrauterine contraceptive device

DONNA L. COOPER, M.D.
ANITA K. MILLEN, M.D.
DANIEL R. MISHELL, JR., M.D.
Los Angeles, California

The Copper T(TCu) intrauterine contraceptive device (IUD) has been found to be an effective method of contraception but has the disadvantage of needing periodic replacement due to loss of copper through dissolution and fragmentation of the copper wire. Modification of the Copper T to overcome this disadvantage involved substitution of copper sleeves for wire on the vertical arm and the addition of copper sleeves to the horizontal arms to give an effective surface area of 220 sq. mm. of copper and an estimated life span of 20 years. A randomized comparative study was undertaken in 999 women to determine if the new model performed as well as the wire-wound Copper T 300. Net cumulative first-event rates at one year were as follows: TCu 220C—pregnancy 0.9, expulsion 3.7, removal for pain or bleeding 14.4; TCu 300—pregnancy 1.1, expulsion 3.1, removal for pain or bleeding 9.3. None of the differences in event rates were significant. If long-term follow-up confirms these findings, this new long-lasting copper intrauterine device could become the IUD of choice for all women.

MANY REPORTS FROM this clinic, as well as others, have shown that the Copper T(TCu) intrauterine contraceptive device (IUD) is an effective and well-tolerated contraceptive method for both nulliparous and multiparous women.[1–3]

In addition to the extensive clinical studies of the TCu 200, various modifications in the amount of copper and its position upon the plastic have been developed and tested clinically. The TCu 300 has approximately 300 mm.^{2} copper wire wound around the vertical arm, while the TCu 380A has two 30 mm.^{2} copper sleeves placed on the horizontal arm in addition to 300+ mm.^{2} copper on the vertical arm. The disadvantage of the use of copper wire is its relatively short duration of action. Devices with copper wire need to be replaced at intervals of about three years.

To overcome this disadvantage, the International Committee for Contraception Research of The Population Council devised a new modification of the TCu, the Copper T 220C. This device has five solid copper sleeves on the vertical arm, as well as two copper sleeves on the horizontal arm of the T-shaped plastic device for a total of seven sleeves with a surface area of 220 mm.^{2} and an estimated duration of effectiveness of more than 20 years.

In order to compare the performance of this long-lasting copper IUD with the wire-wound model, a randomized comparative study of the TCu 220C and the TCu 300 was performed.

Material and methods

Between January and July, 1973, 999 TCu devices were inserted into all women attending the Family Planning Clinic of Women's Hospital who were willing to use an investigational IUD and were able to return for follow-up. The device to be inserted was chosen on the basis of the last digit of the patient's previously assigned hospital number. Patients with odd numbers

Table I. Mean and range of various aspects of total cohort data of two groups

Data	*TCu 300*	*TCu 220C*
Number inserted	516	483
Age	23.1 (14-42)	22.7 (15-45)
Gravidity	1.05 (0-9)	1.20 (0-6)
Parity	0.55 (0-9)	0.48 (0-5)
Nulliparous women	363 (70.3%)	337 (69.8%)

Table II. Mean and range of cohort data of nulliparous women in two groups

Data	*TCu 300*	*TCu 220C*
Number inserted	363	334
Age	22.3 (14-40)	22.2 (15-39)
Gravidity	0.38 (0-6)	0.34 (0-3)
Parity	0	0

received a TCu 220C. Those with even numbers received a TCu 300. A total of 463 women received the 220C and 516 the 300. All devices were inserted by family planning clinic staff physicians with the use of a modified loop inserter and push-in technique.[4]

As would be expected from this randomization, the populations using each device were similar in age, gravidity, parity, and per cent of nulliparous women (Table I). Separate analysis of nulliparous women and multiparous women separately also revealed that the groups using each device were comparable (Tables II and III). Event rates during the first 12 months' experience were calculated by life-table analysis with a computer program.[5]

Results

There was no difference noted in ease of insertion or postinsertion pain between the two devices. First segment net cumulative termination rates for the first year of use for each device are summarized for all patients in Table IV, for nulliparous patients in Table V, and for multiparous patients in Table VI. For each event rate, the 95 per cent confidence intervals of the standard error of the mean overlapped, indicating no significant difference between the two devices. The pregnancy rates at one year were about one per cent for each device. Pregnancy rates were slightly though not significantly higher among multiparous women. About 70 per cent of the nulliparous patients had never been pregnant, and a certain percentage of these women were probably infertile.

Expulsion rates at one year were less than 4.0 per 100 women in both groups with little difference between devices or between nulliparous and multiparous women. The rate of removals for pain and/or bleeding was higher for the TCu 220C than for the TCu 300, but the difference was not significant. Rates of removals for other medical reasons, planned pregnancy, and other personal reasons were also similar for the two devices.

Table III. Mean and range of various aspects of cohort data of multiparous women in two groups

Data	*TCu 300*	*TCu 220C*
Number inserted	153	146
Age	25.1 (15-42)	24.1 (15-45)
Gravidity	2.3 (1-9)	2.0 (1-6)
Parity	1.9 (1-9)	1.6 (1-5)

Over-all continuation rates at the end of one year were also similar for both devices, with rates of 79.7 and 74.9 per 100 users calculated for the TCu 300 and TCu220C, respectively. This difference in continuation rates was also not significant.

Comment

The major disadvantage of the Copper T with wire winding is the need for periodic replacement. This arises because the copper undergoes gradual dissolution in an uneven manner so that breaks in the copper wire can occur. The TCu 220C was developed to overcome this disadvantage. By substituting sleeves for wire, a much greater effective reservior of copper is achieved and the possibility of wire breakage is obviated. The TCu 220C also includes copper sleeves on the horizontal arms, which decreases the chance of fundal pregnancy because of the presence of copper in that area. This is especially important when there is downward displacement or partial expulsion of the device.

The TCu 200 device has been estimated to lose between 25 and 50μg per day of copper,[6] and Tatum[7] has recommended that these devices be replaced at three-year intervals based on the actual amount of copper remaining on the device and the continued contraceptive effectiveness at two years. By substituting sleeves for wire and assuming the rate of release of copper is similar per unit surface area for both sleeves and wire, the copper on the TCu 220C is estimated to last more than 20 years. This clinical trial has shown that enough copper is released to maintain comparable contraceptive effectiveness at least through the first year.

The Copper T has already been shown to have two major advantages in comparison with other plastic IUD's: (1) The TCu is easier to insert and better

tolerated by nulliparous women.[8] (2) There is less menstrual blood loss in both nulliparous and multiparous women with the copper devices.[9] The major disadvantage has been the need for periodic replacement, which is not necessary for the plastic devices. The results of this randomized study indicate that the TCu 220C, which is not expected to have this disadvantage, has event rates similar to those of the wire-wound TCu 300 in the first year of use. If long-term follow-up confirms these findings, the TCu 220C could become the IUD of choice for all women.

We acknowledge the contribution of James Winter, M.D., in developing the computer program used for life-table analysis. The assistance of Harlene Breaux and Marie Fielding is also gratefully acknowledged.

Effect of clomiphene citrate on serum prolactin in infertile women with ovarian dysfunction

KATSUYOSHI SEKI, M.D.*
MITSUNORI SEKI, M.D.
TOSHIKO OKUMURA, M.D.
KO-EN HUANG, M.D.**
Chiba, Japan

Serum prolactin (PRL) levels were determined by radioimmunoassay in 12 normal, menstruating women and in 26 infertile women with ovarian dysfunction for one cycle or for about 30 days in amenorrheic women. Galactorrhea was not observed. No significant change in serum PRL levels was observed throughout the normal, menstrual cycle. Of the 26 patients with ovarian dysfunction, seven showed PRL levels higher than normal. Twelve of the 26 patients were treated with clomiphene citrate (Clomid†), 100 mg. daily for 5 days. Ovulation occurred in seven, and pregnancy was achieved in two of them. Serum PRL, follicle-stimulating hormone, and luteinizing hormone were measured for a preceding control cycle and during the cycle following Clomid treatment in the 12 patients. The serum PRL levels were normal during the control cycle in five of the patients who ovulated with Clomid and high in four patients who failed to ovulate. Although serum PRL levels were not significantly changed by Clomid in the patients who ovulated with the drug, they were markedly decreased during and immediately after Clomid treatment in patients who failed to ovulate with Clomid.

THE MOST OBVIOUS aspect of prolactin (PRL) action in vertebrates is related to reproduction.[1] However, the role of PRL in human reproduction is not certain. Several investigators[2–5] have measured serum PRL during menstrual cycles with a recently developed radioimmunoassay for human PRL and found no consistent pattern. Further, serum PRL levels in patients with ovarian dysfunction have not yet been characterized, though high serum PRL levels were found in women with amenorrhea-galactorrhea syndromes.[6, 7] Therefore, it was our aim to study the variations in serum levels of PRL over a prolonged period of time for two purposes: (1) to compare serum PRL levels in ovarian dysfunction with those of normal, menstruating women; (2) to determine the effect of clomiphene citrate (Clomid) on serum PRL levels in women with ovarian dysfunction.

Material and methods

Serum PRL levels were determined for one menstrual cycle in 12 normal menstruating women, 19 to 23 years of age. Serum PRL levels were also determined in 26 women with ovarian dysfunction for one cycle or for about 30 days in an amenorrheic patient. The clinical diagnoses were as follows: one, primary amenorrhea; seven, secondary amenorrhea; six, oligomenorrhea; six, anovulatory cycle; and six, short luteal phase. Of the 26 patients with ovarian dysfunction, 12 (one, primary amenorrhea; four, secondary amenorrhea; three, oligomenorrhea; three,

†Serum prolactin levels were expressed in terms of nanograms of HPr V-L-S No. 1 per milliliter of serum.

anovulatory cycle; and one, short luteal phase) were treated with Clomid in a dose of 100 mg. daily for 5 days from the fifth day of menses or bleeding induced by subcutaneous injection with 50 mg. of progesterone (Proluton, Schering A.G.). The short luteal phase was defined only by a period of eight days or less from the nadir on the basal body temperature (BBT) chart to the onset of menstrual flow. Sera were obtained serially from the 12 patients through two consecutive cycles (one control and one after Clomid treatment). Ovulation was judged by BBT, urinary pregnanediol excretion, endometrial findings, cervical mucus, vaginal smear, and pregnancy. None of the patients studied showed galactorrhea.

Serum PRL levels were determined by radioimmunoassay[8] with the double-antibody solid-phase method[9] for separating antibody-bound from free labeled hormone with slight modifications. Serum PRL concentrations were expressed as nanograms of HPr V-L-S No. 1 per milliliter of serum. The intra- and inter-assay coefficients of variation were 12 and 20 per cent, respectively. Serum levels of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) were measured by radioimmunoassays as previously described[10] and expressed as micrograms of LER 907 per 100 ml. of serum. The intra- and inter-assay coefficients of variation in the radioimmunoassay for FSH were 8 and 10 per cent, respectively, and those for LH were 7 and 14 per cent, respectively. The radioimmunoassay kit for PRL as well as the kits for FSH, LH, HPr V-L-S No. 1, and LER 907 were supplied by the National Pituitary Agency, National Institute of Arthritis, Metabolic and Digestive Diseases, National Institutes of Health.

Results

Serum PRL concentrations during the menstrual cycle. There was no significant difference between serum PRL levels during the follicular phase (17.8 ± 1.3 ng. per milliliter) and those during the luteal phase (17.9 ± 1.4 ng. per milliliter). The mean serum concentration during the menstrual cycle was 17.8 ± 1.0 (standard error) ng. per milliliter.

Serum PRL levels in patients with ovarian dysfunc-

tion. The means (±standard errors) of serum PRL concentrations in the 26 patients with ovarian dysfunction are shown in Table I. Only one patient with primary amenorrhea was studied, and she had high serum PRL levels. The mean serum PRL levels of seven patients with secondary amenorrhea ranged from normal (8.2 ng. per milliliter) to high (92.4 ng. per milliliter). Five of the seven patients had serum PRL levles within the normal range, and the other two had high levels. The serum PRL levels of patients with oligomenorrhea also ranged from normal (12.1 ng. per milliliter) to high (59.2 ng. per milliliter). Of six patients with anovulatory cycles, four had normal serum PRL concentrations and two had high concentrations. All the patients with short luteal phases had normal serum PRL levels.

Effect of Clomid on serum PRL levels in women with ovarian dysfunction. Twelve patients with ovarian dysfunction were treated with Clomid. Ovulation was induced in seven (two, secondary amenorrhea; one, oligomenorrhea; three, anovulatory cycles; one, short luteal phase), and pregnancy was achieved in two patients with secondary amenorrhea.

Comment

This is the first report describing serum PRL concentrations in women with various types of ovarian dysfunction. Although patients with short luteal phases showed serum PRL concentrations within the normal range, patients with amenorrhea, oligomenorrhea, and anovulatory cycles showed serum PRL concentrations which ranged from normal to high. Thus, the present study indicates that patients with ovarian dysfunction may have associated normal or high serum PRL levels. The high serum PRL levels found in some of the patients studied suggest the associated disturbance of regulation of PRL secretion in addition to that of gonadotropins in these patients without galactorrhea.

Of the 12 Clomid-treated patients, seven ovulated. Two of the patients who ovulated showed high serum PRL concentrations, and the other five patients showed normal levels. Of the five patients who failed to ovulate with Clomid, four showed high serum PRL concentrations. These results would seem to indicate that patients with high serum PRL concentrations are not likely to respond to Clomid treatment. However, the findings that two patients with high serum PRL concentrations ovulated with Clomid and that one of them became pregnant contradict this assumption.

Serum PRL concentrations during the cycle with Clomid treatment in the patients who failed to ovulate were lower than those during the control cycle with the exception of one patient in whom serum PRL levels were within normal range (Table II). Clomid appears to lower serum PRL levels in patients whose serum PRL levels are high. Robyn and associates[11] also reported that Clomid administration resulted in lowering of serum PRL levels in most cases where ovulation was induced by Clomid. However, serum PRL levels did not decrease with Clomid in patients with normal serum PRL levels in the present study. The mechanism of action of Clomid on PRL secretion remains unclear at this time. Estrogen promotes PRL secretion in rats[12] and in hypogonadal women.[13] Accordingly, Clomid might lower serum PRL levels by its established antiestrogenic effect.[14] Amenorrhea-galactorrhea syndromes are characterized by high circulating PRL levels and low or normal excretion of total urinary gonadotropin[15] or low or normal circulating gonadotropins.[7, 16–18] In such patients, a decrease in serum PRL induced with 2-Br-α-ergocryptine (CB-154)[7, 15] or L-dopa[17] was followed by rises in gonadotropin secretion and ovulation. Precipitous fall in serum PRL induced by CB-154 also was associated with a significant rise of serum FSH in normal postpartum women as in the case of amenorrhea-galactorrhea syndrome.[19] The decrease in serum PRL appears to stimulate gonadotropin secretion in these patients. However, two patients with high serum PRL levels ovulated in the present study. Ehara and colleagues[5] described ovulation observed in women in whom serum PRL was increased with amphetamine. Recently, Zarate and co-workers[20] reported that the serum PRL increase induced by thyrotropin-releasing hormone did not interfere with ovulation in women. Thus, the high circulating PRL levels may inhibit gonadotropin secretion in women with the amenorrhea-galactorrhea syndrome, but high serum PRL levels are compatible with ovulation in some cases of ovarian dysfunction without galactorrhea. The relationship between PRL and gonadotropin secretion appears to be complicated and individualized in various cases of ovarian dysfunction.

CO_2 hysteroscopy: Diagnosis and treatment

H. J. LINDEMANN
J. MOHR
Hamburg, West Germany

The authors have been using hysteroscopy for intrauterine examination and also for transuterine tubal sterlization for some years, and have adopted the use of CO_2 gas as the distension medium. They explain their suggested values, review their experience, and state their reasons for believing that hysteroscopy is safe and should be more widely used.

HYSTEROSCOPY is one of the oldest endoscopic examination methods used in gynecology; it is also called utero- or metroscopy. Pantaleoni[20] introduced the first hysteroscope in 1869. Recent improvements in optical and technical instruments have renewed interest in this procedure. For the past 3½ years we have been interested in the use of hysteroscopy to detect intrauterine diseases and subsequently for transuterine tubal sterilization. We have tried all of the known fluids as distension media. Based on our experiences with laparoscopy and tubal pertubation, we adopted the use of CO_2 gas as the distension medium to produce a permanent pneumometra. Compared with other techniques, we think this is the most suitable way to distend the uterine cavity—which is, under normal conditions, a shallow cleft.

In 1970 we started performing the examinations with a 10 Ch. endoscope, but we found that the information obtained of the uterine cavity with the use of a 2.7 mm. optic was insufficient and the light was too weak. For the last 2½ years we have worked with a hysteroscope 7 mm. in diameter. A foroblique optic of 4 mm. enlarges the cavity much better and in addition the light quality is improved. This instrument, made by Storz,* can also be used for the cystoscopy. Through a working channel one can insert a urinary catheter for tubal sounding, an electroprobe for cauterization, and a biopsy forceps or other instruments. In order to prevent the escape of CO_2 gas we developed a hysteroscope adaptor* which is necessary to maintain a permanent pneumometra. For gas insufflation we have used in the last year only the Hysteroflator 1000,† a CO_2 insufflation apparatus made expecially for hysteroscopy. By means of its reliably adjusted technique, the desired quantity of gas for insufflation can be predetermined. An electronic CO_2 gas-volume gauge monitors the insufflated gas. A constant insufflation pressure guarantees a continuous gas flow and consequently a pneumometra for a sufficiently distended uterine cavity. Manometers of the apparatus show exactly the gas flow rate, that is, the gas quantity per minute which is insufflated into the uterus and the intrauterine pressure. The principle of the Hysteroflator is as follows: If the intrauterine pressure increases, the flow drops; the flow stops when a pressure of 200 mm. Hg is achieved. So no complications can result from too much insufflated gas or too high an intrauterine pressure.

The procedure is performed in the proliferative phase, because one obtains at this time the best visualization of the uterine cavity. The endometrium is not abundant and in general the tendency to bleeding and the mucus production is minimized. After careful cervical dilatation to Hegar 7 a hysteroscope is inserted, the hysteroscope adaptor fixed by vacuum on the cervix, and the pneumometra produced. Normally, for permanent distension of the uterine cavity, we used a gas flow of 40 to 60 ml. per minute, while the intrauterine pressure ranges between 40 and 80 mm. Hg. The procedure was originally performed under general anesthesia but in the last two years we have used only local anesthesia. We produce a paracervical

Table I. Indications and contraindications for hysteroscopy

Indications:
1. Premenopausal bleeding
2. Abnormal bleeding
3. Infertility and sterility
   (a) Habitual abortion
   (b) Incompetent cervix
   (c) Enlarged postcoital test
4. Sterilization
5. Deformations and abnormalities of the uterus
6. Evaluation and staging of carcinoma (corpora)
7. Lost IUD

Contraindications:
1. Gravidity
2. Incomplete abortion
3. Heavy bleeding
4. Severe purulent endometritis
5. Infected pelvic inflammatory disease

block with 1 per cent Xylonest,* 7 ml. for each side. We have not observed any side effects and analgesia is almost immediate.

After reviewing more than 1,695 hysteroscopies we have found the indications and contraindications for this procedures listed in Table I.

Visualization of the uterine cavity for diagnostic evaluations and therapeutic procedures was essentially satisfactory in nearly all 1,695 hysteroscopies. One is able to identify details of the cavity and to distinguish between typical pictures of the endometrium according to the phase of the cycle at the time of inspection. Further, one can recognize small, flat, embedded, submucous fibromas, synechiae, mucous membranes, septa, polyps, and carcinomas which are without clinical symptoms and which cannot be discovered by dilatation and curettage or hysterosalpingography because of their minute sizes. The combination of hysteroscopy and exploratory laparoscopy seems especially a progressive result in discovering the causes of sterility and infertility. It is possible to obtain information about intrauterine diseases, the patency of the tubes by chromopertubation, and the interrelationship of the pelvic organs.

The raw data of the diagnostic evaluations are summarized in Table II. A total of 1,100 patients have been examined for diagnostic reasons. In 28.9 per cent we observed pathologic anatomical changes of the endometrium. Mainly we found a polyposis in 96 cases which means histologically glandular cystic hyperplasia of the endometrium; 91 patients had polyps; submucous fibroids were found in 58 cases, uterine malformations in 17 cases, and in three a corpus carcinoma could be diagnosed without clinical symptoms.

Hysteroscopy was performed on 145 infertility and sterility patients. Table III shows the results. In 58 per cent we recognized pathologic changes of the uterine cavity as malformations,[8], synechiae,[16] polypous endometrium,[27] fibromas,[9] and polyps.[25]

Therapy

For 2½ years we have been accumulating data and experiences with transuterine electrocoagulation of the pars intramuralis tubae by means of the hysteroscope as a method for sterilization. Up to now we have treated more than 450 women. Follow-up examinations of 267 cases after about 12 weeks and later showed a success rate of 90.2 per cent, if we coagulated the patients in the early proliferative phase of the cycle with a low temperature of about 90° C. for 60 seconds. For electrocoagulation we employ a high-frequency apparatus of Siemens,* Radiotom 617, and a 60 cm. long electroprobe by Lindemann of 1 mm. diameter. The probe is equipped with an insulation cap to prevent frontal warmth generation, so that thermal injuries to the outer wall or the neighboring organs cannot lead to complications. The heat generated develops nearly radially and can reach only the myometrium.

Table IV. Summary of 267 follow-up examinations 3 months after transuterine tubal sterilization

Phase of the cycle	*No. of cases*	*Occlusion*	*Patency*		*Gravidity*
			One	*Both*	
Patients, 242; Temperature, 90° C.; Time, sec.: 60					
Proliferative phase	234	211	14	9	6 intrauterine, 1 ectopic, 1 interstitial, =3,4%
		90.2%	9.8%		
Secretory phase, 4 to 7 days post abortion	8	0	5	3	3
Patients, 33; Temperature, 140° C.; Time, sec.: 5 to 7					
Proliferative phase	23	15	2	6	3
Secretory phase, 4 to 7 days post abortion	10	0	4	5	4

Our conclusions are summarized in Table IV. A total of 234 patients treated in the early proliferative phase, with a coagulation temperature of 90 ° C. and about 60 seconds' duration, were followed up for 3 months and had a hysterosalpingography or a control hysteroscopy. Of these, 211 (90.2 per cent) had bilateral tubal occlusion; 14 of these had unilateral and nine bilateral patency of the tubes. Eight patients in this group became pregnant (six intrauterine, one ectopic, one interstitial). Three pregnancies were observed in patients treated in the secretory phase with 90° C. or 4 to 7 days after termination. Table IV shows the results in 33 patients treated with 140° C. for 5 to 7 seconds. We recognized bilateral tubal occlusion only in 15 cases. The rate of tubal closure was lower than in the other group. There were three pregnancies in this group treated in the proliferative phase and four treated 4 to 7 days after termination became pregnant. We found that the procedure performed in the early proliferative phase with low temperature (90° C.) and the time of about 60 seconds resulted in a higher bilateral occlusion compared with only 65 per cent of the other group.

The pregnancy rate in our selected material is 3.4 per cent (six intrauterine, one ectopic, one interstitial). We observed four pregnancies in a group of patients who were in the first 3 months after hysteroscopic sterilization and were not using contraceptives. We cannot confirm the theory of functional sterility (Mikulicz-Radecki, 1926; Kipfer, 1950; Kneer, 1951; Horstmann, 1952, Moricard, 1956; Black and Asdell, 1958; Rauscher, 1969; Stegner, 1969; Koster, 1970). This theory states that sterility could occur although the tubes remain open, as long as their musculature and the "sphincter mechanism" have been destroyed. We are unable to prove this theory wrong or right at the moment, because it is impossible to examine the treated tubes histologically in order to see whether the musculature of the pars intramuralis has been damaged or not. From the practical point of view we only can recommend the use of contraceptives until a definitive tubal occlusion is confirmed. Two pregnancies were observed after occlusion was diagnosed by hysterosalpingography and one pregnancy after tubal insufflation control. It is possible that we opened the occlusion again by the control examinations or a recanalization of the tubes has taken place. Another reason could be a diagnostic failure of the hysterosalpingography—that it was only a tubal spasm and not a real occlusion.

Table V. Complications by 450 transuterine tubal sterilizations

	No.
Pelveoperitonitis	2
Perforation with electroprobe	1
Total	3

Complications

We did not observe any complications in the group of more than 1,245 diagnostic hysteroscopies. Two perforations were recognized in the group of 450 transuterine tubal sterilizations (Table V). In one of these cases the coagulation caused a necrosis of the bowel; in the other case only the uterine wall was

perforated. These complications could have been avoided by greater caution on the part of the operator. Two patients suffered from slight peritonitis some days after the procedure. Hysteroscopy seems to result in a very low complication rate.

After a review of about 3,200 CO_2 hysteroscopies in Germany we can say that this is a simple and a safe method as long as one adheres to the suggested values for insufflation. Some CO_2 complications have occurred in other hospitals and not with the insufflation apparatus we use.

The complications observed include cardiac arrhythmias and even cardiac arrest, probably due to acidosis. In each case too much gas, up to 1,000 ml. per minute, had been insufflated, and possibly it entered the bloodstream. An inadequate insufflation apparatus was used. All these patients recovered without any serious consequences. To obtain some data about the CO_2 behavior we use we undertook blood-gas measurements (pH, Pco_2, and Po_2) and electrocardiograms (ECG) during 55 hysteroscopies. We extended the observation time to 20 minutes and we found no significant changes in the blood gases of the patients. There was also no difference if the procedure was done under local or general anesthesia. The amount of CO_2 which can be absorbed depends on (1) Pco_2, (2) pH, (3) percentage of oxygen saturation of hemoglobin, (4) temperature, and (5) blood flow per minute.

We tried to determine, in our animal experiments, the compatibility of CO_2 injections and possible complications. In a group of 20 German shepherd dogs different CO_2 amounts were injected for 15 minutes into the vena femoralis under a pressure of 200 mm. Hg. The following measurements were made in all animals: (1) arterial blood pressure; (2) arterial blood pH, Pco_2, Po_2; (3) ECG changes; (4) heart rate; (5) respiratory rate. Clinical symptoms were also observed. We could recognize that up to a flow rate of 200 ml. per minute for 5 minutes no significant changes in blood gas, blood pressure, ECG, or any other symptoms were noticed. After this time changes could be observed. A flow rate of 400 ml. per minute and more caused an increase in the frequency of the heart and deeper respiration. There were also changes in the ECG such as extrasystoles and a depression of the ST-segment. The arterial blood Pco_2 increased, Po_2 decreased, and the pH changed to a slight acidosis. Clinical symptoms such as tachycardia, tachypnia, reduced respiratory rate, and restlessness were found. The blood pressure and pupillary reflex were nearly the same. Increasing the CO_2 up to 1,000 ml. per minute resulted in bradycardia, an increase of the Pco_2, a clearly visible decrease of the Po_2, and a pH change to acidosis. Two minutes after the CO_2 injection the reflexes were extremely diminished and then apnea resulted. The blood pressure dropped from 100 to 50 mm. Hg and even lower. The ECG showed arrhythmias and right bundle branch block.

The threshold dose for toxic reactions is about 400 ml. per minute for dogs. Lethal dosage was between 400 and 1,000 ml. per minute. Death occurred after a latency period of about 100 to 120 seconds. Autopsy performed immediately after death did not show any signs of a CO_2 embolus. The main cause of these symptoms was the acidosis which resulted from the too high gas flow rate (insufflated gas quantity per minute).

To prove the safety of any gas being injected intravenously, it must be demonstrated that the entire amount could be tolerated if shunted from the right to the left heart through a septal defect. Therefore we injected CO_2 directly into the carotid artery in another group of German shepherds dogs. The flow rate was 100 ml. per minute under a pressure of 200 mm Hg. Even in this group no significant clinical symptoms of embolism were detected. We can confirm the experimental work of Oppenheimer and associates,[21] Durant and associates,[5] Stauffer and associates,[27] and Hoeffken and associates,[9] who also did animal experiments to prove the safety of CO_2.

To transfer these observations to human subjects we must compare the minute blood volume of the dogs with that of man to find the limits of compatability. The quality of CO_2 tolerated is directly proportional to the cardiac output. Only when a greater volume of CO_2 gas per minute is used can complications be expected; if appropriate volume and pressure are applied, problems will be avoided.

We assume that CO_2 hysteroscopy using the above mentioned insufflation values is safe. Rubin[23] reported figures collected from 380 authors and found no CO_2 complications among 80,000 tubal pertubations.

Comment

CO_2 hysteroscopy is a simple and safe method which can be performed as an outpatient procedure under local anesthesia. We think that this procedure is out of the experimental stage and will be a good diagnostic and therapeutic tool for the gynecologist. Hysteroscopy is a direct method for the evaluation of intrauterine diseases and is far better than hysterosalpingography and the information obtained only by dilatation and curettage. Englund and associates[7] proved this in very good work. They reported about a 50 per cent failure rate of hysterosalpingography compared with their hysteroscopic results, and they missed many polyps and fibroids by doing only a

dilatation and curettage in comparison to hysteroscopic evaluation. Hysteroscopy is adding more precision to the diagnosis than hysterograms, endometrial biopsy, or curettage, because the uterine lesion can be visualized and a direct biopsy can be obtained.

As CO_2 hysteroscopy enables a good visualization of the uterotubal junction it is easy to perform transuterine tubal sterilization by cauterization of the intramural part of the tubes. The success rate has been about 90 per cent when the patients were treated in the early proliferative phase with a coagulation temperature of 90° C. As there are some failures in the diagnosis of tubal occlusion after transuterine tubal sterilization, we think the best method of evaluating the success of a transuterine sterilization is by hysteroscopy with the Hysteroflator 1000. By this control examination the apparatus indicates a closure by intrauterine pressure of 200 mm. Hg and a flow rate of zero. By hysteroscopy one can observe the former area of the ostium to see if there is scarring and occlusion. On visualization, if some CO_2 bubbles disappear, one can be sure that it still remains open. Another symptom of tubal patency after sterilization could be the shoulder pain which also appears after a Rubin test if the tubes were patent. By this control hysteroscopy we can avoid as far as possible diagnostic failures of tubal occlusion.

Conclusion

More than 3,200 CO_2 hysteroscopies have been performed in Germany without serious complications. We have proved, with our blood-gas analysis and our dog experiments, that CO_2 hysteroscopy is not hazardous. It is absolutely safe if our recommended values are used.

In our opinion CO_2 is the best distension medium for the uterus because it is a gas natural to the body in contradistinction to the other media which are foreign to the body. CO_2 allows the visualization of the tissue and the identification of intrauterine diseases very clearly and the view is true to nature because it has the same optical qualities as air. Finally, from the practical point of view, CO_2 is the best medium for the use and long life of the instruments.

At the present time, when technologic process has taken such a large step forward, and when all medical disciplines wish to further their knowledge by inspecting the various body cavities, the endoscopic observation of the uterus, which especially provides more subtle diagnosis, should find a place as one of the common diagnostic examination methods in our gynecologic practice.

Diagnostic and therapeutic efficacy of cervical conization

J. R. VAN NAGELL, JR., M.D.
J. C. PARKER, JR., M.D.
L. P. HICKS, M.D.
R. CONRAD, B.S.
G. ENGLAND, B.S.
Lexington, Kentucky

Cervical conization was performed on 756 patients at the University of Kentucky Medical Center from July 1, 1964, to January 1, 1973. Sixty-six patients were pregnant at the time of conization. Eighty-six per cent of patients with cytologic findings of carcinoma in situ had histologic verification of carcinoma in situ or severe dysplasia, and there was absolute correlation between cytology and histology in 75 per cent of patients with occult invasive cancer. Cervical biopsies without colposcopic direction predicted either severe dysplasia or carcinoma in situ in 77 per cent of cases but were accurate in only seven of 24 patients with occult invasive cancer. Carcinoma in situ was present in 30 per cent of hysterectomy specimens following conization but recurred in only seven per cent of patients followed without hysterectomy. Recurrent carcinoma in situ following hysterectomy was more common in patients with residual intraepithelial cancer in the uterus but was independent of the size of the vaginal cuff removed. Major postconization complications requiring hospitalization occurred in 3.4 per cent of nonpregnant patients and in 7.5 per cent of pregnant patients.

SINCE ITS INITIAL description by Lisfranc[1] in 1815, the technique of cervical conization has undergone many changes. Sims,[2] in 1861, closed the cervix with silver wire sutures following conization and was the first to obtain healing by primary intention. Likewise, Sturmdorf,[3] in 1916, described a method inverting cervicovaginal epithelium to cover the conization site which is still used in many institutions today. More recently, several investigators[4, 5] have described methods of injecting vasoconstrictive solutions into the cervix at the time of conization in order to minimize blood loss. Despite these technical advances, cervical conization remains a major operative procedure associated with a five to ten per cent incidence of postoperative complications.[4, 6]

Perhaps even more important than changes in conization technique have been changes in the indications for its performance. Whereas conization was initially performed for invasive cervical cancer and the repair of cervical lacerations,[7] it has been used during the past three decades for the diagnosis and treatment of cervical epithelial abnormalities. With the utilization of colposcopy to direct cervical biopsies, it has been suggested by some investigators that cervical conization is being performed too frequently.[8, 9]

The present study was undertaken to determine the diagnostic and therapeutic efficacy of cervical conization as a method in the evaluation of patients with cervical neoplasia.

Methods and results

From July 1, 1964, to January 1, 1973, cervical conization was performed on 756 patients at the University of Kentucky Medical Center. Sixty-six of these patients were pregnant at the time of conization.

From the Departments of Obstetrics and Gynecology and Pathology, University of Kentucky Medical Center.

Conization was carried out as a diagnostic method in patients with cytologic or biopsy findings of cervical epithelial abnormalities. Cytologic and histologic abnormalities were graded according to the following classification: mild dysplasia, moderate dysplasia, severe dysplasia, atypical cellular changes, carcinoma in situ, microinvasive carcinoma, and invasive carcinoma. Cervical conization was performed in the absence of biopsy-proved invasive cancer within two months on all patients with cytologic or biopsy evidence of persistent moderate dysplasia, severe dysplasia, carcinoma in citu, or microinvasive carcinoma. Persistent moderate dysplasia was defined as moderate dysplasia on two occasions separated by at least three months. Microinvasive cancer was defined as the presence of stromal invasion to a depth of less than 5 mm.

Conization was performed according to the method of Parker and colleagues.[10] Twelve to sixteen sections were made of each conization specimen, and additional step sections were cut when an area indicative of epithelial abnormality was noted. Areas of cervical epithelial abnormality were described as involving squamous epithelium, both glandular and squamous epithelium, or glandular epithelium alone.

Basic characteristics of the patients studied are presented in Table I. The mean age, gravidity, and location of cervical epithelial abnormality was essentially the same in those patients who were pregnant and in those who were not.

Seven hundred and seven patients had cervical conizations at this institution within eight weeks of cytologic examination. Conization findings in these patients are presented in Table II. Cytology and histology specimens were reviewed in all cases in which there was not absolute cytology-histology correlation. Eighty-six per cent of patients with cervical cytologic findings of carcinoma in situ had histologic verification of severe dysplasia or intraepithelial carcinoma on conization. Seventeen patients with normal or mildly dysplastic cytologic findings had severe dysplasia or carcinoma in situ on conization. However, no patient whose cervical cytology was normal or showed mild or moderate dysplasia had histologic evidence of invasive cancer in the conization specimen. Twenty-eight patients (four per cent) with no visible cervical lesions had invasive cancer at conization. Twenty-one of these patients had cytologic diagnoses of invasive cancer, and the remainder had cytologic abnormalities ranging from atypical cellular changes to microinvasive cancer. Age as an independent variable had no direct effect on the cytology-histology correlation. Thirty-eight patients (5.4 per cent) had cytologic findings which were not severe enough to warrant conization. However, cervical biopsy abnormalities were more advanced and indicated the need for conization.

Table I. Basic characteristics of patients undergoing cervical conization

Characteristics	*Nonpregnant*	*Pregnant*
No. of patients	690	66
Mean age (yr.)	37.0	33.3
Mean gravidity	4.6	5.2
Location of lesion		
Squamous epithelium alone (%)	62.6	57.8
Squamous and glandular epithelium (%)	34.5	35.9
Glandular epithelium alone (%)	2.9	6.3

Cervical biopsies were performed on 537 patients prior to conization. Biopsies were taken from areas in the cervix which failed to take up Schiller's stain, since colposcopy was not performed at this institution during the time of investigation. Endocervical curettage was carried out only in those patients with visible endocervical lesions. The histologic correlation between punch biopsies and conization is presented in Table III. Twenty-four patients with invasive cancer and no visible cervical lesions had punch biopsies prior to conization. Invasive cancer was confined to the squamous epithelium in eleven cases and involved both squamous and glandular epithelium in three cases. Punch biopsies showed microinvasive or invasive cancer in nine patients (37.5 per cent) and carcinoma in situ in 11 patients (45.8 per cent). Thirteen patients with suspected invasive cancer on punch biopsy had cervical conization in order to determine the extent of invasion. Seven of these patients had invasive cancer and six had intraepithelial or microinvasive cancer.

The relationship between location of the epithelial abnormality and the diagnostic accuracy of cervical biopsy is presented in Tables IV and V. Cervical biopsies showed either severe dysplasia or carcinoma in situ in 145 of 193 patients (75.1 per cent) with carcinoma in situ limited to the squamous epithelium and in 119 of 151 patients (78.7 per cent) whose carcinoma in situ involved both squamous and glandular epithelium. Diagnostic accuracy of punch biopsies was significantly reduced in those lesions confined to the endocervical glands. Eleven patients had either carcinoma in situ or invasive adenocarcinoma of the endocervix, and only six of them (54.5 per cent) were diagnosed accurately on punch biopsy.

Table II. Cytology-histology correlation in patients undergoing cervical conization

Cervical cytologic findings	No. of patients	Conization findings: Mild dysplasia or less		Moderate dysplasia		Severe dysplasia		Carcinoma in situ		Micro-invasive carcinoma		Invasive carcinoma	
		No.	%	No.	%	No.	%	No.	%	No.	%	No.	%
Normal	9	4	44.4	0		1	11.2	4	44.4	0		0

Table IV. Punch biopsy–conization correlation according to location of lesion in patients with carcinoma in situ

Location of carcinoma in situ on conization	Patients	Biopsy findings: Severe dysplasia		Carcinoma in situ		Other	
		No.	%	No.	%	No.	%
Squamous epithelium only	193	34	17.6	111	57.5	48	24.9
Squamous and glandular epithelium	151	21	13.8	98	64.9	32	21.3
Glandular epithelium only	1	0		1	100	0	

Sixty-six patients were pregnant at the time of conization and sixty-three of these patients had conization within six weeks of cytologic examination. Thirty-seven (82.2 per cent) of the 45 patients with carcinoma in situ on conization had cytologic evidence of severe dysplasia or carcinoma in situ. The one pregnant patient with occult invasive cervical cancer had cytologic evidence of malignancy. Fifty-three of these patients had cervical biopsies prior to conization. Cervical biopsies were accurate in 78.9 per cent of pregnant patients with carcinoma in situ. However, only one of the three patients with microinvasive cancer was diagnosed on cervical biopsy. The one pregnant patient with invasive cancer was not biopsied

Table V. Punch biopsy–conization correlation according to location of lesion in patients with occult invasive cervical cancer

Location of invasive carcinoma on conization	*No. of patients*	*Biopsy findings*							
		Carcinoma in situ		*Microinvasive carcinoma*		*Invasive carcinoma*		*Other*	
		No.	*%*	*No.*	*%*	*No.*	*%*	*No.*	*%*
Squamous epithelium only	11	6	54.5	1	9.1	2	18.2	2	18.2
Squamous and glandular epithelium	3	1	33.3	1	33.3	0		1	33.3
Glandular epithelium only	10	4	40.0	0		5	50.0	1	10.0

prior to conization. Hysterectomy was performed with cesarean section or in the immediate postpartum period in 43 patients with carcinoma in situ. Twelve patients (27.9 per cent) had residiual carcinoma in situ and one had microinvasive carcinoma in the hysterectomy specimen.

Complications of conization are presented in Table VI. Sixteen patients required readmission for excessive cervical bleeding. This bleeding was successfully treated with resuture, vaginal packing, or cryotherapy in thirteen patients, and emergency hysterectomy was required in three patients. Bleeding occurred five to ten days after conization in all patients. Six patients required blood transfusions following conization related bleeding. Uterine perforation at the time of conization occurred in two patients, and three patients experienced spontaneous abortion within one week of conization. The incidence of major conization complications, excluding the 161 patients whose hysterectomy immediately followed frozen section examination of the cone specimen, was 3.4 per cent in nonpregnant patients and 7.5 per cent in pregnant patients.

Three hundred and seventy four patients with carcinoma in situ or microinvasive carcinoma who desired no further pregnancies underwent hysterectomy following conization. Vaginal hysterectomy was performed in 299 patients and abdominal hysterectomy in the remainder. A wide vaginal cuff was excised with the hysterectomy specimen in 226 cases. All hysterectomy specimens were examined microscopically to determine the incidence of residual epithelial abnormality. Sections were routinely taken through the anterior, posterior, and lateral walls of the cervix as well as additional sections in areas of histologic abnormality. No patient had undiagnosed invasive cancer in the hysterectomy specimens following conization. Carcinoma in situ was present in 112 hysterectomy specimens (29.9 per cent) and microinvasive cancer in six (1.6 per cent). Following conization, patients were seen in the gynecologic oncology clinic every three months for two years and every six months thereafter. The duration of follow-up ranged from 12 to 110 months (mean 50 months). Recurrent vaginal cancer following hysterectomy occurred in five patients (1.1 per cent), and there was residual carcinoma in situ in the hysterectomy specimen of four of these patients. Vaginectomy was performed on three of these patients and radiation therapy in two. All of these patients are alive with no evidence of recurrent disease three to 60 months following therapy. One hundred and nine patients with histologically proved carcinoma in situ who desired further pregnancies have been followed without hysterectomy. Seven of these patients (6.4 per cent) have required a second conization and hysterectomy for recurrent carcinoma in situ.

Table VI. Complications of cervical conization

Complications	*Nonpregnant*		*Pregnant*	
	No.	*%*	*No.*	*%*
No. of patients	529		66	
Complication

Uterine perforation	2	0.4	0	
Pelvic infection	2	0.4	0	
Pregnancy loss	0		3	4.5
Total	18	3.4	5	7.5

Comment

The findings of this study indicate that cervical conization is an effective method in the diagnosis of cervical epithelial abnormalities. However, it is a major operative procedure associated with a significant incidence of complications. For this reason, conization should be performed only in those instances in which it

can provide definite diagnostic or therapeutic advantages to less radical procedures. Cervical cytologic examination is an excellent screening procedure and suggests the need for further histologic confirmation by biopsy or conization. Furthermore, cytologic examination and cervical biopsies are often complementary in the diagnosis of cervical epithelial abnormalities. This is exemplified by those patients (5.4 per cent) from this institution with normal or mildly dysplastic cytologic findings whose conizations were performed because of biopsy evidence of more advanced epithelial abnormalities.

The most effective method for reducing the number of cervical conizations is to increase the accuracy of cervical biopsies. In the present series, only seven of 24 patients with invasive carcinoma in the absence of a cervical lesion had the correct diagnosis made by cervical biopsy. Similarly, only 76.8 per cent of the carcinoma in situ or severe dysplasia was diagnosed by biopsy alone. Stafl and Mattingly[11] reported colposcopic prediction of histopathology to be clinically accurate in 85 per cent of patients with cervical epithelial abnormalities. Likewise, Townsend and associates[12] noted an absolute correlation between colposcopically directed biopsies and cervical conization of 84.5 per cent when the lesion did not involve the endocervical canal. Clearly, the accuracy of colposcopy depends upon the skill and experience of the colposcopist. However, it does provide an additional diagnostic alternative to conization if the lesion can be completely defined and the squamocolumnar junction fully visualized.

Conization during pregnancy was directly responsible for a five per cent incidence of fetal loss. In addition, two patients experienced significant postconization hemorrhage. Ortiz and Newton,[13] in a study of 47 pregnant patients with abnormal cervical cytologic findings, found that colposcopically directed biopsy was an effective means to histologically evaluate the cervix and was unlikely to miss invasive cancer because of the physiologic eversion of the cervix during pregnancy. Similarly, Stafl and Mattingly[11] found that no unsatisfactory or incomplete colposcopic examinations occurred in 89 pregnant patients, and conization was not required in any case. Conization during pregnancy is therefore most clearly indicated when the squamocolumnar junction cannot be visualized or when there is biopsy evidence of microinvasive cancer.

The observation that the recurrence rate of carcinoma in situ following conization is significantly less than the incidence of residual intraepithelial carcinoma in the hysterectomy specimen is not new. Creasman and Rutledge[14], in a study of 861 patients treated for carcinoma in situ at the M. D. Anderson Hospital, noted residual carcinoma in situ in 22 per cent of hysterectomy specimens, whereas recurrent carcinoma in situ following conization was found in only seven per cent. In a previous investigation from this institution, van Nagell and colleagues[15] found that the incidence of residual carcinoma in situ following conization was inversely related to the amount of inflammation present in the hysterectomy specimen. Perhaps the inflammatory response of the cervix following conization destroys residual carcinoma in situ or makes epithelial abnormalities difficult to interpret. Recurrent vaginal carcinoma in situ following hysterectomy occurred most commonly in those patients who had residual carcinoma in situ in the hysterectomy specimen but was independent of the size of the vaginal cuff excised.

There is little doubt that the definitive therapy for cervical intraepithelial carcinoma in the woman who has completed her family is hysterectomy. However, for the patient who desires further pregnancy, directed biopsy and conization provide satisfactory diagnostic and, in certain cases, therapeutic alternatives to more radical procedures. In this regard, conization is particularly useful in the diagnosis of lesions extending up the endocervical canal in which the squamocolumnar junction cannot be visualized.

Many advances in the management of malignant cervical disease have come about through greater individualization of therapy. It is not unreasonable to suspect that similar advantages will result from the application of this philosophy to patients with premalignant disease of the cervix.

Endometrial adenocarcinoma and the polycystic ovary syndrome

GARY P. WOOD, M.D.
RICHARD C. BORONOW, M.D.
Jackson, Mississippi

While endometrial adenocarcinoma is the second most common female genital malignancy, only four per cent of the cases occur in women less than 40 years of age. The relative rarity of this disease in young women requires that we be especially attuned to those who are at high risk. This paper presents two case reports of women with polycystic ovarian disease who developed endometrial adenocarcinoma at 24 years of age. The pathophysiology of polycystic ovarian disease and its relationship to the development of endometrial adenocarcinoma are discussed.

ENDOMETRIAL adenocarcinoma, the second most common female genital malignancy, is primarily a disease of older women, with 75 per cent of all cases occurring after the age of 50 and only 4 per cent occurring before the age of 40.[1] While the clinical associations of hypertension, diabetes mellitus, obesity, and nulliparity are well established for older patients, a somewhat different profile is apparent for the very young women who develop endometrial adenocarcinoma.

There have been recent reports of patients with Turner's syndrome who developed endometrial adenocarcinoma after long-term treatment with oral diethylstilbestrol[2–5] and the occurrence of endometrial adenocarcinoma in patients with the polycystic ovary syndrome (PCO) has also been reported.[6–8] Our report of two patients with PCO who both developed endometrial adenocarcinoma at 24 years of age will illustrate the profile of the patient who is at risk for this malignancy at an early age.

Case reports

Case 1. W. S., a 24-year-old, married, black, nulligravid woman, was initially referred because of very heavy "periods" for about 4 months prior to admission. Her menarche had occurred at 15 years of age and menses had always been very irregular. She had also had an increased growth of dark, heavy facial hair for about 6 years.

The patient's height was 65 inches, weight 293 pounds, blood pressure 152/90 mm. Hg. She was extremely obese, with moderate facial hirsutism (Fig. 1). Breast development was good and the findings on pelvic examination were unremarkable, although the examination was somewhat difficult.

Significant laboratory data included: Hemoglobin (Hgb.), 8.0 Gm. per 100 ml.; hematocrit (Hct.), 24 per cent; white blood cell count (WBC), 10,600 per cubic millimeter; platelets, 360,000 per cubic millimeter; serum iron, 55 μg; serum iron-binding capacity, 449 μg per 100 ml.; Hgb. electrophoresis, AA; blood urea nitrogen (BUN), 5 mg. per 100 ml.; bilirubin (total), 0.7 mg. per 100 ml.; glucose (fasting), 90 mg. per 100 ml. Thyroid studies were within normal limits, as were 24 hour urinary 17-ketosteroids and 17-OH steroids. The intravenous pyelogram and skull x-rays were unremarkable and the Papanicolaou smear was negative.

She did not return again for 9 months. During the interval she had had more profuse vaginal bleeding and, at the time of her second admission, the Hgb. was 3.8 Gm. per 100 ml. and Hct. was 15 per cent. After adequate transfusion, a dilatation and curettage was performed and a large amount of tissue obtained which showed both endometrial adenomatous hyperplasia and adenocarcinoma. On obtaining the tissue diagnosis, a total abdominal hysterectomy and bilateral salpingo-oophorectomy were performed. The ovaries were enlarged, with numerous subcapsular follicular cysts but no recent or old corpora lutea. The ovaries showed "capsular" thickening as well as thecal hyperplasia.

Case 2. S. S., a 24-year-old, unmarried, white, nulligravid woman, had had her menarche at 15 years of age. Her menses had always been very irregular and were usually quite heavy. Ten months prior to admission she had been started on oral contraceptives to "regulate" her menses. Even with oral contraceptives she continued having excessive vaginal bleeding both during and between menses, and just prior to admission a dilatation and curettage was done which showed endometrial adenomatous hyperplasia and adenocarcinoma. She had had moderate facial acne and heavy, dark hair on her chest and breasts for several years.

Her height was 59 inches, weight 170 pounds, and blood pressure 130/-0 mm. Hg. She was moderately obese, with good breast development. She had facial acne and numerous dark hairs on her chest and breasts. Pelvic examination was unremarkable.

Significant laboratory data included: Hgb., 10.3 Gm. per 100 ml.; Hct., 29 per cent; WBC, 4,000 per cubic millimeter; platelets, 286,000 per cubic millimeter; bilirubin (total), 0.6 mg. per 100 ml.; BUN, 10 mg. per 100 ml. Plasma testosterone was 109 ng. per 100 ml. (normal female, 30 to 95). The 17-ketosteroid output (urine) was unremarkable and the Pap smear was reported as negative.

Initial therapy consisted of intrauterine radium, which was followed in one week by total abdominal hysterectomy and bilateral salpingo-oophorectomy. Both ovaries were slightly enlarged with bilateral cortical thickening, numerous follicular cysts, and thecal hyperplasia. No corpora lutea were present but there were several old corpora albicans.

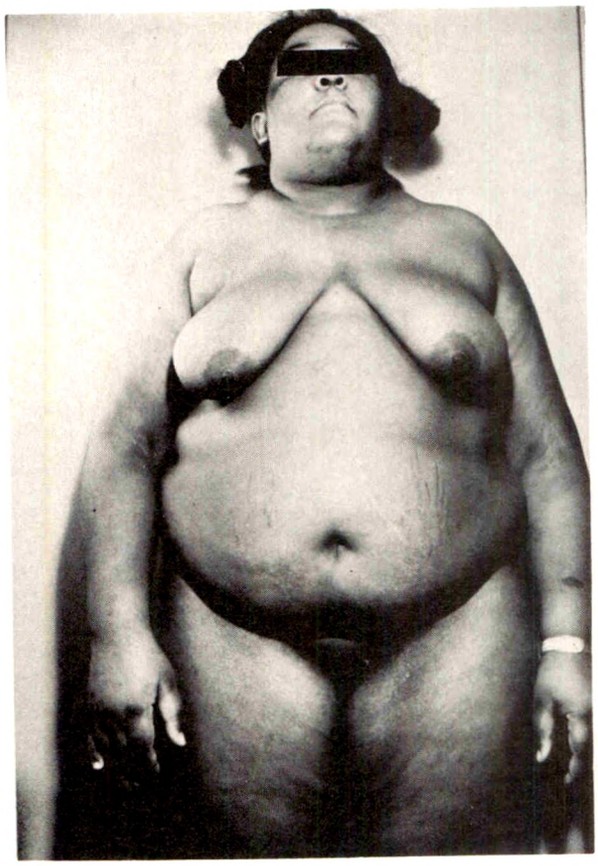

Fig. 1. Patient W. S. (case 1) showing the obesity and hirsutism characteristic of these patients.

Comment

It has only been in the last few years, with the development of sensitive and specific radioimmunoassays for protein and steroid hormones, that the true nature of polycystic ovarian disease has become apparent. Recent work by Yen and associates[9] has shown that women with PCO have chronically depressed serum levels of follicle-stimulating hormone (FSH) as well as chronically elevated levels of luteinizing hormone (LH) which are devoid of any cyclic peaks usually associated with ovulation. The low levels of FSH are consistent with the failure of follicular maturation seen in the PCO ovary and the elevated LH levels explain much of the remainder of the ovarian pathology.

Kirschner and Jacobs,[10] by means of 3 sampling from ovarian and adrenal vein catheters, have shown that the ovary is the major site of androgen production (primarily androstenedione and testosterone) in patients with PCO. Several studies have shown that, in the female, acute treatment with human chorionic gonadotropin (HCG) or LH will result in increased androgen production.[11–13] In view of this growing bulk of data, there can be little question that chronic hyperstimulation of the ovary with LH can result in ovarian hyperthecosis and increased androstenedione and testosterone production. It has also been shown that, in the rhesus monkey, chronic androgen stimulation will result in ovarian capsular fibrosis similar to that seen in the PCO syndrome.[14] It seems, therefore, that the ovarian changes seen in the PCO syndrome are a result of abnormal stimulation rather than being a primary ovarian disorder.

While the cause of the abnormal gonadotropin release is not known, it is known that female rats, if treated with androgens during the first 5 days of life, will later develop a syndrome which is quite similar to the human PCO syndrome, with increased androgen production, polycystic ovaries, and anovulation.[15] It is speculated that this early androgen exposure results in a "masculinization" of the hypothalamus and, while this etiology is unlikely for most human subjects with PCO, the concept of a male-type hypothalamic drive is quite plausible.

The persistent, if asynchronous and incomplete follicular activity in the PCO syndrome does result in persistent estrogen production which may be augmented to a considerable degree by extraovarian conversion of androstenedione to estrone as has been shown by MacDonald and associates.[16] In view of present data, we must assume that this prolonged estrogen stimulation of the endometrium, without the modifying effect of intermittent progesterone, can produce hyperplastic and eve the endometrial glands. The disorder with the progressio neoplastic changes in the end well documented by Chambia

Since the endometrial ade velop in these young women t tiated, the prognosis for s therapy is very good.[18]

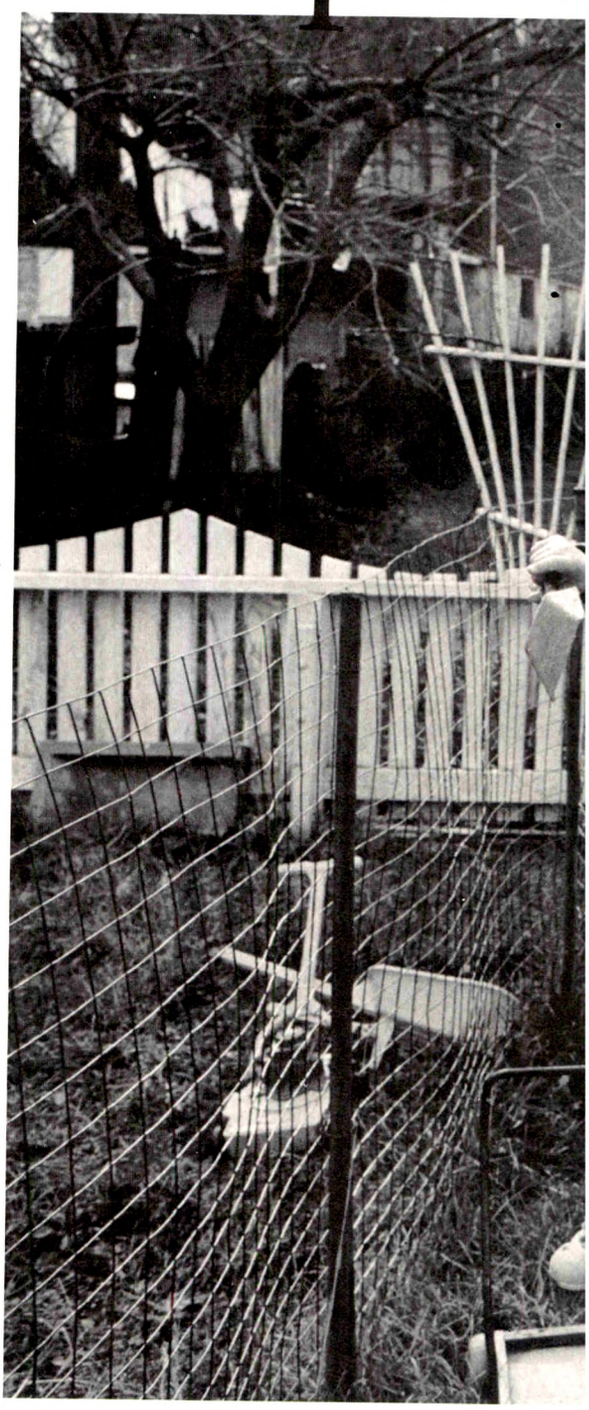
The reasons for acceptance or rejection of an oral contraceptive are many. Some are hers and some are yours.



In the main, her reasons for rejection, often highly subjective, are based on side effects—and side effects are only partially predictable from history and examination.

The ultimate test, then, of oral contraceptive acceptability must be what happens when she takes it since both your judgment and hers will be based on...

Real Life Experience

From real life...

A Woman satisfied her oral contraceptive

One important reason for patient satisfaction: Usually no G.I. discomfort

ZORANE 1/50 is a highly effective and generally well-tolerated oral contraceptive—providing the estrogen content and progestin:estrogen ratio that appears to be highly acceptable to the majority of women.

From clinical studies: In a study population of 1156 women, 25,983 cycles, the incidence of nausea and vomiting was 3.3%. Actual patient dropout rate* due to nausea and vomiting was 2.9% (33 subjects.) Overall patient dropout rate was 14.4% due to all adverse reactions. Serious reactions, as well as minor adverse reactions, have been reported following the use of all oral contraceptives. Before prescribing, the complete product information should be consulted for *special note, contraindications, warnings, precautions* and *adverse reactions*. Thereafter, the physician should remain alert to the earliest manifestations of any serious disorder. Should any occur or be suspected, the oral contraceptive should be immediately discontinued.

The woman profiled here is an actual ZORANE 1/50 user. However, not all women can be expected to have the same tolerance for side effects, should any occur. (Data on file, Lederle Laboratories)

*Dropout rates are based on total patient population (1,156); incidence reflects only those patients who completed one or more cycles (956).

Zorane 1.5/30 Norethindrone Acetate, 1.5 mg. and Ethinyl Estradiol, 30 mcg.

Zorane 1/20 Norethindrone Acetate, 1 mg. and Ethinyl Estradiol, 20 mcg.

Special Note: Oral contraceptives have been marketed in the United States since 1960. Reported pregnancy rates vary from product to product. The effectiveness of sequential products appears to be somewhat lower than that of combination products. Both types provide almost completely effective contraception. The dropout rate for medical reasons, as observed in clinical trials, with ZORANE 1.5/30 appears to be the same as that of higher dose combination products. The dropout rate due to irregular bleeding was somewhat higher, but dropouts were equally split between irregular bleeding and other medical reasons attributable to the drug. (ZORANE 1/20 only: The effectiveness is somewhat lower than that of the higher dose combination products. Both provide almost completely effective contraception. Dropout rate for medical reasons appears to be somewhat higher than with higher dose combination products, due particularly to irregular bleeding.) An increased risk of thromboembolic disease associated with use of hormonal contraceptives has now been shown in studies conducted in both Great Britain and the United States. Other risks, such as those of elevated blood pressure, liver disease, reduced tolerance to carbohydrates, have not been quantitated with precision. Long-term administration of both natural and synthetic estrogens in subprimate animal species in multiples of the human dose increases the frequency for some animal carcinomas. These data cannot be transposed directly to man. Possible carcinogenicity due to the estrogens can neither be affirmed nor refuted at this time. Close clinical surveillance of all women taking oral contraceptives must be continued.

Indications: For control of conception.

Contraindications: Thrombophlebitis, thromboembolic disorders, cerebral apoplexy, or a past history of these conditions; markedly impaired liver function; known or suspected carcinoma of the breast; known or suspected estrogen-dependent neoplasia; undiagnosed abnormal genital bleeding; pregnancy.

Warnings: If early signs of thrombotic disorders (thrombophlebitis, cerebrovascular disorders, pulmonary embolism, retinal thrombosis) occur or are suspected, discontinue use of drug immediately. (Studies indicated a higher risk of these conditions with use of these drugs, not persisting after drug stoppage and not enhanced by long-term use.[1-4]) If sudden partial or complete loss of vision occurs, or if there is sudden onset of proptosis, diplopia or migraine; or if examination reveals papilledema or retinal vascular lesions, discontinue medication. Safety of use in pregnancy has not been established, therefore rule out pregnancy in any patient who has missed two consecutive periods before continuing contraceptive regimen; if prescribed schedule has not been adhered to, consider possibility of pregnancy with first missed period. A small fraction of hormonal agents has been identified in the milk of mothers receiving these drugs; long-range effect to the nursing infant has not yet been determined.

Precautions: Pretreatment and periodic physical examinations of breasts and pelvic organs should include Papanicolaou smear. (Estrogens have produced tumors, some malignant, in 5 species of subprimate animals.) If endocrine and liver function tests are abnormal in patients taking these drugs, repeat tests after drug withdrawal for 2 months. With use of these drugs, pre-existing uterine fibromyomata may increase in size; and some conditions (*i.e.*, epilepsy, migraine, asthma, cardiac or renal dysfunction) may be influenced by fluid retention; observe carefully for such. With use of ZORANE 1.5/30 or ZORANE 1/20, alteration in menstrual patterns may be induced. Since the amount and duration of flow and cycle length may vary, this must be considered in attempting to determine if cause of bleeding is organic. (ZORANE 1/50 only: In breakthrough bleeding or all cases of irregular bleeding per vaginam, keep in mind nonfunctional causes and take adequate diagnostic measures.) With history of psychic depression, discontinue drug if depression recurs to a serious degree. Possible influence of prolonged ZORANE therapy on pituitary, ovarian, adrenal, hepatic or uterine function awaits further study. A decrease in glucose tolerance has been seen in some patients on oral contraceptives; carefully observe diabetics on such therapy. Patient age is no absolute limiting factor, although these drugs may mask onset of climacteric. The pathologist should be advised of ZORANE therapy when relevant specimens are submitted. Susceptible women may have an increase in blood pressure following use of contraceptive steroids.

Adverse Reactions Observed in Patients Receiving Contraceptives: Statistically significant association demonstrated between use of oral contraceptives and: thrombophlebitis, pulmonary embolism, cerebral thrombosis. Suggestive evidence, neither confirmed nor refuted, between use and neuro-ocular lesions (*e.g.*, retinal thrombosis, optic neuritis). Known to occur: nausea, vomiting, G.I. symptoms (abdominal cramps, bloating), breakthrough bleeding, spotting, change in menstrual flow, amenorrhea during and after treatment, edema, chloasma or melasma, breast changes (tenderness, enlargement, secretion), weight change (increase or decrease), changes in cervical erosion and secretions, suppression of lactation when given immediately post-partum, cholestatic jaundice, migraine, allergic rash, rise in blood pressure in susceptible women, mental depression. Reported association with use, neither confirmed nor refuted: anovulation post treatment, premenstrual-like syndrome, changes in libido, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, fatigue, backache, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, itching. *May Alter Laboratory Results in:* hepatic function (increased sulfobromophthalein retention and other tests), coagulation tests (increase in prothrombin, Factors VII, VIII, IX, X), thyroid function (increase in PBI_1, and butanol extractable protein bound iodine, and decrease in T^3 uptake values), metyrapone test, pregnanediol determination.

The metabolic clearance rate of dehydroisoandrosterone sulfate

IV. Acute effects of induced hypertension, hypotension, and naturesis in normal and hypertensive pregnancies

N. F. GANT, M.D.
J. D. MADDEN, M.D.
P. K. SIITERI, PH.D.
P. C. MACDONALD, M.D.
Dallas, Texas

In the present study, the metabolic clearance rate of dehydroisoandrosterone sulfate (MCR_{DS}) decreased in normotensive gravidas during short-term studies utilizing angiotensin II–induced elevation of blood pressure. Therapy with hydralazine hydrochloride in chronic hypertensive gravidas resulted in a decrease in blood pressure and an accompanying decrease in the MCR_{DS}. A variable response was observed in the apparent volume of distribution of DS (AVD_{DS}) during therapy with hydralazine hydrochloride. Decreases in MCR_{DS} also occurred in chronic hypertensive gravidas following therapy with 40 mg. of intravenously administered furosemide despite a failure of blood pressure to be altered. The AVD_{DS} increased in four of five patients receiving furosemide, suggesting a possible direct action of furosemide upon vascular smooth muscle.

IN A PRECEDING report,[10] the effects of chronic administration of thiazide diuretics upon the metabolic clearance rate of dehydroisoandrosterone sulfate (MCR_{DS}) were measured in normal and future preeclamptic patients. In all but one instance, the MCR_{DS} decreased following 1 week of thiazide diuretics.

The purpose of the present study was to measure acute changes in MCR_{DS} evoked by the administration of angiotensin II in normotensive volunteers and following the administration of hydralazine hydrochloride and furosemide to near-term gravidas with

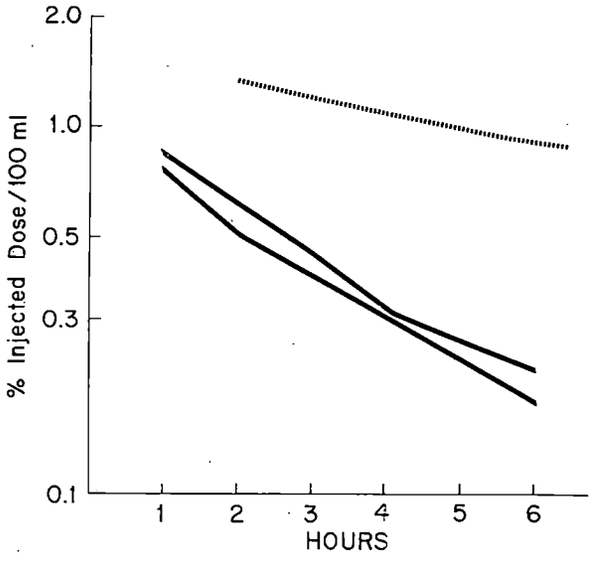

Fig. 1. Disappearance curves of tritium-labeled dehydroisoandrosterone sulfate (^{3}H-DS). The dotted line represents the disappearance of ^{3}H-DS in a nonpregnant subject. The solid lines are those of term pregnant patients. Note that in term pregnant subjects the disappearance rate is increased.

essential hypertension. In all instances, these drugs decreased the MCR_{DS} and in some instances marked decreases occurred which corresponded well with the clinical condition and gross pathologic description of the placenta.

Materials and methods

The MCR_{DS} was measured following the intravenous injection of tritium-labeled DS by determining the concentration of ^{3}H-DS remaining per 100 ml. of plasma as previously described.[1] By determining the concentration of DS remaining per 100 ml. of maternal plasma at 60, 120, 180, 240, 300, and 360 minutes (Fig. 1), typical disappearance curves were established and from these disappearance curves the metabolic clearance rate of DS was calculated from the "slow" component of the curve, as described by Gurpide and associates.[2]

In addition to calculating the metabolic clearance rate from the disappearance slope, the apparent volume of distribution of DS (AVD_{DS}) was calculated by estimating the intercept at time zero.[2]

In these acute studies, immediately following the collection of the 180 minute sample of blood, pharmacologic manipulations were initiated. After the desired pharmacologic change was made, plasma samples were drawn at 20 to 40 minute intervals in order to establish a new disappearance curve (Figs. 2 and 3). In this manner, the acute effect of a pharmacologic agent or treatment regimen was evaluated as to its effect on the MCR_{DS} and the AVD_{DS} following a single injection of ^{3}H-DS.

The utility of this type of study was initially established by evaluating the effect of angiotensin II (A-II)–induced hypertension upon the MCR_{DS} in two normotensive term pregnant volunteers without renal or cardiovascular disease. After the 3 hour plasma sample was drawn, the patient's diastolic blood pressure was elevated 20 mm. Hg and held at this level by a continuous infusion of A-II for 2 hours. The maximum diastolic blood pressure achieved was 86 mm. Hg in Subject G. J. (Fig. 2). During the pressor response, multiple blood samples were drawn and a new disappearance curve established. In this manner, two separate straight lines of disappearance were obtained, that is, a disappearance curve was established before and after administration of A-II (Figs. 2 and 3).

With the same technique, the acute effects of hydralazine hydrochloride and furosemide also were measured. In the studies utilizing hydralazine, all patients were term or near-term severe chronic hypertensive subjects in whom delivery and control of blood pressure was mandatory; in all cases, these studies were conducted within 48 hours of delivery.

At the time of study, patients were placed in the left lateral position and injected with a single dose of ^{3}H-DS and several samples were collected during the first 180 minutes as described above. Following this, a dilute solution of hydralazine (0.2 mg. per milliliter) was administered intravenously by a Harvard Infusion Pump* until the diastolic blood pressure was in the desired therapeutic range of approximately 90 mm. Hg. Care was taken to monitor maternal pulse and keep it at or below 120 per minute. Fetal heart tones were also monitored throughout the infusion period and no fetal tachycardia was noted. Once the desired diastolic blood pressure had been established (90 mm. Hg), blood samples were collected at 20 to 30 minute intervals.

The same technique was applied next in five chronic hypertensive near-term pregnant volunteers. Three hours after the administration of ^{3}H-DS, a single intravenous injection of furosemide, 40 mg., was administered and blood samples were collected at 30 minute intervals to establish a second disappearance curve. Maternal blood pressure and pulse as well as fetal heart tones were monitored throughout the study and in no instance was a decrease in maternal blood pressure observed or an instance of fetal distress noted.

Results

Angiotensin II studies. In both studies utilizing A-II–induced hypertension in normal term pregnant subjects, the MCR_{DS} was decreased (Figs. 2 and 3). The decreases observed were 9 and 17.7 per cent below control values, for a mean decrease of 13 per cent. The largest decrease occurred in Subject G. J., who also had the highest elevation of blood pressure throughout the infusion period.

The only change in AVD_{DS} occurred in Subject G. J. who, as previously mentioned, had the highest level of A-II–Induced blood pressure change. In this patient, the AVD_{DS} was decreased 12.5 per cent.

Hydralazine hydrochloride studies. The results obtained in eight near-term chronic hypertensive gravidas, following hydralazine therapy, are shown in Table I. The MCR_{DS} decreased in all patients studied, with a mean decrease of 23.5 per cent and a range of 5.6 to 58.7 per cent. Although the apparent volume of distribution was increased in four studies and decreased in the other four, the mean values indicate an increase of 8.1 per cent over control values. The mean decrease in diastolic blood pressure in these subjects was 37 mm. Hg, with a range of 26 to 44 mm. Hg. In each instance the diastolic blood pressure was not lowered below 90 mm. Hg.

Furosemide studies. The acute effects of 40 mg. of furosemide administered intravenously to five near-term chronic hypertensive gravidas are shown in Table II. The MCR_{DS} decreased in all patients studied despite a lack of blood pressure change during the course of the study. The average decrease in MCR_{DS} was 18.8 per cent, with a range of 13.9 to 22 per cent. The AVD_{DS} surprisingly increased in four of the five subjects studied, with a mean increase of 14 per cent.

Comment

An increase in diastolic blood pressure of 20 mm. Hg in the two normotensive patients studied resulted in a decrease in the MCR_{DS} in both subjects. Interestingly, the greatest decrease in MCR_{DS} occurred in the patient who had the highest elevation in diastolic blood

pressure (Subject G. J.). In this patient, the blood pressure never was allowed above 86 mm. Hg, but the elevation from 66 to 86 mm. Hg resulted in a greater than 17 per cent decrease in MCR_{DS}. Although it is not possible to make absolute comparisons between this form of artifically induced hypertension and the hypertension which occurs in chronic essential hypertension or pre-eclampsia, nevertheless, the increase in diastolic blood pressure induced by antiotensin II suggests that similar increases in diastolic blood pressure occurring as a result of disease processes might also decrease functional placental reserve.

In Subject G. J., the AVD_{DS} decreased 12.5 per cent and, although the AVD_{DS} does not correspond to blood volume, recent studies in this laboratory suggest that the AVD_{DS} corresponds with total albumin space.[3] Thus an acute decrease in AVD_{DS} may represent a sudden decrease in vascular volume induced by intense and prolonged (2 hour infusion) arteriolar spasm.

The utilization of hydralazine hydrochloride as an antihypertensive agent to treat hypertensive complications of pregnancy has been widespread in the United States. The choice of this agent during pregnancy has been based largely upon the assertion that it does not decrease renal or cerebral blood flow and increases cardiac output and oxygen consumption.[4, 5] The effect of hydralazine hydrochloride on utero-placental perfusion remains unsettled. Johnson and Clayton,[6] using clearance of ^{24}Na from myometrium, reported an increase in clearance after hydralazine therapy, but Dixon and colleagues,[7] using the same technique, observed no improvement in clearance of ^{24}Na from myometrium. Using a more direct measurement of uterine blood flow in the sheep, Lader and associates[8] observed a decrease in uterine blood flow proportional to the decrease in maternal blood pressure. A similar decrease in ovine uterine blood flow was reported also by Greiss and Wilkes.[9]

In the present study, the MCR_{DS} was decreased in all eight subjects studied, with a range of 5.6 to 58.7 per cent following the use of hydralazine hydrochloride. That these decreases in MCR_{DS} represented, at least, in part, a decrease in placental function is illustrated by the study in Patient O.W. (Table I).

O. W. was a 25-year-old black woman, gravida 3, para 0, who was admitted near term with a blood pressure of 180/120. The outlined therapy resulted in a decrease in this patient's diastolic blood pressure to 90 mm. Hg. Interestingly, the MCR_{DS} decreased from 46 to 19 L. per 24 hours, a decrease of 58.7 per cent, following the 30 mm. Hg decrease in diastolic blood pressure. Two days later, at cesarean section, a viable infant was delivered. The placenta had a large infarcted area covering approximately 40 per cent of the surface area. In this patient, with at least 40 per cent of functional placental area already compromised, lowering the diastolic blood pressure to 90 mm. Hg resulted in a severe compromise of placental function. This observation strongly supports the contention that the measurement of MCR_{DS} is, at least in part, reflective of perfusion in the placenta. Of equal importance, this observation displays that even in severe hypertension the placenta manifests a marked degree of functional reserve. In instances where this functional reserve has been compromised already, as was evident in this patient, a further reduction in placental perfusion may markedly jeopardize the fetus.

The rapid-acting and extremely potent diuretic furosemide induced a decrease in the MCR_{DS} in all subjects studied despite a failure of blood pressure to decrease in any of the subjects studied. In addition, despite its well-known diuretic effect, this agent surprisingly did not decrease the apparent volume of distribution. In fact, the AVD_{DS} increased in four of the five subjects studied, resulting in a mean increase in AVD_{DS} of 14 per cent, a result contrary to what intuitively might have been expected following volume depletion. The results of this study suggest that furosemide may have a direct effect on vascular smooth muscle as well as its well-recognized diuretic effect. Certainly the decrease in MCR_{DS}, with no change in blood pressure and the accompanying increase in the AVD_{DS}, suggest that the decrease in MCR_{DS} observed in all five of these subjects was the result of alterations in perfusion of the placenta and/or liver.

The present study indicates that caution should be exercised before and during administration of antihypertensive or potent diuretic agents to hypertensive pregnant women. Specifically, it is probably unwise to reduce maternal diastolic blood pressure to below 100 mm. Hg if fetal viability is a major consideration. In addition, it seems unwise to utilize a potent diuretic agent like furosemide except in a life-threatening situation such as pulmonary edema. Unless these rather specific indications are considered, the use of these pharmacologic agents may adversely effect functional placental reserve and jeopardize our second patient, the fetus.

The authors gratefully acknowledge the excellent cooperation of the resident staff in Obstetrics at Parkland Memorial Hospital, Dallas, Texas, and the expert technical assistance of Miss Kay Cox, Miss Mazie Calvert, and Mr. Mark Jones.

Maternal mortality rates in eclampsia

MARIO LÓPEZ-LLERA, M.D.
GUILLERMO RUBIO LINARES, M.D.
JOSÉ LUIS HERNÁNDEZ HORTA, M.D.
Mexico City, Mexico

This study evaluates the dominant factors that influence the course of eclampsia toward a lethal outcome by means of statistical analysis of various clinical, laboratory, and morphologic data of 365 cases of toxemia with convulsions, that included 49 deaths and 33 autopsies, registered during a 9 year period. This communication suggests that the death of eclamptic patients resulted from a combination of several factors that showed a very wide individual variation. Since advancing age of the mother was associated with a high incidence of coincidental renal and vascular diseases, this was the most clearly influential factor. The presence of twins, delay in hospitalization, undue haste in deciding upon cesarean delivery, and underestimation of the initial clinical condition were all influential factors, although without statistical significance. Cesarean section, performed in 141 instances of ante- and intrapartum eclampsia (40.4 per cent), was not associated with a higher maternal mortality rate.

COLLEGE OF MEDICINE
LIBRARY

THE MATERNAL mortality rate in eclampsia varies from 0 to 20.0 per cent in contemporary medical literature,[1, 12] even though most authors pursue similar general therapeutic objectives. Furthermore, many modern managements have not been able to improve significatively, and sometimes not even duplicate, the results reported by Stroganoff[15] in the early part of this century. This fact becomes a flagrant contradiction in view of the spectacular medical progress seen in the last 50 years.

Eden,[3] Stroganoff,[15] and Peckham[11] recognized important differences in the clinical picture of eclamptic women. Some cases would follow a rather benign uncomplicated course, with prompt recovery, while others would frequently end in death. It became evident that any rational therapy could give optimal results in the first type of patients and be relatively unsuccessful with the second group. Thus, without underestimating the importance of a correct therapeutic approach that requires expertly balanced individualization,[17] we consider that it was imperative to try to identify the dominant factors that may influence the course of the disease toward a lethal outcome independent of therapeutic considerations.

The death of a patient may be viewed as the result of a variable association of factors within a limited clinicopathologic and therapeutic spectrum. The simultaneous or successive analysis of multiple factors has met with serious conceptual and programmatic difficulties. Its utility depends on the proper selection of variables, on the possibility of quantitative estimation of corresponding parameters, and on the existence of significant differences in the data under study.

The present report, based on analysis of various clinical, laboratory, and morphologic data, attempts to identify and evaluate the major factors that influence the course of eclampsia toward a low or high maternal mortality rate.

Clinical material

All maternal deaths due to toxemia of pregnancy and its direct complications, registered at the Hospital de Gineco-Obstetricia No. 2 del Centro Médico Nacional during the 9 years ending on Dec. 31, 1973, formed the material of the present study. Toxemic women who died of coincidental diseases or obstetric complications unrelated to the toxemic process and its management were not included in this analysis. Hence, the natural history of the disease, influenced only by the conventional therapeutic measures recommended

Table I. Maternal mortality rate in antepartum, intrapartum, and postpartum eclampsia

	Antepartum eclampsia (n = 189)	*Intrapartum eclampsia (n = 110)*	*Postpartum eclampsia (n = 66)*	*Total cases (n =365)*
Maternal mortality rate (per cent)	16.9	10.0	9.1	13.4

Chi square = 4.14 (N.S.).

Table II. Maternal mortality rate in early eclampsia

	21-29 wks. (n = 28)	*30-44 wks. (n = 335)*	*Total cases (n = 363)*
Maternal mortality rate (per cent)	28.5	12.2	13.5

Chi square = 5.89 ($P < 0.02$).

by the "toxemia clinic" throughout this period,[7, 9] was evaluated.

Maternal age, parity, amenorrhea, blood pressure, proteinuria, number of convulsions, type of delivery, blood chemistries, plasma proteins, complete clinical diagnosis, and main postmortem findings were the parameters studied. Chronologic aspects such as timing of admission, convulsions, delivery, and laboratory sampling were also considered. A similar analysis was carried out in a comparable group of patients surviving the eclamptic episode. Most of these parameters were subjected to simple descriptive statistical techniques and, when feasible group data received comparative processing.

Analysis of the data

Antepartum, intrapartum, and postpartum eclampsia. Table I presents maternal deaths in eclamptic women divided according to the classical concept of antepartum, intrapartum, and postpartum cases. Although antepartum eclampsia showed the highest mortality rate (16.9 per cent), the differences were not significant. This fact, however, does not rule out entirely the greater risk of antepartum eclampsia, since the differences would become significant if the same tendencies were observed in a population twice the size of the present study.

Early eclampsia. The greater risk of early antepartum eclampsia becomes distinct if the patients are divided in two groups depending on whether convulsions took place before or after the thirtieth week of amenorrhea (Table II). If the cases are further divided by 5 week intervals, the significance is smoothed out as a consequence of the smallness of the first two groups (Table III). Thus, excepting the group of very early eclampsia, the timing of convulsions in regard to the length of gestation does not seem to be of great importance as far as maternal mortality rates are concerned, since the figures become similar after the thirtieth week of amenorrhea.

Clinical and laboratory data in survivors and nonsurvivors of eclampsia. Table IV presents the main characteristics of ante- and intrapartum eclampsia depending on maternal outcome. Postpartum eclampsia cases were not included since they differ in various clinical aspects and pose relatively different therapeutic problems. Blood samples for laboratory work were taken within the first 12 hours after admission in 45.5 per cent of the cases and within the second 12 hour period in the remaining cases. Since there were no statistically significant differences in timing this factor was disregarded under the circumstances of the present study.

As a whole, the eclamptic patients who died showed more severe clinical and laboratory data than those that survived, but significant differences existed only in the magnitude of hypertension and in the age of the patients. The differences in the total number of convulsions and in the levels of blood creatinine were only probably significant. Proteinuria and the levels of blood urea were higher in the group of nonsurvivors and the differences would have reached the significance level if the series were at least two thirds larger. The degree of hypoproteinemia, and particularly of hypoalbuminemia, that characterized these patients is noteworthy, even though there were no differences between survivors and nonsurvivors. The importance of metabolic and respiratory acidosis in eclampsia is well indicated by the levels of blood CO_2 found in the present study, even though this condition is much better evaluated with complete acid-base balance studies. Thus, in spite of several limitations, the synthesis of these data seems to indicate a more severe vasospasm with worse repercussions in the renal, cerebral, and metabolic systems in the nonsurvivors, who were significantly older than the survivors.

with a total maternal mortality rate of 5.5 per cent are compared with those of 89 women after 30 years of age with a maternal mortality rate of 20.0 per cent ($P < 0.005$), only two statistically significant differences are observed. The highest and the average systolic blood pressure readings are lower in the teenage eclamptic patients (175.5 and 153.9 mm. Hg, respectively, vs. 188.3 and 164.7 mm. Hg in the older patients: $P < 0.005$). Even these significant differences may lose their importance since older women show a physiologic tendency for higher blood pressure readings than their younger peers. The younger eclamptic patients may have experienced worse vasoconstriction, despite their lower blood pressure readings, since they started from a lower normal age-related blood pressure level. These clinical and laboratory similarities between two relatively extreme groups point out the importance of age in the maternal outcome of eclampsia. Furthermore, two of the four deaths in teenagers occurred in twin pregnancies, whereas there

Table V. Age groups and maternal mortality rate in eclampsia

	15-24 yr. (n = 203)	*25-34 yrs. (n = 118)*	*35-46 yrs. (n = 43)*	*Total cases (n = 364)*

Chi square = 8.33 ($P < 0.02$).

were none among patients after 30 years of age (see paragraph on twin pregnancies and following discussion). If only single pregnancies are considered in these two age groups, the maternal mortality rates become 2.9 and 21.2 per cent, respectively ($P < 0.001$).

Age and maternal death in eclampsia. Table V presents maternal mortality figures in eclamptic women divided in three groups according to age. The differences are statistically significant and it is evident that they result from a lower mortality rate in the youngest group. A further correlation of death and maternal age in 11 groups with spans of 3 years gives a Pearson's coefficient of 0.766 ($P < 0.01$ with 9 degrees of freedom) which indicates a significant positive correlation between these parameters.

Maternal death and clinical data in cesarean and noncesarean cases of ante- and intrapartum eclampsia. Previous parity was the only parameter showing significant differences in these groups (1.4 and 2.4, respectively: $P < 0.005$). The figures for maternal deaths (14.9 and 13.9 per cent, respectively), maternal age, amenorrhea, highest and average blood pressure, proteinuria, and number of convulsions were almost all identical. The laboratory data for total serum proteins, serum albumin, blood urea, creatinine, and CO_2 did not show any significant differences.

The 21 deaths in the group of cesarean operations included at least 9 cases in which the operation was performed after the diagnosis of extensive brain hemorrhage was established in the mother, in order to offer the fetus a chance for survival. Actually, only two fetuses were lost in these nine cases that included two sets of twins. On the other hand, the 22 deaths in the group without cesarean operation included nine cases that died undelivered, with only two fetal survivals in three instances of postmortem cesarean sections. If these types of deaths are exluded from their respective groups, neither the mortality differences nor the rest of clinical and laboratory data change substantially.

Eclampsia in twin pregnancy. There were 18 twin pregnancies in the total group of 365 cases of eclampsia. The incidence of multiple pregnancy in eclampsia was about three times higher than in the general population, and its maternal mortality rate was double the figure of the whole eclampsia group (27.8 vs. 13.5 per cent). Extensive brain hemorrhage accounted for three of the five maternal deaths in this high-risk group in spite of their relatively young ages (19, 19, 21, 23, and 24 years). This higher mortality rate was associated with lesser degrees of clinical and laboratory abnormalities than those presented in Table IV, with the exception of total serum proteins and serum albumin that reached the lowest levels in the present study (4.53 ± 0.58 and 2.26 ± 0.53 Gm. per 100 ml., respectively). As a consequence of the small number of twin pregnancies registered, the differences were not significant, and it is doubtful that their higher mortality rate could affect the over-all mortality figures, since their incidence was only 4.9 per cent of all eclamptic cases. As a matter of fact, if the 18 twin pregnancies are excluded, the maternal mortality rate drops only 0.7 per cent.

Intercurrent eclampsia and delayed delivery cases. There were six patients with intercurrent eclampsia who gave birth to surviving premature fetuses and nine patients with early antepartum eclampsia who improved rapidly after the fetus died "in utero," but delivery did not take place for several days. The average interval between the first convulsion and the time of delivery in these 15 cases was 15.7 ± 10.3 days. There were no maternal deaths in these atypical cases, and their clinical and laboratory characteristics when compared with the group of survivors in Table IV showed only two significant differences; these patients were older (29.7 ± 1.76 years, $P < 0.01$) and had fewer convulsions (3.07 ± 0.68, $P < 0.025$) than the rest. Another interesting fact of this type of eclampsia was its early presentation since the average amenorrhea was 32.2 ± 2.26 weeks, but due to the small size of the series this difference was not significant. This clinical behavior seemed to indicate a very prompt response to treatment made possible by the rapid death of the fetus in some cases and/or by an unusual reversibility of the pathologic process.

Chronology of main events. Convulsions began before admission to the hospital in 171 patients with ante- and intrapartum eclampsia (57.2 per cent of the group) and on admission or shortly thereafter in 128

cases. The maternal mortality rates were very similar in both groups—14.03 and 14.8 per cent, respectively.

Eighty cases of convulsions before admission and cesarean delivery had a maternal mortality rate of 12.5 per cent; and in 76 similar noncesarean cases this figure was 18.4 per cent. On the other hand, 59 patients with eclampsia after admission and cesarean delivery had a mortality rate of 18.6 per cent; and in 69 similar vaginal delivery cases this figure was 11.6 per cent. However, if the 12 patients that were considered moribund on admission, nine cases of cesarean operation with preoperative diagnosis of cerebral hemorrhage, and four instances of cesarean delivery due to obligatory indications (three cases of severe abruptio placentae and one case of previous section) are excluded, the corrected maternal mortality rates become 4.1, 8.8, 9.4, and 6.1 per cent, respectively, in the previous four subgroups.

When the time intervals between the beginning of convulsions and admission to the hospital and eventual vaginal or cesarean delivery are considered, the group with eclampsia before admission has two important observations. The period between the first convulsion and the moment of arrival at the hospital is longest in the nonsurvivors with vaginal delivery (6.85 ± 6.36 hours), and the interval between admission and delivery in the group of survivors with cesarean operation is the shortest (10.5 ± 9.8 hours).

When a similar analysis is made in the group with convulsions starting after admission, the period between the first convulsion and the time of delivery in the nonsurvivors with cesarean section is the shortest (6.23 ± 5.25 hours), but this group also shows the longest interval between arrival and delivery (20.5 ± 26.1 hours). None of the three differences is statistically significant.

Morphologic data. Table VI presents the main postmortem findings in a total of 33 eclamptic women, divided into two groups according to age. Parenchymatous brain hemorrhages were found in 57.6 per cent of the cases. Microscopic evidence of chronic pyelonephritis, chronic glomerulonephritis, and/or nephrosclerosis existed in 42.4 per cent of the patients. The toxemic renal lesion was evident in all cases but one, that of a patient with chronic glomerulonephritis in whom the signs of a superimposed toxemia would have required electron microscopy studies for definite demonstration. There were three instances of subcapsular liver hemorrhages, three of acute tubular necrosis, and 10 patients with brain changes other than hemorrhage but important enough to jeopardize their survival. Finally, the weights of the liver and of the heart were abnormally increased in most cases.

Since the average height of 107 survivors of eclampsia from the same obstetric population was 150.7 ± 6.1 cm., with a corresponding calculated average weight of the heart of 247 ± 30 grams,[16] cardiac hypertrophy in the autopsy cases was defined as a weight greater than 307 grams and/or a left ventricle thickness of 12 mm. or more. Morphologic

evidence of cardiac hypertrophy was present in 78.8 per cent of the cases.

As a whole, patients 30 years of age or more (n = 14) showed more pathologic changes and more coincidental diseases than younger women (n = 19). This was noticeable in most organs, but it was more evident in the frequency of coincidental renal pathology and in the frequency and magnitude of cardiac hypertrophy. None of the differences was statistically significant.

Comment and conclusions

The data presented in this study seem to indicate that the death of eclamptic patients resulted from the combination of several factors that show wide individual variability. Only a few patients with clear-cut clinical, laboratory, and morphologic evidence sometimes present a single dominant factor as the cause of death, and this is often found to be gross mishandling of the case by inexperienced medical and paramedical personnel.

Contrary to logical expectations, statistical analysis in most instances was not capable of defining satisfactorily the importance of those potential influences. This was an inevitable consequence of the size of the series and of its necessary fragmentation for the evaluation of chosen variables under different circumstances. In spite of the relatively small number of cases, in certain groups, some factors showed a significant association with the final outcome of eclamptic women and others seemed to be indifferent. *The most clearly influential factor was the age of the patient at the time of eclampsia.* Since this complication occurs preferentially in young primigravid women whose ages show a narrow range, the prognostic importance of aging has seldom been detected.[1, 2, 5, 7, 10] Age per se, however, within the increasingly shorter reproductive span of modern woman, does not show a very clear effect in most gestational pathology. What it most likely indicates is an over-all loss of optimal efficiency in the essential homeostatic mechanisms that reduces the adaptability of vital systems to various types of pathogenic influences and stress.

On the other hand, relative aging and pregnancy may be associated with the emergence of previously nondetectable underlying pathology. An increase in age, even within a narrow range, may be accompanied by general and regional changes that potentiate each other reciprocally, and in the proper pathogenic setup render the individual more prone to fatal consequences. The fact that very early eclampsia, that is frequently associated with underlying disease, showed a significantly higher maternal mortality rate, is in keeping with this interpretation.

The postmortem studies of 33 eclamptic patients detected two important facts: a high incidence of chronic pyelonephritis and cardic hypertrophy. Whether the first finding was merely coincidental and had no influence on the pathogenesis of eclampsia cannot be ascertained at the present time, but it must be carefully assessed in view of their frequent association.[6] Furthermore, according to Freedman,[4] the incidence of nonobstructive chronic pyelonephritis found at autopsy varies from 0.6 to 2.4 per cent, and Sheehan and Lynch[14] reported an incidence of "large pyelonephritic" scars in 5.7 per cent of autopsied toxemic and eclamptic women. These figures are several times smaller than those found in the present report. Even though it is a fact that urinary infections thrive among poor people, to which group toxemic patients usually belong, one must keep in mind the limitations for establishing the role of bacterial infections on the basis of morphologic information alone[4] and the possible differences in diagnostic criteria among authors.

As far as cardiac hypertrophy is concerned, the paramount question is whether it resulted from the toxemic episode alone or whether it existed prior to pregnancy. The fact that it was more frequent and more marked in women after 30 years of age would seem to support the latter possibility, but the lack of statistical significance in the differences among age groups and our limited knowledge about the chronologic and hemodynamic requirements for early left cardiac hypertrophy make uncertain any interpretation.

In a group of 67 eclamptic deaths among English and Scottish women, Sheehan and Lynch[13] found an incidence of 25.4 per cent of hearts weighing more than 340 grams, and estimated that at least two thirds of them were due to chronic hypertension. If this same criteria is followed in the present study, the total incidence of abnormally heavy hearts becomes 29.0 per cent, with a striking difference between young and older women (17.6 vs. 42.8 per cent), although no statistical significance existed because of the size of the series. The figures used by Sheehan and Lynch are not suitable for the present communication in view of the important differences in stature between English and Scottish and Mexican women. Thus, the top limit of 307 grams, that resulted from Zeek's[16] average plus two standard deviations for an average height of 151 cm., seems more applicable to an eclamptic Mexican population and, as such, a remarkable majority of these patients presented indisputable evidence of important left cardiac hypertrophy, possibly associated with preclinical and undetected chronic hypertension or

chronic anemia and malnutrition, in an at present undefinable percentage of the cases.

The previous clinical and morphologic description and discussion provide strong evidence for stating that the eclamptic population of the present study included a remarkably high proportion of coincidental renal and vascular diseases that jeopardized their most vital homeostatic mechanisms. This association increased with advancing age of the patients and led to a significantly higher maternal mortality rate in older women. A similar conclusion had been reached after analysis of a smaller group of eclamptic women.[8]

Eclampsia in twin pregnancies had a higher mortality rate despite the young ages of these patients, and with lesser degrees of clinical and laboratory abnormalities than those found in the total group of survivors. This may indicate that the hemodynamic and obstetric characteristics of twin pregnancy per se accentuate the consequences of the toxemic condition by decreasing even more the homeostatic capabilities of the whole organism. The fact that this group showed the lowest values of serum proteins of all eclamptic cases and that three out of five deaths in young women were due to cerebral hemorrhage may support this latter view.

Cesarean section in this study of eclamptic women was not associated with a higher maternal mortality rate if nine cases with the diagnosis of extensive brain hemorrhage prior to surgery and four instances of surgical delivery because of obligatory indications are excluded. When the chronology of events is considered and the individual records are revised, one gets the impression that the cesarean operation was decided upon too soon after a convulsion and before adequate control of the condition in two patients, but its influence on the fatal outcome of these cases remains difficult to assess.

The mortality figures found in the different groups correlated with chronologic data agree with the logical opinion stating that prompt hospitalization and well-timed management are important prognostic factors in eclamptic patients. In this context, the fact that 42.8 per cent of ante- and intrapartum eclampsia patients had their first convulsion on admission or shortly thereafter, is a most disturbing finding. Thirty-three patients began convulsions while in the admitting department and/or within the first hour of hospitalization, before therapy could be effective. The remaining 95 (31.7 per cent of the total) began convulsing at an average of 9.2 hours after being admitted for three possible reasons: (1) these patients had a rapidly progressive type of toxemia; (2) the stress of labor, if present, increased the severity of the disease; and/or (3) their clinical condition was underestimated, a common error when inexperienced personnel handle toxemic women.[5] Clarification of the relative significance of each one of these three possibilities goes beyond the scope of the present communication, but it is obvious that, if convulsions and their often fatal consequences are to be largely prevented, no single case of pre-eclampsia should be underestimated.

Effects of epinephrine on distribution of blood flow in the pregnant ewe

CHARLES R. ROSENFELD, M.D.
M. DENNIS BARTON, M.D.
GIACOMO MESCHIA, M.D.
Denver, Colorado

Seven pregnant ewes ranging from 85 to 140 days of gestation were infused with systemic doses of epinephrine and uterine arterial flow dose-response curves were determined. With a constant systemic infusion of epinephrine at a mean rate of 0.29 ± 0.03 μg/Kg. · min., and the radionuclide labeled microsphere method to measure arterial blood flow, a 38.5 per cent decrease in total uterine arterial blood flow was demonstrated while systemic pressure was unaltered. At this dose the reduction in endometrial blood flow was significantly greater (−58.7 per cent) than that in either the myometrium (−36.9 per cent) or placental cotyledons (−34.5 per cent) ($p < 0.025$ and < 0.005, respectively). There also occured a decrease in blood flow to the mammary gland and the pancreas, whereas increases in blood flow to the skeletal muscle, adipose tissue, and spleen were documented. It is evident from this study that during the period of ovine pregnancy investigated, the vascular beds of all tissues comprising the pregnant uterus, including the placental cotyledons, are sensitive to the vasoconstrictive effects of epinephrine.

THE RESPONSE of the uterine vascular bed to vasoactive agents is the subject of numerous studies. Previous studies[1–6] have demonstrated that adrenergic drugs can influence the magnitude of uterine blood flow. The presence of both alpha- and beta-adrenergic drug receptor sites has been demonstrated in the uterine vascular bed.[4]

Studies by Barton and associates[6] have also shown that similar concentrations of exogenous epinephrine and norepinephrine can cause similar reductions in uterine arterial flow when infused into the uterine artery. A 50 per cent reduction in uterine arterial flow occured with an intra-arterial concentration of exogenous epinephrine ranging from 2 to 10 ng. per milliliter of arterial blood. This study raised two further questions. (1) Were some components of the uterine circulation spared from the action of catecholamines? (2) If epinephrine caused significant vasoconstriction in the pregnant uterus at these low concentrations, what were the systemic effects of epinephrine in this same concentration range?

In order to answer these questions, we employed a chronic unanesthetized sheep preparation with implanted uterine artery flow probes. Radioactively labeled microspheres were infused systemically before and during an intravenous epinephrine infusion in order to determine the effect of epinephrine on the placental, myometrial, and endometrial circulation, as well as other vascular beds.

Methods

The study was performed in seven pregnant ewes ranging from 85 to 140 days of gestation and included three singleton and four twin pregnancies. The preparation was the same as that described by Rosenfeld and associates[7, 8] consisting of pregnant animals with electromagnetic flow probes (Micron Instruments, Los Angeles, California) implanted around both uterine arteries and polyvinyl catheters (0.9 mm. inner diameter by 1.2 mm. outer diameter) in both femoral arteries passed to the trifurcation of the abdominal aorta and in a femoral vein passed to the high inferior vena cava. A radiopaque catheter (1.2 mm. inner

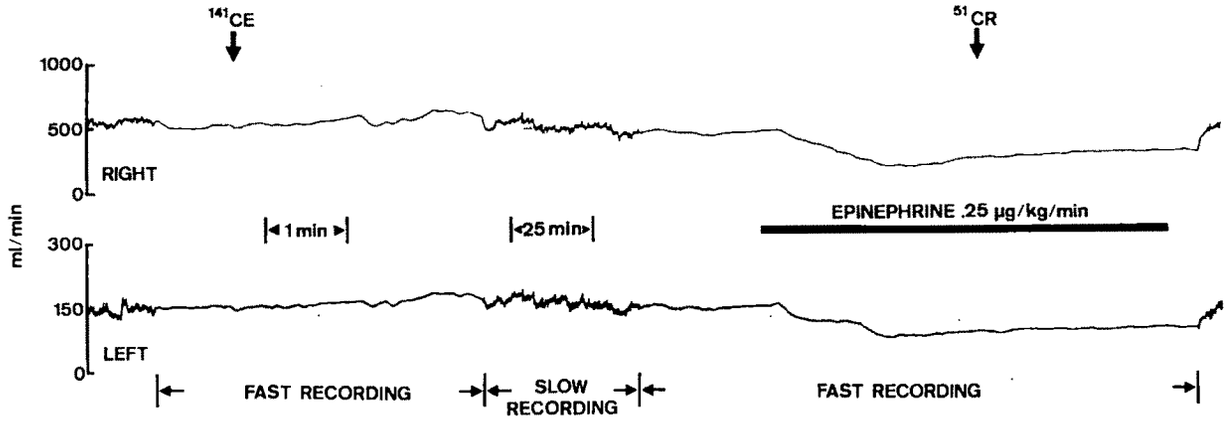

Fig. 1. Continuous flowmeter recordings of right and left uterine arteries in an ewe of 130 days of gestation carrying a singleton pregnancy on the right. The time of infusion of isotope-labeled microspheres is noted. The systemic infusion of epinephrine at 0.25 µg/min.·Kg. produced a lower steady flow in both uterine arteries.

diameter by 2.2 mm. outer diameter) was also passed via the left common carotid artery into the left ventricle.[7] The flow probes and inguinal catheters were carried out to the flank through a subcutaneous tunnel and were maintained in a canvas pouch fastened to the ewe's skin with steel pins. The left ventricular catheter was kept in a separate pouch attached to the neck. All catheters were flushed daily with heparinized saline (1,000 U. per milliliter).

Following surgery the ewes were maintained in stalls in the laboratory and studied after they had recovered from surgical trauma, generally within 4 days. Systemic arterial and venous pressures were monitored by pressure transducers connnected to a Gould amplifier (model N-4307-04, Cleveland, Ohio) and a two-channel Brush recorder (Model 220, Gould Inc., Cleveland, Ohio). Uterine blood flow was monitored with Micron Instruments electromagnetic flowmeters (Model RC 1000, Los Angeles, California) and recorded on another two-channel Brush recorder. The flow probes employed have a linear response to flows in the range studied and are provided with flow signal and zero flow calibrations.

The response of uterine arterial blood flow to systemic doses of epinephrine was investigated as follows.

Epinephrine solutions were freshly made by adding 4 ml. of 1:1000 epinephrine chloride (Adrenalin, Parke Davis) to 996 ml. of 5 per cent dextrose in isotonic saline, giving a concentration of 4 µg per milliliter of base, and used for no more than 4 hours at a time. This solution was infused with a Harvard infusion pump at varying rates through the inferior vena cava catheter. The period of infusion was 5 minutes for each rate examined, followed by a rest period of 10 to 15 minutes, permitting flows to return to preinfusion levels. No more than six infusions were performed per day. Simultaneous blood pressure, pulse rate, and uterine arterial blood flow measurements were obtained and electronically integrated. The speeds of the infusions were randomly chosen and dose-response curves constructed. A rate of epinephrine infusion was identified for each animal that caused a 30 to 40 per cent reduction of uterine blood flow. One to 2 days after determining the dose-response curve to systemic epinephrine infusion, the procedure was repeated, using the predetermined dose of epinephrine with the objective of infusing isotope-labeled microspheres into the left ventricle of the ewe before and during the constant epinephrine infusion (Fig. 1).

The method for the infusion and analysis of microspheres has been described in detail elsewhere[7] and is summarized here. Radioactive carbonized microspheres (Minnesota Mining and Manufacturing Co.) with ^{141}Ce and ^{51}Cr labels, a specific activity of 10mCi. per gram, and a mean diameter of 25 $\mu \pm 5$ S.D. were employed. The exact amount of microspheres in the infused suspension was determined by adding the microspheres, 8 to 10 ml. of sterile isotonic saline, and 1 drop of Tween 20 to a preweighed counting vial containing a magnetic stirring rod and reweighing the vials. The suspension was mixed on a magnetic stirer for 45 minutes and four 0.1 ml. samples of the suspension were removed in preweighed lengths of polyvinyl tubing while the mixing continued. These catheters were placed in preweighed counting vials, weighed, and counted. The mean counts per minute (c.p.m.) per gram of suspension were calculated. The suspension, whose weight and radioactivity per gram

was known, was infused by air desplacement through the left ventricular catheter while the microspheres were kept in suspension with a stirring warming unit. The suspension was infused over 30 to 40 seconds and the ventricular catheter flushed with 10 ml. of isotonic saline. Afterward the entire administration unit was reweighed and the total counts per minute and number of microspheres infused were determined (see Table I). In the experiments reported here, the microspheres were infused before the epinephrine infusion and again during the epinephrine infusion. The latter microsphere infusion was not begun until the uterine blood flow, monitored by the implanted flowprobes, had reached a lower, steady rate of flow.

Starting just prior to the microsphere infusion, arterial reference samples were withdrawn into counting vials under oil from both femoral artery catheters at a rate of 3.66 ml. per minute for 3 minutes with a Harvard pump. This method allows the calculation of cardiac output as well as individual organ flows. Individual organ blood flows were calculated with the arterial samples by solution of the following equation:

$$\text{Organ flow (ml./min.)} = \frac{\text{Total c.p.m. for organ}}{\text{Mean c.p.m. in arterial sample}} \times \text{Withdrawal speed (ml./min.)} \quad (1)$$

Cardiac output (CO) was obtained by the solution of the following equation:

$$\text{CO (ml./min.)} = \frac{\text{Total microspheres infused}}{\text{Mean microspheres in arterial sample}} \times \text{Withdrawal speed (ml./min.)} \quad (2)$$

Samples for arterial blood gases were drawn from the femoral artery before each epinephrine infusion during construction of dose-response curves and also before and after each isotope-labeled microsphere infusion.

The ewes were killed within 24 hours after the second microsphere infusion and dissected for tissue preparation. The uterus, vagina, and cervix were removed *en bloc* and the cervix and vagina then dissected from the uterus. The endometrium and myometrium were separated by sharp and blunt dissection. The efficacy of this method has previuosly been confirmed by histologic examination.[7] The three components of the uterus (cotyledons, endometrium, and myometrium) were then weighed. The following organs were also removed and weighed: brain, mammary gland, lungs, heart, liver, spleen, pancreas, kidneys, ovaries, Fallopian tubes, thyroid gland, and adrenal glands. Representative samples of foreleg skin, mammary gland skin, hindleg muscle, chest wall muscle, and small bowel were also removed and placed directly into counting vials.

Samples were counted in a Nuclear-Chicago automatic dual-channel gamma counter with a 3 inch crystal detector and a wide well. The ^{51}Cr was counted as an emission peak of 0.321 Kev. (window range, 0.271 to 0.371 Kev.) and the ^{141}Ce was counted at a peak of 0.145 Kev. (window range, 0.127 to 0.162 Kev.). Under these conditions 4.5 to 5.5 per cent of the ^{51}Cr counts appeared in the ^{141}Ce window and 0.3 to 0.7 per cent of the ^{141}Ce counts appeared in the ^{51}Cr window. The true counts per minute for each isotope were calculated by the solution of the appropriate simultaneous equation.

Control flows before epinephrine infusion and experimental flows during epinephrine infusion for each organ or tissue studied were calculated. The paired t test was used to determine degrees of significance between control and experimental flows. All mean values are presented as ±1 standard error of the mean (S.E.M.).

Results

Fig. 2 demonstrates the dose-response curves of mean systemic arterial pressure and uterine blood flow to the intravenous infusion of epinephrine. The curves depicting the changes in mean arterial pressure and uterine blood flow are similar in each of the animals studied. There is no significant change in the systemic pressure as the infused dose of epinephrine increases until there occurs a decrease in uterine arterial blood flow of greater than 40 to 50 per cent.

With the use of these dose-response curves, an infusion rate of epinephrine which would lead to the largest decrease in uterine blood flow without alteration in the systemic pressure was chosen for use in the subsequent microsphere studies. The dose employed in these studies ranged from 0.192 to 0.410 μg/min. · kg. with a mean of 0.287 μg/min. · kg. ± 0.034. At this rate of infusion there was a significant change in heart rate, increasing from 102 ± 9.1 to 122 ± 13.4 beats

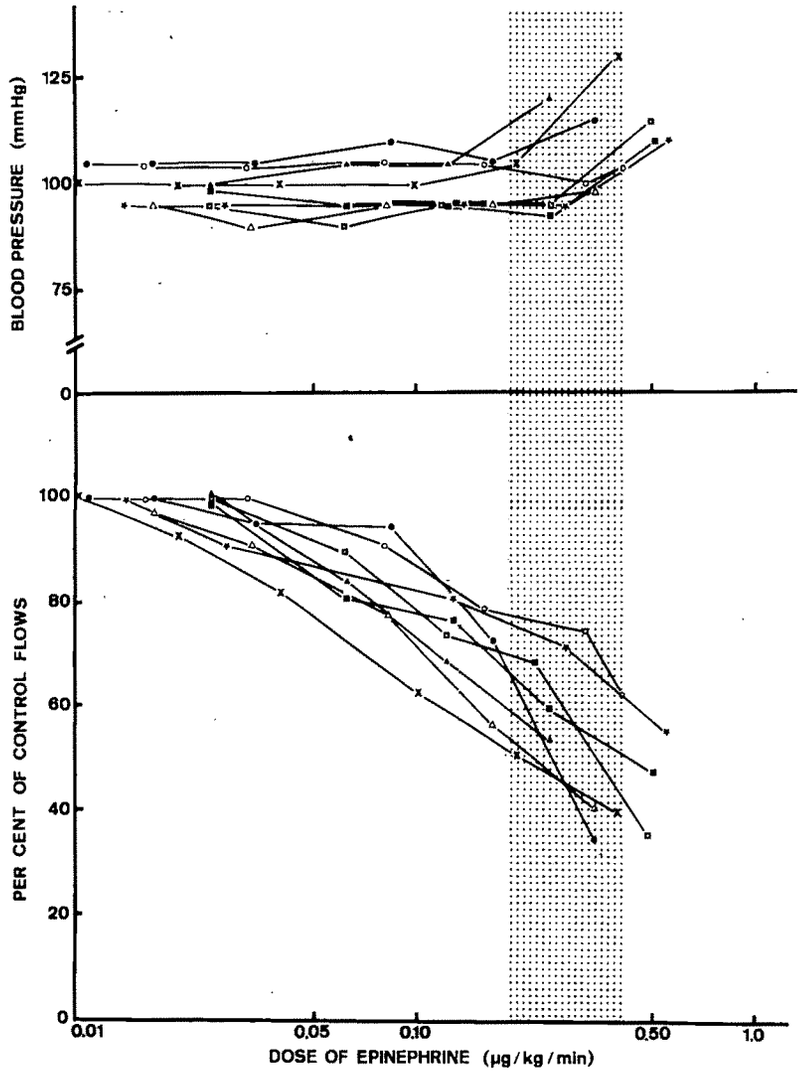

Fig. 2. The responses of uterine blood flow as measured with the flowmeters and mean systemic blood pressure to increasing doses of epinephrine. The shaded area represents the dose range employed in the microsphere portion of the study. (0.2 to 0.4 μg/Kg.·min.). Uterine blood flow is presented as per cent of control flows.

per minute ($p < 0.05$) but no significant alteration in the mean systemic pressure (control of 92.0 mm. Hg ± 3.7 and experimental of 92.3 mm. Hg ± 6.0). A typical response of uterine blood flow to the epinephrine infusion is demonstrated in Fig. 1.

After studying the first two animals and calculating the uterine arterial blood flow from the microsphere data, a discrepancy between this data and the simultaneously observed flowmeter data was noted. This had not been our experience in the past[8] and led to the discovery of a malfunctioning component in the gamma counter. From previous experiments, which permitted the comparison of 61 simultaneous determinations of uterine blood flow by the microsphere and flow probe methods, we were able to construct an ecuation[8] which related the two measurements:

$$\text{Microsphere flow (ml./min.)} = \frac{\text{Flowmeter flow (ml./min.)} - 36 \text{ ml./min.}}{0.86} \quad (3)$$

The uterine arterial flows for the first two animals studied were corrected with the use of Equation (3). As the per cent distribution of the microspheres was known and not affected by the gamma counter malfunction, it was possible to determine the arterial blood flow to each of the uterine tissues. Once the gamma counter was repaired this descrepancy did not recur.

In a third animal we were unable to place the microsphere infusion catheter into the left ventricle.

Table II. The effect of a systemic infusion of epinephrine on total uterine blood flow and blood flow rate to the separate uterine tissues as measured with the microsphere method

Table III. Tissues and organs demonstrating a significant change in arterial blood flow during an epinephrine infusion

Tissue or organ	*Per cent change**	*p*
Skeletal muscle	+434.6 ± 112.4	0.025
Intra-abdominal fat	+180.0 ± 41.5	<0.05
Spleen	+138.9 ± 29.2	<0.01
Pancreas	−27.8 ± 7.6	<0.025
Mammary gland skin	−44.2 ± 10.1	<0.05
Total uterus	−38.5 ± 4.6	<0.025

*Mean ± S.E.M.

The catheter was left in the ascending portion of the thoracic aorta. Because of this, cardiac output and blood flow to those organs served by the ascending aorta were not calculated. Thus, we were able to analyze blood flow to all organs in only four animals, and flows to organs served by the descending aorta for an additional animal. Uterine blood flow data are available for all seven animals studied.

Cardiac output was available in four animals. The mean cardiac output was 7,279 ml. per minute in the control period and 8,937 ml. per minute during the epinephrine infusion. The cardiac output increased 18 to 76 per cent in three animals and decreased 10.5 per cent in the fourth.

Table II shows the effect of epinephrine on myometrial, endometrial, and placental blood flows. When the separate uterine tissues are compared it can be seen that the endometrium exhibited a significantly greater decrease in blood flow (−58.7 per cent ± 5.3) than either the myometrium (−36.9 per cent ± 6.4, $p < 0.025$) or the placental cotyledons (−34.5 per cent ± 4.7 $p < 0.005$). There was no significant difference between the responses seen in the myometrium and placental cotyledons ($p > 0.50$).

In the three ewes carrying singleton pregnancies, the responses to epinephrine in the pregnant and nonpregnant horns of the uterus were compared and no difference was observed. Cervical blood flow was also examined and found to decrease from 6.03 ± 1.06 to 3.94 ± 0.91 ml. per minute but these changes were not statistically significant. No significant changes were seen in ovarian and Fallopian tube flows.

Because of the nature of the animal preparation and the method for measuring blood flow with the isotope-labeled microspheres, it was possible to compare blood flow changes within the uterus with changes of blood flow to other organs and tissues. The results of this comparison are presented in Tables III and IV and Fig. 3. Skeletal muscle obtained from the hindlimb and the chest wall, pooled samples from peritoneal and

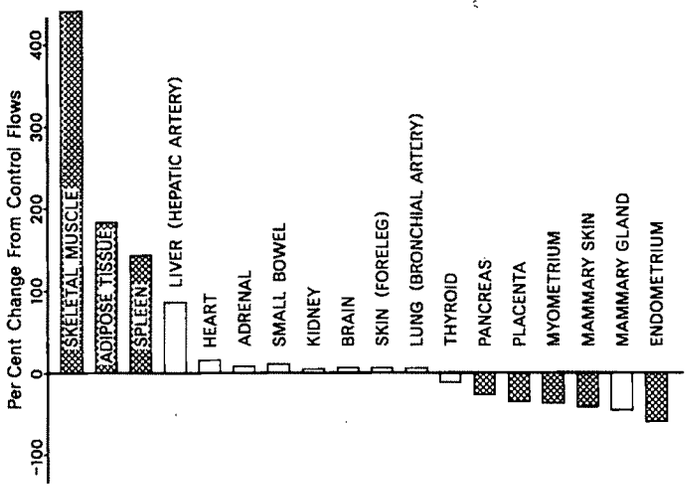

Fig. 3. The per cent change in organ and tissue blood flows during a systemic infusion of epinephrine (0.2 to 0.4 μg/min. · Kg.) in pregnant ewes. The shaded bars are statistically significant at $p < 0.05$.

omental fat, and the spleen demonstrated significant increases in flow, whereas the uterine tissues, skin overlying the mammary gland, and the pancreas showed significant decreases in flow. There was a slight increase in flow to the hind leg skin that was not statistically significant.

The data for organ blood flows in the four ewes in which cardiac output was determined were analyzed in order to determine the change in the distribution of cardiac output that occured during the infusion of epinephrine (Table IV). It should be noted that there was a significant decrease in the percentage of cardiac output going to the kidneys.

The blood flow to the ovine mammary gland was noted to increase with gestational age of the animals in these experiments. Our data demonstrated control mammary blood flow of 15.9 ml. per minute at 85 days of gestation and 228 ml. per minute at 140 days of gestation. In each of the animals studied the infusion of epinephrine consistently caused a decrease in mammary blood flow ranging from 13 to 70 per cent but, because of the large variation in the control flows, the decrease demonstrated was not statistically significant ($0.10 > p > 0.05$). No significant changes were seen in arterial pH or $Paco_2$ during the studies. Values were consistent with those previously recorded.[9]

Comment

The vascular effects of catecholamines have been widely studied with systemic and individual organ infusions in both man and laboratory animals.[10] The new features of the present study are (1) the demonstration of epinephrine-induced vasoconstriction in each component of the vascular bed of the pregnant uterus and (2) the greater sensitivity of the reproductive tissues to the vasoconstrictive properties of epinephrine than the other organs or tissues of the body.

Table IV. Organs demonstrating a significant change in the percentage of cardiac ouput received, as determined in four ewes

Organ	*Per cent cardiac output**		*p†*
	Control	*Experimental*	
Right kidney	5.3 ± 0.3	4.14 ± 0.2	<0.05
Left kidney	5.2 ± 0.5	4.13 ± 0.5	N.S.

†Paired analysis, Student's t test.

The effect of catecholamines on uterine blood flow was first studied in detail by Robson and Schild.[11] Writing in 1938, they found that epinephrine produced uterine arterial vasoconstriction in both pregnant cats and spayed cats treated with estrone or with estrone and progesterone. The contractile response of the myometrium to catecholamines is known to depend on the hormonal state of the animal.[12] Their results indicated that the response of the uterine vasculature to epinephrine was free of female hormonal influence. In subsequent studies by Ahlquist and Woodbury[2] in pregnant dogs and by Adams and associates[1] in pregnant sheep, the vasoconstrictive effects of epineph-

rine on uterine blood flow were confirmed. Studies on the effect of systemic catecholamine infusions on blood flow to the gravid ovine uterus have been reported by Greiss.[3] In these studies, he reported a 50 per cent reduction in uterine vascular conductance following systemic infusions of greater than 0.5 μg/Kg./min. of epinephrine or norepinephrine. There was no significant difference in response over the period of gestation studied, 112 to 147 days. Our study, which demonstrates in ewes from 85 to 140 days of gestation a 39 per cent reduction in uterine arterial flows during systemic infusions of epinephrine ranging from 0.2 to 0.4 μg/Kg./min., is in good agreement with Greiss' data.

The present study documents that, at the dose levels that were employed, the vasculature of all three uterine tissues (endometrium, myometrium, and placental cotyledons) are sensitive to the vasoconstrictive effects of epinephrine. It was further demonstrated that the response of the endometrial vasculature to epinephrine (a 59 per cent reduction in blood flow) was greater than that noted in either the placental cotyledons (a 35 per cent reduction) or the myometrium (a 37 per cent reduction), whereas the responses in these two tissues were similar. This documentation of a vascular response by all of the uterine tissues to epinephrine suggests the presence of alpha receptors in the arterioles of each of the uterine tissues and presents evidence that these receptor sites remain sensitive to the vasoconstrictive effects of epinephrine during pregnancy.

Arterial blood flow to the mammary gland and to the skin overlying the mammary gland was decreased by the epinephrine infusion (see data). Mammary gland arterial blood flow has been shown to decrease in response to epinephrine.[13, 14] In contrast to the mammary gland skin, skin from the ventral surface of the hind leg did not demonstrate a significant reduction in blood flow. Skin vasculature may vary in its reactivity to systemic catecholamine infusions according to its location.

In the dose range of epinephrine studied here, 0.2 to 0.4 μg/Kg./min., skeletal muscle, intra-abdominal fat, and splenic blood flows were all increased significantly, whereas blood flows to the pancreas were decreased.

The vasodilatory effect of epinephrine on skeletal muscle has been attributed to beta/receptor stimulation. Low doses of epinephrine given intra-arterially into the forearm muscle of man produce a transient sharp rise in the arterial flow of greater than 100 per cent of control, followed by a lower, sustained flow that is greater than 50 per cent of control.[15] These results are supported by data from the present study which demonstrate a striking increase in blood flow to chest wall and hindlimb muscle (>400 per cent of control) in the face of unaltered mean systemic pressure.

Epinephrine has been domonstrated to cause an increase in blood flow to adipose tissue in this study. The phenomenom has been demonstrated in canine subcutaneous adipose tissue infused with epinephrine at a concentration of 0.01 μg per milliliter.[16] In the same study isoproterenol was noted to increase fat blood flow, suggesting that beta-receptor stimulation can lead to vasodilation in adipose tissue.

The splenic vasculature has been widely studied and found to respond to infused catecholamines.[17, 18] Beta-adrenergic stimulation led to increases in splenic blood flow, whereas alpha stimulation decreased flow. Epinephrine was demonstrated in the cat to increase splenic blood flow from 60 to 160 per cent of control flows[17, 18] following doses from 0.1 to 1.0 μg per kilogram. In the pregnant sheep studied here splenic blood flow also increased without a systemic blood pressure increase. It is possible that with the use of higher doses of exogenous epinephrine, splenic vasoconstriction might have occurred.

The arterial bed of the pancreas has been shown by other investigators to possess both alpha and beta receptors,[19] but the response of this organ to catecholamines is by no means settled. We were able to demonstrate a significant reduction in pancreatic blood flow of approximately 28 per cent, occurring 2 to 3 minutes after the initiation of the epinephrine infusion, and not associated with an alteration in systemic arterial pressure.

Arterial blood flow to tissues such as heart, brain, kidney, liver, and bowel has been found to be altered by catecholamines in various studies, but did not demonstrate a significant change following the 0.2 to 0.4 μg/Kg.·min. epinephrine infusion employed here in pregnant sheep. Though no significant change in blood flow to the kidneys was documented during the epinephrine infusion, the per cent cardiac output reaching them was significantly reduced. As the skeletal muscle makes up a large part of the body mass in these animals, it is conceivable that the increase in flow to this tissue (>400 per cent) accounts for both the increase and redistribution of cardiac output.

Epinephrine is of use in various clinical situations in obstetrics, such as an adjuvant for local anesthetic solutions. If epinephrine were inadvertently given in sufficient quantity into the vascular system during a local anesthetic injection, it might have a deleterious effect on uterine blood flow in the pregnant human. Slow intravenous or subcutaneous epinephrine in the human subject has little effect on mean blood pressure,

but does significantly decrease peripheral resistance and increase both cardiac output and heart rate.[10] In the experiments reported here, a dose of epinephrine that produced no significant change in mean systemic blood pressure did significantly increase muscle blood flow, did significantly increase heart rate, and in three of four instances did increase cardiac output. The same dose also led to a 38 per cent reduction in total uterine blood flow in the pregnant ewe. On the basis of these findings, it can be suggested that deleterious effects might occur in a pregnant woman exposed to relatively low arterial concentrations of epinephrine.

A double-blind investigation into the effects of ritodrine on uterine blood flow during the third trimester of pregnancy

J. P. BRETTES
R. RENAUD
R. GANDAR
Strasbourg, France

The object of this double-blind crossover study was to investigate the effect of a β-mimetic agent–ritodrine–administered intravenously at increasing infusion rates on uterine blood flow and the maternal cardiovascular system during the third trimester of normal pregnancies and pregnancies complicated by intrauterine growth retardation and/or hypertension. Uterine blood flow, maternal arterial blood pressure, maternal and fetal heart rate, and uterine activity were simultaneously recorded throughout the study. In normal pregnancies the changes in different parameters during ritodrine and placebo administration were slight. In the "pathologic" pregnancies there was a highly significant increase in maternal heart rate, differential blood pressure, and uterine blood flow during ritodrine administration. The differences in response to ritodrine and placebo were statistically significant in this later group. This study demonstrates increased sensitivity of the maternal cardiovascular system to this β-mimetic agent in certain categories of high-risk pregnancies and possibly an increase in uteroplacental blood flow.

DURING recent years there have been many reports on the use of a beta-mimetic agent, ritodrine, for the treatment of premature labor[1–4] and as a uterus relaxant.[5, 6] In addition, animal studies have suggested a possible effect of β-mimetic drugs on uterine and placental blood flow.[7–9] Sivasambo[3] showed an increased infant weight at the thirty-ninth week of pregnancy, which has not been confirmed by other authors.[10]

The object of this study was to investigate in a double-blind cross-over study the effect of ritodrine, given by the intravenous route in a very low dose, on the uterine blood flow and cardiovascular system during the third trimester of pregnancy.

Materials and methods

Included in the study were 18 patients in the third trimester of normal pregnancy and 11 patients in the third trimester of pregnancies which were termed "pathologic"—that is, with confirmed intrauterine growth retardation or hypertension. After detailed explanation of the procedures involved and after obtaining consent of the patient to these procedures, the study commenced.

All patients were informed that they were free to drop out of the study at any time without any personal consequences.

Trial procedures

A thermistor probe* was inserted into the anterior lip of the cervix to a depth of 20 mm. and, by utilizing the technique of anenometric thermometry described by Brotanek and associates,[11] increases or decreases in the rate of heat dissipation from the probe tip could be registered. The changes have been shown to reflect changes in blood flow past the probe tip. Local blood

*Captor made by "Institut de physique biologique," Strasbourg University.

flow is one of the most prominent factors involved, but not the only one. Interstitial fluid flows, and probe movement, for example, can modify the indication of blood flow. The placement of the probe 20 mm. deep in the cervix measures, at best, blood flow in cervical tissues. This may not reflect total uterine blood flow and, even more importantly, placental perfusion. The uteroplacental and myometrial vascular beds may show different reactivities.

In one patient, at 38 weeks of gestation with intrauterine growth retardation, the membranes ruptured during insertion of the thermistor probe. The patient went into labor and a healthy 2,200 gram infant was born.

Maternal cardiovascular response. The maternal heart rate was recorded from digital photoplethysmography or from the electrocardiogram. Maternal systolic and diastolic blood pressures were measured indirectly by use of an external sphygmomanometer.

Uterine activity. This was monitored continuously throughout the study by external tocography* and initially in the first two cases by internal tocometry through an open-end fluid-filled catheter.†

In these two patients uterine contractions appeared during the insertion of an intrauterine catheter. After that event the intrauterine pressure recorder was not used in this study.

Fetal heart rate. This was continuously recorded from the phonocardiogram.

Simultaneous recording of all these parameters was done on a Philips polygraph.‡

This study, which was executed under strictly double-blind conditions and on a randomized cross-over basis, consisted, for each patient, of a 4 hour study period divided into five phases. There was an initial phase of 30 minutes during which the various records were allowed to reach a stable baseline. This was followed by a second phase during which three intravenous infusions were given, each of 10 minutes' duration, at a rate of 50, 100, and 150 μg per minute of ritodrine in 5 per cent dextrose, or an equivalent amount of a placebo of identical appearance, via an infusion pump.§

This was followed by a third period of 20 to 60 minutes during which the various recorded parameters were once more permitted to reach a constant baseline. Thereafter, the procedure was repeated according to the cross-over design.

Table I. Excluded cases

Case	*Reason for exclusion*
Two normal cases	Uterine contractions after insertion of transparietal intrauterine catheter for intrauterine pressure recording
One "pathological" case	Rupture of membranes during insertion of thermistor probe in cervix

Table II. Changes in uterine blood flow during administration of ritodrine and placebo

Pregnancy	*Increased flow*	*Decreased or unchanged*	*Uninterpretable*	*N.S.*
Normal:				
R*	2	10	4	N.S.
P	3	10	3	
Pathologic:				
R	7	3	0	P = 0.02; Fisher's exact test, two-sided
P	1	9	0	

*R = Ritodrine; P = placebo.

The study was performed always in the same room with a controlled environmental temperature, by the same personnel, and with the patient in the same posture throughout (semilateral left decubitus).

Results

There were 29 patients included in the study but the results of three were excluded from the analysis. Details of the reasons for exclusion are given in Table I.

Uterine blood flow. Table II shows the uterine blood flow responses for the two patient groups. In the normal pregnancy group no consistent responses were seen to the infusion with either ritodrine or placebo.

In the group of "pathologic pregnancies" uterine blood flow increased in seven of the 10 subjects during ritodrine infusion as compared with one of 10 during infusion with placebo. This difference in response is statistically significant ($p = 0.02$ Fisher's test, two-sided).

Maternal cardiovascular responses.

Maternal heart rate. The maternal heart rate responses of the two groups are shown in Fig. 1. In the normal pregnancies there was no significant difference in the responses to ritodrine and placebo; in the "pathologic pregnancies" significant tachycardia was seen within 20 minutes of commencing ritodrine

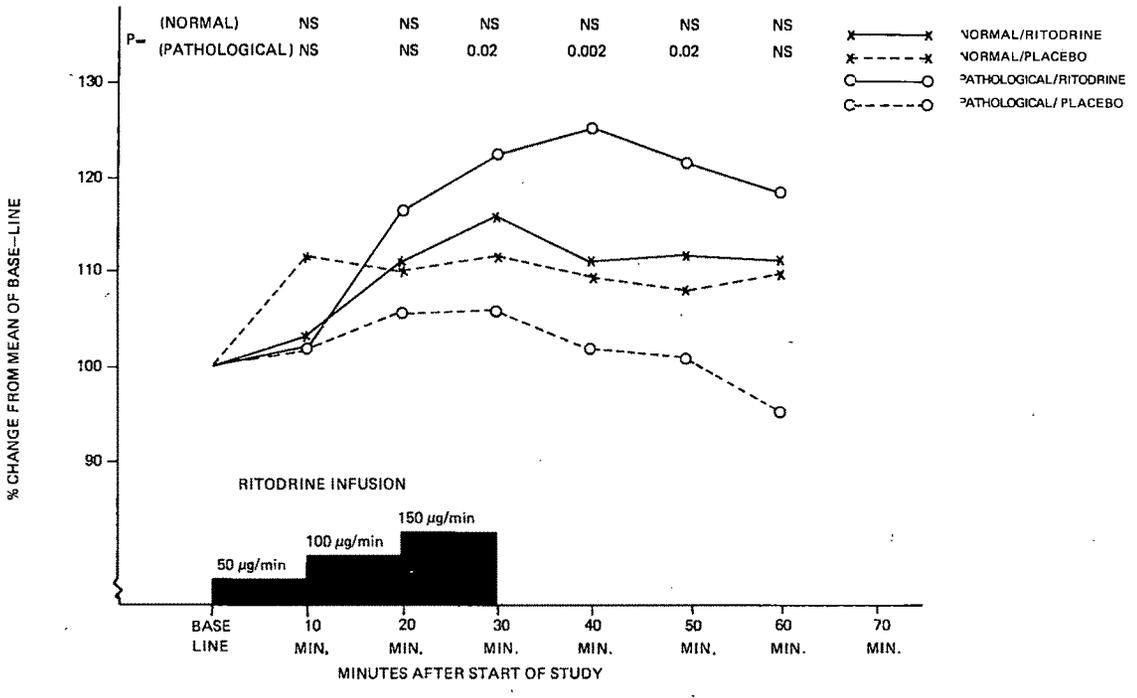

Fig. 1. Changes in maternal heart rate during ritodrine and placebo infusion.

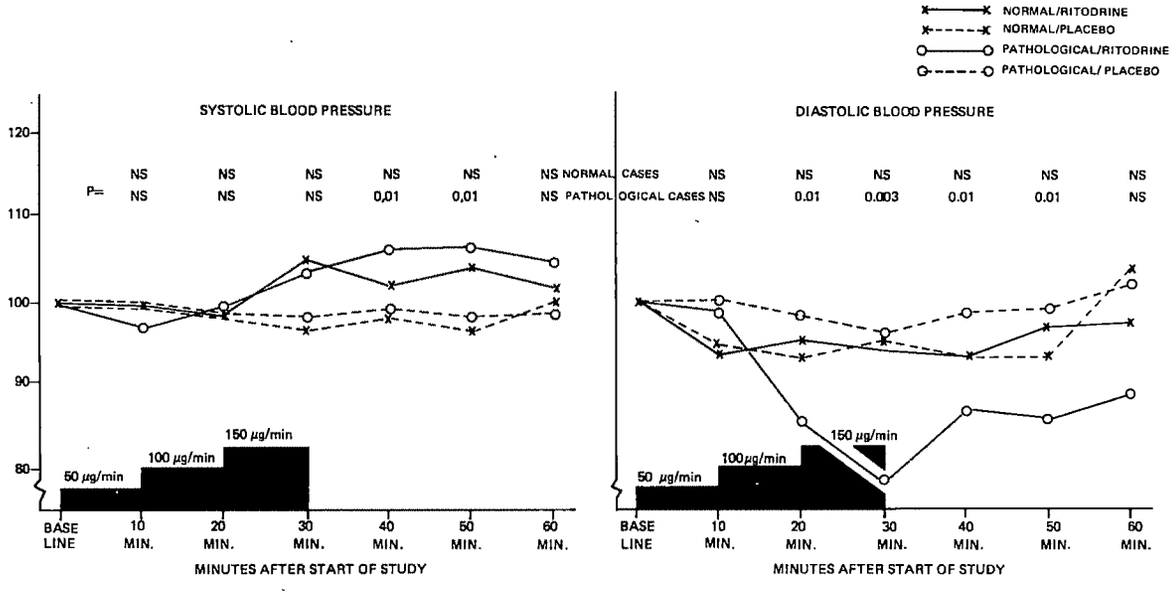

Fig. 2. Effect of ritodrine and placebo on maternal blood pressure.

infusion. This difference was still apparent 20 minutes after stopping the infusion ($p = 0.02$).

Maternal blood pressure. The maternal blood pressure responses are shown in Fig. 2. In the normal pregnancies, there was no significant effect of ritodrine or placebo on diastolic or systolic blood pressure.

In the group of pathologic pregnancies during ritodrine infusion there was a small but significant increase in the systolic blood pressure and a marked decrease in the diastolic pressure. The difference in response to ritodrine and placebo was still apparent at 20 minutes after stopping the infusion ($p = 0.01$). The blood-pressure changes resulted in highly significant effects on the differential blood pressure (pulse pressure), which was increased during ritodrine infusion in the pathologic pregnancies ($p = 0.006$ at 30

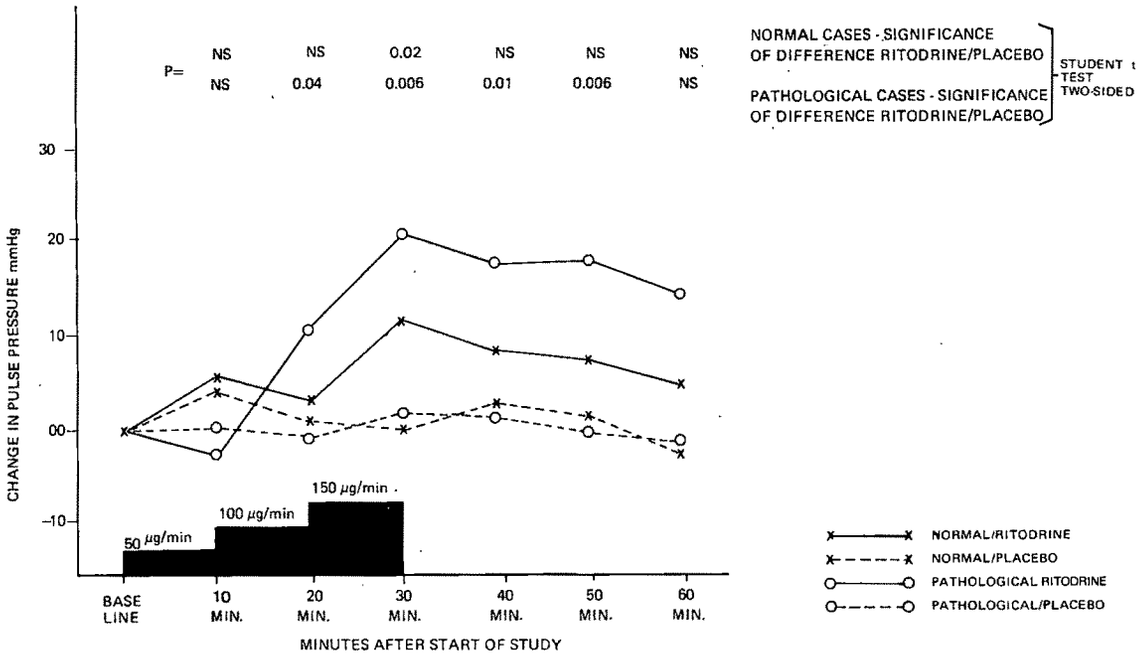

Fig. 3. Changes in pulse pressure during infusion of ritodrine and placebo.

minutes of infusion); in the normal pregnancies the difference in response to ritodrine and placebo was significant only during the last 30 minutes of infusion ($p = 0.02$) (Fig. 3).

Effect on fetal heart rate. In none of the study periods in either group was any significant effect on fetal heart rate observed, at the dosage used.

Uterine activity. With the exception of the two patients who had uterine contractions after the insertion of an intrauterine catheter, in none of the other patients was any effect seen on uterine activity.

Comment

The results of this study suggest that in patients with uncomplicated pregnancies intravenous infusion of ritodrine at the low dose of 150 µg per minute has no effect on uterine blood flow as measured by heat loss from the tip of a heated probe. In pathologic pregnancies, however, beta stimulation appears to result in an increase in uterine blood flow in certain patients, whereas infusion of a placebo in the same patients under the same experimental conditions does so rarely. A further difference in response to beta stimulation is seen in the maternal cardiovascular system. At the infusion rates used in this study the maternal cardiovascular responses in the patients with uncomplicated pregnancies were very slight and with the exception of differential blood pressure at the maximum infusion rate the differences in response to ritodrine or placebo were not statistically significant. In the patients with hypertensive pregnancies are intrauterine growth retardation there was a highly significant difference between the responses to ritodrine and placebo. Despite the low infusion rate of the beta mimetic there was a significant increase in maternal heart rate, a small but significant increase in systolic blood pressure, and a marked fall in diastolic pressure.

The most significant net response was a large increase in the differential blood pressure (pulse pressure). It is possible that the increased heart rate during ritodrine infusion results in increased uterine blood flow.

Bieniarz and associates[12] have demonstrated an increase in cardiac output during infusion of high doses of ritodrine. This study confirms the cardiovascular effects which Bieniarz described but suggests that patients with certain types of high-risk pregnancy may be more sensitive to the beta mimetic in terms of cardiovascular responses and indirectly, perhaps, in uterine blood flow responses.

A number of authors have suggested that there may be an effect on fetal weight as a result of administration of ritodrine during pregnancy. Sivasambo[3] mentioned increased weight for gestational age following ritodrine administration in a controlled trial in premature labor. Seidl and associates[10] compared the infant weights of patients treated with ritodrine and untreated patients. They could find no significant difference between the mean weights at any gestational age;

however, when treatment was started after the thirty-sixth week of pregnancy, the number of babies weighing less than 3,000 grams was larger than when the treatment was started before the thirty-fifth week; nevertheless, this difference was not significant.

Animal studies have demonstrated a highly significant effect on the incidence of intrauterine growth retardation.[13] It is interesting to note in these studies that there was no increase in the incidence of large offspring but a very significant reduction in the incidence of growth-retarded ones.

Janisch and associates[14] have reported studies on placental blood flow using the passage of a technitium-99 bolus through the placental site as an index of change in flow and concluded that beta-mimetic infusion resulted in increased flow in 10 cases and decreased flow in four other pathologic cases.

Wallenburg and associates,[9] using another beta mimetic, suggested an effect of beta-mimetic administration on placental flow in monkeys.

Our results are consistent with those findings.

There is a possibility that ritodrine would be of great interest in the treatment of intrauterine growth retardation.

Controlled clinical trials are still necessary to evaluate whether these changes persist during long-term administration and with other routes of administration.

Termination of midtrimester pregnancy by serial intramuscular injections of 15(S)-15-methyl-prostaglandin $F_{2\alpha}$

NIELS H. LAUERSEN, M.D.
KATHLEEN H. WILSON, B.S.
New York, New York

Midtrimester abortion was successfully induced in 117 of 120 patients with serial intramuscular injections of 15(S)-15-methyl-prostaglandin $F_{2\alpha}$ (15-me-$PGF_{2\alpha}$). The mean abortion time was 14.12 hours, and parous patients aborted in a mean of 12.85 hours—significantly faster than nulliparous patients who aborted in a mean of 15.24 hours. Ninety-four per cent of the 117 successfully induced abortions occurred in less than 24 hours and 46 per cent in less than 12 hours. Uterine activity was monitored and analyzed in nine patients. Uterine response to a single intramuscular injection of 100 μg of 15-me-$PGF_{2\alpha}$ was characterized by the appearance of low-amplitude, high frequency contractions and a rapid increase in baseline intrauterine tonus. A high level of uterine activity, 900 Montevideo Units, was observed within 30 minutes of the first intramuscular injection of 15-me-$PGF_{2\alpha}$. This activity was not maintained and decreased by approximately 30 per cent at the time of the second injection at 1 hour. It was not until 6 hours of 15-me-$PGF_{2\alpha}$ therapy that activity stabilized at approximately 500 Montevideo Units. Even though all patients were premedicated with antiemetic and antidiarrhea agents, 68 of 120 patients experienced gastrointestinal side effects related to the 15-me-$PGF_{2\alpha}$ administration. Vomiting was the most prevalent side effect, occurring in 65 patients, but the episodes were not severe, were well tolerated by the patients and did not necessitate the termination of prostaglandin administration in any of the patients. In this study abortion was successfully induced between weeks 9 to 27 of gestation. It was observed that patients with gestations of 16 weeks or less aborted significantly faster than patients with gestations of 17 weeks or more, which indicates that this method is highly effective in the induction of abortion within the "gray zone", 12 to 16 weeks of gestation.

DURING THE PAST several years there have been a number of reports describing the uterine stimulating and abortifacient effects of naturally occurring prostaglandins. The uterine response to a single injection of these compounds was relatively short, probably due to a rapid enzymatic inactivation. Dehydrogenation occurs at carbon-15 and the resulting prostaglandins possess greatly reduced biologic activity. In order to maintain good uterine activity and achieve abortion, continuous infusion or repeated administration by the intrauterine or vaginal route was required.

Bundy and co-workers[1] reported the synthesis of prostaglandins modified at carbon-15, and that these prostaglandins resisted enzymatic degradation by the enzyme prostaglandin 15-dehydrogenase. The modified prostaglandins 15(S)-15-methyl-prostaglandin E_2 and $F_{2\alpha}$ (15-me-PGE_2 and 15-me-$PGF_{2\alpha}$) were then evaluated for clinical usefulness. Karim and Sharma[2] reported that the 15(S)-15-methyl-prostaglandin E_2 methyl ester and 15(S)-15-methyl-prostaglandin $F_{2\alpha}$ free acid were more potent and had a longer duration of uterine-stimulating action than did PGE_2 and $PGF_{2\alpha}$. The uterine-stimulatory effects of the 15-

methyl analogue of prostaglandins E_2 and $F_2\alpha$ were confirmed in the rhesus monkey by Kirton and Forbes.[3] Toppozada and co-workers[4] reported that the threshold dose for inducing contractions in midpregnancy with single intravenous doses of 15-me-$PGF_{2\alpha}$ was approximately one tenth of the threshold dose of the naturally occurring $PGF_{2\alpha}$. Intramuscular injection of this 15-methyl analogue in a dose of 1.0 to 1.5 mg. administered to women in the midtrimester induced a marked uterine-stimulatory effect which was sustained from 5 to 7 hours. Karim and associates[5] successfully induced midtrimester abortion by intramuscular injection of 15-me-$PGF_{2\alpha}$. Lauersen and Wilson[6] reported on successful induction of midtrimester abortion in a series of 35 women by serial intramuscular injection of 15-me-$PGF_{2\alpha}$. A preliminary group of five patients in that study were treated with a dose scheduled of 250 μg intramuscularly every 6 hours, but only one patient aborted within 24 hours on that dose schedule. The remaining patients aborted in 30 to 37 hours. The dose schedule for the following 35 patients was then altered to 250 μg initially, followed by 250 μg in 2 hours, and then 500 μg every 2 hours until the time of abortion; the mean abortion time with this dose schedule was 16 hours and 86 per cent of the patients aborted in under 24 hours. It was observed that the appearance of gastrointestinal side effects, which occurred in 90 per cent of the patients, was mostly related to the first dose of 15-me-$PGF_{2\alpha}$. A greatly expanded series has therefore been undertaken in which the initial dose of intramuscular 15-me-$PGF_{2\alpha}$ has been reduced to 100 μg in an attempt to reduce the gastrointestinal side effects of the drug. This study has been designed to determine the abortifacient efficacy of the revised dose schedule and to monitor the effects of abortion induced by intramuscular 15-me-$PGF_{2\alpha}$ on uterine activity, as well as progesterone and cortisol levels.

Materials and methods

A total of 120 healthy women volunteers, ranging in age from 12 to 41 years (mean age, 23 years) and with gestational ages ranging from 9 to 27 weeks (Table I), were included in this study. There were 63 nulliparous patients and 57 multiparous patients in this series. Abortion was induced by serial intramuscular injections of 15(S)-15-methyl-prostaglandin $F_{2\alpha}$* (15-me-$PGF_{2\alpha}$). An initial dose of 100 μg of 15-me-$PGF_{2\alpha}$ was administered intramuscularly, followed in 60 minutes by 250 μg intramuscularly, then 2 hours later by 500 μg intramuscularly. A dose schedule of 500 μg of 15-me-$PGF_{2\alpha}$ was then administered intramuscularly every 2 hours until the time of abortion or a maximum of 24 hours of therapy. If a patient had not aborted within 24 hours, the dose was increased to 750 μg of 15-me-$PGF_{2\alpha}$ intramuscularly every 2 hours until the time of abortion. There were two exceptions in this series to the regular dose schedule. One patient was a 31-year-old woman, para 0, gravida 1, at 26 weeks' gestation, with severe pre-eclampsia, who received 50 μg every 2 hours for a total dose of 200 μg. This patient aborted in less than 7 hours. The second patient, a 28-year-old women, para 1, gravida 2, in the thirteenth week of gestation, developed very strong uterine contractions with the 15-me-$PGF_{2\alpha}$. The dose schedule in this patient was 100 μg, followed in 1 hour by 250 μg and in 2 hours by 250 μg. She aborted in 4.50 hours at a total dose of 600 μg. The dose range in the remaining patients was 1.35 to 11.85 mg. (mean, 3.30 mg.).

In order to minimize gastrointestinal side effects all patients were premedicated and continued on antiemetic and antidiarrhea agents throughout the abortion period. The premedication was 10 mg. of Compazine† (prochlorperazine) and four tablets of Lomotil‡ (each tablet contains diphenoxylate hydrochloride 2.5 mg. and atropine sulfate 0.025 mg.) administered orally 60 minutes prior to the initial injection of 15-me-$PGF_{2\alpha}$. Two tablets of Lomotil were then administered every 2 hours and the Compazine 10 mg. was given intramuscularly every 6 hours until the time of abortion.

A complete blood count, including hematocrit, hemoglobin, white blood cell count, differential, and platelet count, as well as liver function tests, plasma progesterone, and plasma cortisol levels were performed prior to the administration of the 15-me-$PGF_{2\alpha}$, at 8 hours and at 24 hours after initiation of the procedure, in 63 patients. In the remaining 57 patients blood tests, excluding cortisol and progesterone, were

‡G. D. Searle and Company, Chicago, Illinois.

carried out prior to the initiation of the 15-me-$PGF_{2\alpha}$, at 8 hours, and at the time of abortion. Following routine hospital procedure, the patients were given an intravenous infusion of Ringer's lactate and blood was obtained for typing and cross-matching. Vital signs including heart rate, blood pressure, temperature, and respiration were monitored throughout the procedure at frequent intervals.

Uterine activity was monitored in nine patients via an open-end catheter inserted intra-amniotically as previously detailed.[7] The catheter was connected to a pressure transducer (Hewlett Packard, Waltham Division, Model 267 BC, Waltham, Massachusetts) and a dual-channel carrier amplifier recorder (Hewlett Packard, Sanborn Division, Model 321, Waltham, Massachusetts). Spontaneous uterine activity was observed for approximately 20 minutes prior to the prostaglandin administration.

When the fetal and placental tissue were completely expelled from the uterus, or the placenta was removed from the cervical os manually or with sponge forceps without the need for anesthesia, the abortion was defined as being complete. An incomplete abortion was defined as partial expulsion of the products of conception from the uterus, requiring surgical evacuation under general anesthesia for completion.

Results

Mid-trimester abortion was successfully induced in 117 of 120 patients by serial intramuscular injections of 15(S)-15-methyl-prostaglandin $F_{2\alpha}$. The mean abortion time(the interval from the first intramuscular injection to the expulsion of the fetus) was 14.12 hours. Parous patients aborted somewhat faster(mean,12.85 hours) than the nulliparous(mean, 15.24 hours) and this difference was statistically significant ($p < 0.05$) (Table II). In this series of the 117 successfully aborted patients 95 per cent aborted in less than 24 hours, and 46 per cent aborted in less than 12 hours (Fig. 1). Two patients, who aborted in more than 24 hours, were former heroin addicts and at the time of the abortion were on methadone maintenance, receiving 80 to 90 mg. of methadone per day. Both patients were extremely tense and anxious, presenting difficult management problems. Included in this series, there was a patient with twin pregnancy of 20 weeks' gestation. The patient responded well to the medication and aborted in under 10 hours without complication.

There were three trials that were declared failures in this series. The first failure occurred in a 41-year-old multiparous patient, with a uterine myoma, in the twentieth week of gestation. This patient developed

adequate uterine contractions and the membranes ruptured at 20 hours, but she did not abort despite high uterine activity. The patient subsequently developed endometritis and the response to prostaglandin diminished. She was started on antibiotics and a surgical completion was eventually performed without difficulty since the cervix was soft and well dilated and the products of conception were removed in parts. The patient was subsequently discharged in good condition.

The second failure occurred in a 30-year-old woman, para 1, in the fifteenth week of gestation. This patient did not abort within 24 hours despite high uterine activity; a sonogram was thereafter obtained which demonstrated a 10 by 10 cm. cervical fibroid that obstructed the cervical canal. A surgical completion was subsequently performed without difficulty and the patient was discharged in good condition.

The third failure took place in a 19-year-old nulliparous patient in the twentieth week of gestation. This patient did not abort despite strong uterine activity. A review of the family history revealed that the

patient's sister had a double uterus and sonogram performed on this patient then revealed a double uterus with the pregnancy in the left uterine horn. When the patient did not abort within 27 hours she was taken to the operation suite for surgical completion. A stenotic ring was felt at the level of the internal os of the left uterine horn, which could have explained the patient's failure to abort with intramuscular 15-me-$PGF_{2\alpha}$. The patient was subsequently discharged in good condition.

Intramuscular 15-me-$PGF_{2\alpha}$ was an effective abortifacient throughout the gestational periods tested in this series (Table III). It was observed that patients with lower gestational ages, 9 to 16 weeks, aborted significantly faster (mean, 12.42 hours) than patients with gestational ages of 17 weeks and higher (mean, 15.96 hours) ($p < 0.01$).

The uterine response to the initial intramuscular injection of 100 μg of 15-me-$PGF_{2\alpha}$ was characterized by the appearance of low-amplitude, high-frequency contractions and a rapid rise in baseline intrauterine tonus. Subsequent injections produced further increments in uterine activity (Fig. 2). The initial 100 μg of 15-me-$PGF_{2\alpha}$ intramuscular injection produced a mean of 905 Montevideo Units (M.U.) (average amplitude × number of contractions in 10 minutes) within 30 minutes in the nine patients monitored. Uterine activity then declined to a mean of 612 M.U. at 1 hour and at this time a subsequent dose of 150 μg of 15-me-$PGF_{2\alpha}$ increased uterine activity to a mean of 923 M.U. within 30 minutes. Uterine activity declined to a mean of 386 M.U. at 3 hours of therapy when a

third dose of 15-me-PGF$_{2\alpha}$ was administered and again activity increased. At about 6 hours into the prostaglandin therapy uterine activity stabilized around a mean of 500 M.U. (Fig. 3). Frequency of contractions peaked at 20 minutes after the first injection of 15-me-PGF$_{2\alpha}$ at a mean of 23 contractions per 10 minutes. The frequency of contractions then subsided, and the second injection of 15-me-PGF$_{2\alpha}$ produced a second increase in frequency to 14 contractions per 10 minutes. The frequency then slowly declined to stabilize at mean of seven contractions per 10 minutes throughout the abortion period. The amplitude of contractions increased steadily after the first two injections of prostaglandin to a mean maximum of 74 mm. Hg within 30 minutes of the second injection. Amplitude declined to a mean of 51 mm. Hg at 3 hours, immediately prior to the third dose of prostaglandin, and then rose; declined at 5 hours, and then steadily rose throughout the abortion period to a mean of 78 mm. Hg at 8 hours. Intrauterine baseline tonus increased rapidly to a maximum mean of 32 mm. Hg 30 minutes after the first 15-me-PGF$_{2\alpha}$ injection. The

Table VI. The effect of midtrimester abortion induced by intramuscular 15-me-$PGF_{2\alpha}$ on hematocrit, white blood cells, and platelet count

	Control	*8 hours*	*At abortion*	*No. of patients*
Hematocrit (%)	34.1 ± 3.2	34.8 ± 3.4	33.6 ± 3.8	57
White blood cells ($\times 10^3$)	8.8 ± 2.6	13.0 ± 3.5	13.3 ± 3.8	57
Platelet count	268 ± 68	274 ± 67	277 ± 77	57
			24 hours	
Hematocrit (%)	34.2 ± 2.9	36.2 ± 3.1	33.8 ± 2.9	63
White blood cells ($\times 10^3$)	8.8 ± 2.4	12.7 ± 3.5	11.0 ± 2.8	63
Platelet count	263 ± 63	270 ± 64	257 ± 65	63

subsequent prostaglandin injection produced a mean intrauterine baseline tonus of 36 mm. Hg. Like amplitude, tonus decreased at 3 hours, peaked again at 4 hours, and then stabilized around 22 mm. Hg at 6 hours.

Of the 120 patients included in this series, 68 experienced gastrointestinal side effects related to the administration of intramuscular 15-me-$PGF_{2\alpha}$. Vomiting was the most prevalent side effect, experienced by 65 patients, and 54 patients had more than one episode of vomiting. Nausea was experienced by 17 patients, with 10 patients having more than one episode. Diarrhea was the least common gastrointestinal side effect, and only eight patients (7 per cent) experienced diarrhea. There was a temperature elevation of more than 2° F. in 30 patients but this temperature elevation was small and only seven patients had a temperature of 102° or higher. Temperatures returned to normal levels in all patients within 4 to 6 hours after the last intramuscular injection of 15-me-$PGF_{2\alpha}$ (Table IV). There were three failures of technique in this series, as previously detailed, and two incomplete abortions. One patient who failed to abort with intramuscular 15-me-$PGF_{2\alpha}$ developed endometritis. The placenta was removed by sponge forceps in 16 patients and manually in 14 patients.

There was an estimated blood loss of 300 ml. or more in three patients but there was no need for transfusion for any patient (Table V). The mean estimated blood loss in this series was 82.81 ± 69.71 ml. (range, 30 to 450 ml.). Mean hematocrit and platelet levels reflected the minimal blood loss observed in this series of abortions. There were no statistically significant changes in mean hematocrit and platelet levels throughout the procedure. The mean white blood count (WBC) increased significantly at 8 hours, with a further increase in mean WBC at the time of abortion. There was some decrease at 24 hours, but the 'mean WBC had not returned to preinjection levels at this time (Table VI).

Plasma progestrone levels decreased significantly in the 63 patients tested 8 hours after the first intramuscular injection of 15-me-$PGF_{2\alpha}$ to 50 per cent of the control level, and at 24 hours the plasma progesterone was 9 per cent of the control level. Plasma cortisol increased significantly at 8 hours after the first injection and decreased to preinjection levels by 24 hours (Fig. 4).

Comment

Abortion was successfully induced in 117 of 120 patients from the ninth to the twenty-seventh weeks of gestation with serial intramuscular injections of 15-me-$PGF_{2\alpha}$ with a mean time of 14.12 hours. The initial dose of 15-me-$PGF_{2\alpha}$ was 100 μg, followed by 250 μg in 60 minutes, and then 500 μg every 2 hours until abortion, as compared to our previous study[6] where the dose schedule was 250 μg every 2 hours for the first 2 hours, followed by 500 μg every 2 hours until the time of abortion. The mean abortion time in this latest, expanded study compares favorable with the abortion time in the previous study, with a mean time of 15.98 hours, which indicates that a high initial dose of intramuscular 15-me-$PGF_{2\alpha}$ is not necessary for a successful outcome. The incidence of gastrointestinal side effects on the new dose schedule was only 56 per cent, as compared to 90 per cent in the previous study, where high initial doses were employed. It therefore appears that the initiation of prostaglandin-induced abortion with a low initial dose helps to reduce gastrointestinal side effects of the drug without increasing the over-all abortion time. Once a patient's sensitivity to the drug was established the patient tolerated high doses of the drug given repeatedly without gastrointestinal disturbances.

A high level of uterine activity was observed within 30 minutes of the first intramuscular injection of 100 μg of 15-me-$PGF_{2\alpha}$; however, this level of activity was not maintained and it decreased by approximately 30 per cent at the time of the second injection at 1 hour. Activity increased rapidly immediately after the second injection, but within 2 hours activity had again

decreased by 60 per cent, and it was not until 6 hours of 15-me-$PGF_{2\alpha}$ therapy that the activity stabilized. In a previous study of the abortifacient effectiveness of serial intramuscular injections of 15-me-PGE_2[8] a high level of uterine activity (mean, 500 Montevideo Units) was observed within 40 minutes of a 5 μg intramuscular injection of 15-me-PGE_2. There was no rapid decrease in activity with 15-me-PGE_2, indicating that this drug has a more sustained effect on the uterus than 15-me-$PGF_{2\alpha}$, and the 15-me-PGE_2 appeared to be a minimum of 20 times more potent than the 15-me-$PGF_{2\alpha}$. In another previous study with extraovular administration of the naturally occurring $PGF_{2\alpha}$ for midtrimester abortion,[9] 5 mg. of the drug were required to achieve a similar level of uterine activity as obtained with 100 μg of 15-me-$PGF_{2\alpha}$, indicating that the 15-me-$PGF_{2\alpha}$ is approximately 50 times more potent than the naturally occurring $PGF_{2\alpha}$, although a direct comparison cannot be drawn due to the differences in the methods of administration.

The most prevalent side effect observed in this series of abortions induced by intramuscular 15-me-$PGF_{2\alpha}$ was vomiting, which occurred in 65 of the 120 patients. The vomiting was transient in nature; in none of the cases was it necessary to terminate prostaglandin therapy due to this side effect. Diarrhea was the least common gastrointestinal side effect observed; it occurred only in 7 per cent of the patients. When abortion was induced with 15-me-PGE_2[8] the incidence of gastrointestinal side effects was low—in only five of 30 patients. There was a temperature elevation in only 30 of the 120 patients treated with intramuscular 15-me-$PGF_{2\alpha}$ as opposed to a temperature elevation in 29 of 30 patients treated with intramuscular 15-me-PGE_2. These results seem to indicate a difference between the actions of 15-me-$PGF_{2\alpha}$ and 15-me-PE_2. The E_2 compound may have a more specific effect on temperature regulation, whereas the $F_{2\alpha}$ compounds may have a more specific effect on gastrointestinal motility.

It has been established from a number of studies that the incidence of changes in coagulation factors consistent with DIC is higher in saline-induced abortion than the incidence encountered when midtrimester abortion is induced with intra-amniotic instillation of $PGF_{2\alpha}$[10–12]. Although there have been no studies on the clotting factors when abortions have been induced by 15-me-$PGF_{2\alpha}$, we found no incidence of severe hemorrhage in the total of 160 patients treated with 15-me-$PGF_{2\alpha}$ in the two series we have performed. Evaluation of hematocrit and platelet count showed no significant change during the abortion and postabortion periods, which might indicate that the incidence of DIC in midtrimester abortion induced by 15-me-$PGF_{2\alpha}$ is low, similar to that found in abortion induced with naturally occurring prostaglandin by the intra-amniotic route.

Midtrimester abortion induced by intramuscular injections of 15-me-$PGF_{2\alpha}$ was well accepted by the patients and by the nursing staff of the abortion unit. The patient was spared the painful, time-consuming, and potentially hazardous procedure of amniocentesis required for instillation of hypertonic saline or prostaglandin. The intramuscular injection of 15-me-$PGF_{2\alpha}$ caused very little pain, and no local reaction at the injection site was observed. We believe after conducting this series that the initial three doses of 15-me-$PGF_{2\alpha}$ of 100, 250, and 500 μg should be administered by a physician in order to determine the patient's sensitivity to the drug and that, once the patient's sensitivity has been established, it is safe for subsequent injections to be administered by an alert and informed nurse.

Four patients in this study presented with a history of bronchial asthma and prophylactic aminophylline suppositories were administered, they had no indication of asthma or even minimal asthma attacts during the 15-me-$PGF_{2\alpha}$ therapy. In five patients the fetus was expelled but the placenta was retained; intramuscular 15-me-$PGF_{2\alpha}$ therapy was continued and the placenta was subsequently passed. Intramuscular 15-me-$PGF_{2\alpha}$ might have clinical usefulness in cases of incomplete abortion.

Several patients in this series had originally been admitted to the hospital for suction abortion. Upon examination they were found to be beyond the gestational age acceptable for this operative procedure. Induction of abortion with intramuscular injections of 15-me-$PGF_{2\alpha}$ was very successful and these patients could be discharged within 24 hours. Patients with gestational ages of 16 weeks or less aborted significantly faster than patients with gestational ages of 17 weeks and higher. The abortifacient effectiveness of intramuscular injections of 15-me-$PGF_{2\alpha}$ in early gestations contrasts with our findings in earlier studies on the effect of $PGF_{2\alpha}$ administered via intra-amniotic instillation[7] and continuous extraovular infusion.[9] In these previous studies the $PGF_{2\alpha}$ was found to be a more efficient abortifacient during later gestations of 18 weeks and higher. 15-me-$PGF_{2\alpha}$ administered by intramuscular injection may prove to be a valuable clinical tool, particularly in the induction of abortion during the so-called "gray zone," gestations between the twelfth and sixteenth weeks. From the study of uterine activity it appeared that administration of 15-me-$PGF_{2\alpha}$ was necessary every 2 hours to initially

maintain effective uterine activity, but it is possible that after 6 hours of administration, when uterine activity had stabilized, the frequency of injection could be decreased to every 4 to 6 hours without substantially affecting the outcome of the abortion.

We would like to thank the Nursing Staff of the Abortion Unit for their assistance in this study. We should also like to thank Dr. Joseph T. Sobota of the Clinical Research Laboratories, The Upjohn Company for blood hormone and cortisol studies, and Mr. Glenn Gutknecht and Louis Piccoli of The Upjohn Company for their support.

Effectiveness of certified nurse-midwives

A prospective evaluation study

A prospective evaluation study of the effectiveness of the services of certified nurse-midwives demonstrated that in a hospital setting the care of low-risk maternity patients provided by nurse-midwives was as effective as that provided by house staff physicians. A total of 438 low-risk maternity patients were studied. Selected outcomes pertaining to the prenatal period, labor and delivery, and early infancy demonstrated, with two exceptions, no significant differences. The two exceptions were: (1) overcompliance with appointment attendance was more common among the nurse-midwifery group of patients; (2) a higher rate of forceps delivery was reported among the house staff group of patients.

THE INCREASING UTILIZATION of nurses in expanded roles and its potential for meeting the health needs of a large sector of the population have generated the need for the evaluation of the services they provide. The evaluation of one such extended role, that of the certified nurse-midwife (CNM), constitutes the focus of this report.

Recent concern over relatively high maternal and infant mortality and morbidity rates in the nation and the awareness of a large pool of expectant mothers who receive little or no prenatal, intrapartal, and postpartal care have prompted an increase in the training and employment of nurse-midwives. A number of evaluation studies of nurse-midwifery services have been carried out.

Most of them are of a "before and after" nature, in which the study population serves as its own control, with the inherent assumptions and weaknesses of that method. In 1969, Montgomery[1] published a study which showed the effectiveness of a nurse-midwifery "nurse obstetric assistant" service in a rural California county hospital. Following the introduction of the service for normal patients, the proportion of patients receiving first trimester care doubled from five per cent and among primiparous patients increased from 30 to 40 per cent. An increase in the frequency and regularity of prenatal visits was found, and, during the last six months of the study period, 78 per cent of deliveries in the hospital were attended by a nurse obstetric assistant. Over a three-year period from 1959 (before the project's inception) to 1961 (after it began), there was a decline in prematurity rates from 11 per

cent to 6.4 per cent and in neonatal mortality rate from 23.9 per 1,000 live births in 1959 to 10.3 per 1,000 live births in 1961.

Similar positive results were shown by Levy and co-workers.[2] The effectiveness of the nurse-midwifery program was shown not only by an increased utilization of services, but also by a resultant decline in rates of prematurity and neonatal deaths. These indications of effectiveness were further corroborated by a significant reduction in prenatal attendance and a rise in neonatal death and prematurity in the hospital following cessation of the CNM program.

Similar beneficial results were shown in a private team practice in Ohio[3] and in a prepaid group practice.[4]

One evaluation study[5] did attempt to apply an experimental design through the random allocation of patients to the CNM or the resident staff services of two hospitals. This further documented the effectiveness of nurse-midwives. Unfortunately, the potentially biased nature of the determination of "uncomplicated" status performed by the nurse-midwife and the absence of statistical tests lend caution to ready acceptance of the findings.

This report describes a prospective study to evaluate the effectiveness of nurse-midwives in a university hospital clinic setting in Jackson, Mississippi.

Study setting

The service described in this paper has operated at the University of Mississippi Medical Center, since 1969. The nurse-midwifery care team consists of CNM's, nurse-midwife assistants, obstetricians, and residents in obstetrics and gynecology who serve as consultants, provide back-up care, and assume temporary or permanent management of complicated cases. The same house staff, obstetricians, residents, and medical students provide care to all other maternity patients. All patients are delivered in the hospital.

The nurse-midwifery service provides prenatal, intrapartal, postpartal, family planning, and infant health supervision services.

Both CNM and house staff (HS) service programs are designed to provide clinical practice for students. Patients do not see the same provider consistently in either service.

The HS team provides comprehensive prenatal, intrapartal, and early postpartal care for the patients.

Purpose of the study

The study was intended to evaluate the effectiveness of care provided to obstetric patients by nurse-midwifery and house staff services. Variables selected to measure the effectiveness of the two services included the following prenatal, intrapartal, and immediate postpartal outcomes in the mother and infant. (1) prenatal outcomes—prenatal visit score (actual number of visits ÷ expected number of visits × 100; anemia (hematocrit < 30 per cent); incidence of hypertension rise of >30 mm. systolic or > 15 mm. diastolic pressure; incidence of diabetes (physician's diagnosis based upon urine test, fasting blood sugar, and glucose tolerance test); incidence of indicators of toxemia (physician's diagnosis based upon proteinuria, edema, average weight gain > two pounds per week, rise of blood pressure >30 mm. systolic or >15 mm. diastolic); incidence of urinary tract infection (as diagnosed by culture and sensitivity >100,000 colonies or more than "slight growth" or on microscopy at least two of the following: ten to 15 red cells, 15 to 20 white cells, moderate to heavy bacteruria); rates of investigation for urinary tract infection (performance of urinalysis, culture, sensitivity, or testuria, plus evaluation of clinical findings); rates of investigation for diabetes (performance of urinalysis, fasting blood sugar and glucose tolerance test); (2) maternal outcomes of labor and delivery (obtained from the record of delivery)—length of labor, abnormalities of labor, hours membranes ruptured before delivery, type of delivery, episiotomy, amniotomy, abnormalities of puerperium; (3) infant outcomes (evaluated by the attending neonatologist)—gestational age, weight, length, head circumference, apgar score, fetal distress (Presence of meconium, tachycardia or bradycardia, or fetal acisosis), newborn condition (presence or absence of congenital abnormalities or birth injury or aspiration).

Sample and methods

This prospective study followed two groups of pregnant women from registration for prenatal care through labor, delivery, and the immediate postpartal period. The study population consisted of a sample of patients who registered for care at the University Medical Center's prenatal clinic. At the Medical Center, patients are cared for either by certified nurse-midwives or the house staff of the Center. Patients from both services are delivered at the University Medical Center hospital.

The study samples were selected from patients who registered at these clinics for prenatal care between October 1, 1972, and April 30, 1973, and who met the criteria of eligibility for the nurse-midwifery service, described below.

On admission, a clerk obtained the following data through questions and observation: the number of

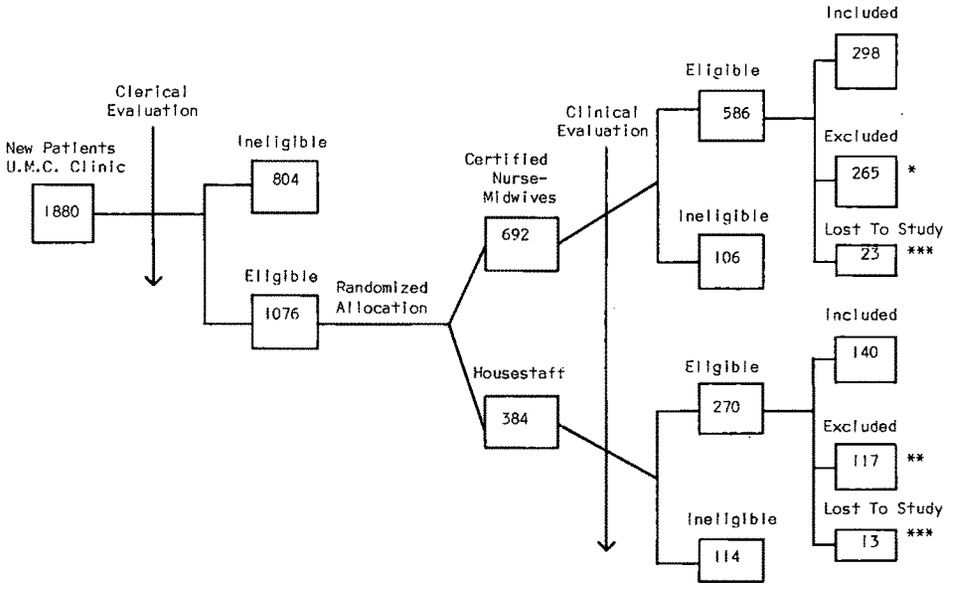

Fig. 1. Selection of patients into study. *Forty-four delivered prior to January, 1972; 221 delivered after December, 1972. **Of these, 29 delivered prior to January, 1972; 88 delivered after December, 1972. ***Delivered elsewhere, moved, or not pregnant.

pregnancies; history of previous cesarean section; diabetes mellitus in the patient; edema and/or varicosities. In the obstetric clinic, urine specimens, blood pressure, height, and weight were determined and the results recorded.

On the basis of these data, initial screening was carried out by the clinic clerk. Patients were excluded if any of the following characteristics were recorded: (1) blood pressure—systolic over 140 mm. or diastolic over 90 mm.; (2) weight above 180 pounds; (3) history of eight or more pregnancies; (4) history of diabetes mellitus; (5) history of cesarian section; (6) history of varicosities or edema.

Patients who requested either house staff or nurse-midwifery services were not included in the study. Those eligible after this "clerical" evaluation were then randomly allocated to nurse-midwifery or house staff service. Patients were allocated to a service according to a computer generated random sequence and implemented by the clerk. The ratio of nurse-midwifery patients to house staff patients was variously 1:1 or 2:1 as the case load of patients for the nurse-midwifery service varied. In the allocated service, a physical examination was provided with initial laboratory test values added to the clinical record.

As a result of this "clinical" evaluation, a further subset of ineligibles was omitted from the study if any of the following characteristics were present: (1) Rh sensitivity; (2) toxemia; (3) multiple gestation; (4) medical history of diabetes mellitus, chronic hypertension, chronic renal disease, severe varicosities of vagina, vulva, or legs, or other severe medical problems; (5) significant bony or soft tissue abnormalities of the pelvis.

Fig. 1 shows the samples in the selection of Medical Center patients. Of the 1,880 new patients admitted during the study period, 804 (43 per cent) were found to be ineligible on clerical evaluation and a further 220 (12 per cent) on clinical evaluation. Thus, 1,024 (55 per cent) of the new patients were deemed ineligible for nurse-midwifery service by set criteria.

Despite efforts to ensure administration of standardized selection criteria, a statistically significantly larger proportion of HS patients (30 per cent) than CNM patients (15 per cent) were eliminated from the study by the clinical evaluation. The possibility exists that an unknown selective factor was operative in the determination of eligibility and may have resulted in some consistent differences between the study groups.

Data were extracted from medical records by coders trained and supervised by a medical records research assistant. By checking against the medical records, quality checks of the data processing were carried out by a nurse on every tenth code sheet and on any questionable codes. Where appropriate, an obstetrician or neonatologist was consulted for clarification.

This report presents the findings with respect to the 438 women who were eligible for study who attended the Medical Center and were delivered there from January 1 to December 31, 1972. Of these, 298 were

nurse-midwifery patients and 140 were house staff patients.

In all comparisons, the chi-square test and t test were applied for categorical and continuous variables, respectively, with the use of a five per cent confidence level as an indicator of statistical significance.

Results

Comparability of the groups. In assessing the comparability of the two service study groups, it was found that there were no significant differences between the groups with respect to age, race, marital status, gravidity, gestation at registration, initial hematocrit, or systolic blood pressure. The mean age was 20.4 years among the CNM patients and 21.7 for the HS patients. The majority of the patients in both groups was black (78.9 per cent in the CNM group and 77.1 per cent in the HS group). Fifty-nine per cent of the CNM group and 64.3 percent of the HS patients were married. Although patients met the low-income criteria for admission to the clinic program, no data were available to compare the groups with respect to socioeconomic status or education. Slightly over 50 per cent of the patients in each group were primigravida, and the average gestation at registration was 26 weeks in each group. The prevalence of anemia at registration (hematocrit less than 30 per cent) was four per cent among CNM patients and five per cent among HS patients. There were no differences between the groups in histories of previous premature births or abortions or in the interval since the last pregnancy. A small but statistically significant discrepancy between the two groups in the distributions at the lower levels of diastolic blood pressure was considered unimportant as a determinant of future outcomes. It was concluded, therefore, that the two patient groups were comparable with respect to relevant and available prenatal characteristics.

Prenatal outcomes. There were no significant differences between the groups during pregnancy in the incidence of excess weight gain, edema, hypertension, urinary tract infection, and diabetes.

About 60 per cent of the patients manifested one or more indicators of toxemia of pregnancy.

Diabetes and urinary tract infections occurred in about one per cent of the subjects.

Nurse-midwifery patients had significantly higher prenatal visit scores than did house staff patients (Table I).

On the average, CNM patients kept 94 per cent of the expected prenatal visits, and the HS patients kept 80 per cent. A higher proportion of CNM patients (27.5 per cent) made more visits than scheduled compared with the HS patients (12.9).

This finding was not explained by a difference in health problems which were found to be equally distributed in the two groups. However, statistically significant differences were found between CNM and HS groups in the rates of investigation for urinary tract infection (UTI) and for diabetes. The CNM's carried out one or more tests for UTI in 90 per cent of their patients compared to 65 per cent by the house staff. Similarly, a greater proportion of CNM patients (43.3 per cent) was investigated for diabetes compared with 27.9 per cent investigated by the house staff. Significantly more overcompliance among CNM patients than among HS patients occurred, regardless of investigation for either UTI or diabetes (Tables II and III).

Table IV. Type of delivery among all patients—Primigravida and multigravida—by type of service

Type of delivery	*All patients (%)*		*Primigravida (%)*		*Multigravida (%)*	
	CNM (298)	*HS (140)*	*CNM (158)*	*HS (71)*	*CNM (140)*	*HS (69)*
Spontaneous	82.6	62.1*	72.8	35.2*	93.6	89.9
Low forceps	9.7	29.3*	17.1	52.1*	1.4	5.8
Mid forceps	2.3	2.9	3.8	4.2	0.7	1.4

Cesarean section	3.7	4.3	4.4	8.5	2.9	0

Numbers in parentheses are numbers of patients.
*Statistically significant, $p < 0.05$.

Outcomes of labor and delivery. A significantly greater proportion of CNM patients (82.6 per cent) than HS patients (62.1 per cent) had spontaneous deliveries (Table IV). This difference was explained mainly by the rate of low forceps deliveries which was three times higher in the HS patients than in the CNM patients. This excess of low forceps deliveries was found among both primigravida and multigravida.

Low forceps deliveries were still significantly more frequent in the HS patients, even among women without two conditions which indicate forceps deliveries—namely a second stage of labor longer than 60 minutes, or the delivery of a low–birth weight infant (Table V). This suggests that physicians are more likely to perform forceps deliveries for reasons other than the medical indications of prolonged second stage of labor or low birth weight.

There were no significant differences between the groups with respect to the length of the first and third stages of labor, abnormalities of labor, course of labor, the number of hours membranes ruptured before delivery, lacerations, episiotomies, and abnormalities of the puerperium. A significant difference in the duration of the second stage of labor for those with spontaneous deliveries was found among multigravid patients, whereas the HS patients had an average duration of the second stage of labor of 29 minutes compared with an average of 18 minutes among CNM patients. No such difference was found for primigravidas.

Infant outcomes. There were no differences between the two groups with respect to gestational age, newborn condition, or infant length.

While the rate of low–birth weight babies (≤2,500 grams) was higher (9.1 per cent) in the CNM group than in the HS group (five per cent), this difference was not statistically significant. Similarly, there was no significant difference in the mean birth weights of the two groups (3,128 and 3,172 grams, respectively).

Indications of fetal distress (abnormal heart rate and/or the presence of meconium) were reported more often in patients of the HS group than in those of the CNM group. The difference was almost entirely due to the greater proportion of HS group babies with meconium. These differences, while not statistically significant, were demonstrated mainly in primigravida who had spontaneous deliveries.

Table V. Type of delivery by service (excluding low birth weight and second stage labor > one hour)

Type of delivery	*Nurse-midwifery service** (%)	*House staff service†* (%)
Spontaneous	86.0	66.1‡
Low forceps	7.4	27.8‡
Mid forceps	1.7	1.7
Other	4.8	4.3

*229 Patients.
†115 Patients.
‡Statistically significant, $p < 0.00001$.

There were no differences between the CNM and HS groups in the one-minute and five-minute Apgar scores, applying a cutoff point of seven as the minimal acceptable score.[6] Three infants in the CNM group and one in the HS group were stillborn and there was one neonatal death within each group. These numbers were considered too small for statistical analysis.

Comment

It appears that in the hospital setting, prenatal, intrapartal, and postpartal care provided by certified nurse-midwives with physician consultant back-up produces health outcomes equivalent to those of the traditional physician service. Some differences were found.

A number of interpretations which bear upon the evaluation of the services may explain the over-compliance of the certified nurse-midwifery patients. The certified nurse-midwives may be applying a greater number of expected routine visits for their

patients, suggesting that the usual routine number is inadequate to provide good care. Extra visits may be scheduled by the nurse-midwives for additional educational services or the care of social needs. On the other hand, overcompliance may suggest uncertainty of the nurse-midwife, necessitating more frequent patient visits than routinely indicated. Further detailed study will be needed to more correctly interpret this finding.

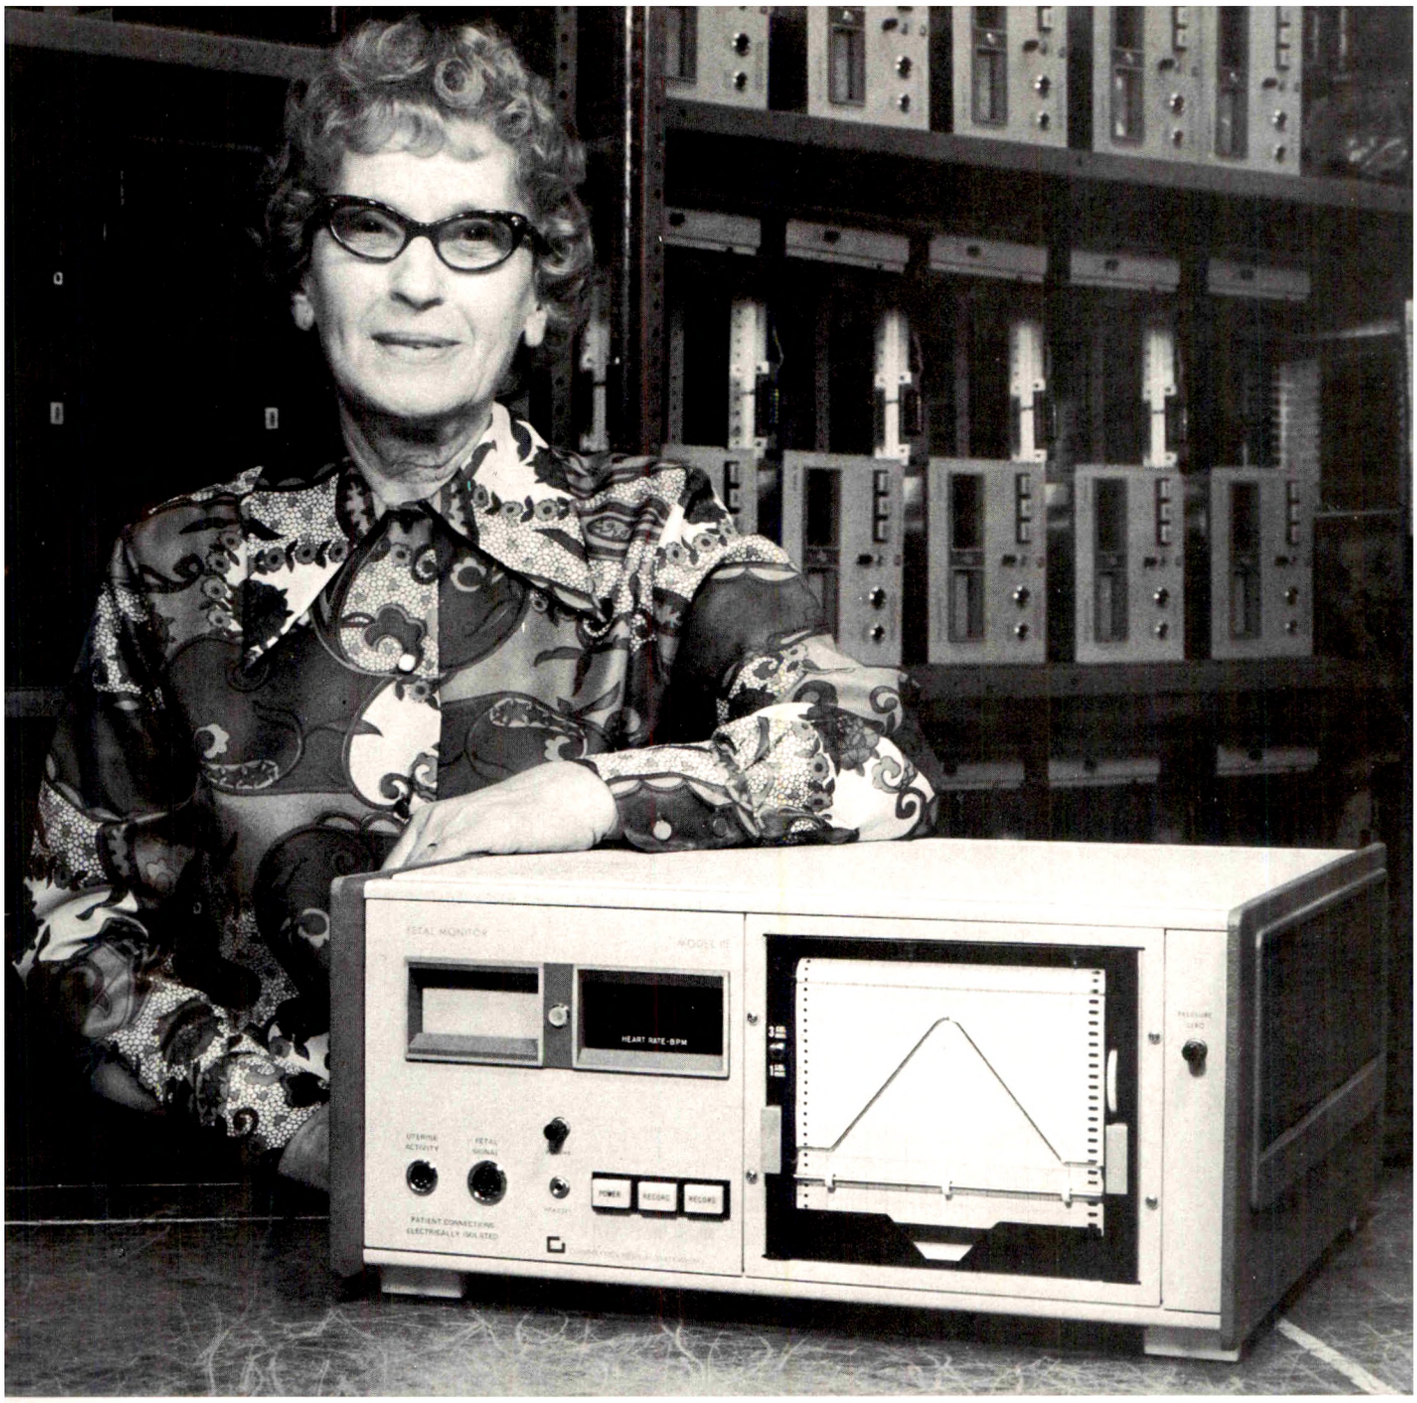
The rate of forceps deliveries among house staff patients may reflect differences between the services in their respective practices for normal deliveries. The application of forceps may be viewed as a more routine procedure for physicians than for nurse-midwives who do not carry out the procedure themselves. In addition, forceps deliveries may be performed by house staff, when not medically indicated, for teaching purposes.

A number of possible explanations for the higher rate of premature babies among the CNM patients exists. Although standard criteria were administered for the inclusion of subjects into the study, it was pointed out previously that the proportion of house staff patients eliminated from the study at the stage of clinical evaluation was twice that of the nurse-midwifery group. If some form of selectivity was applied here, the house staff group may have been initially a healthier population and, for this reason, experienced a lower rate of low birth weight. This can be confirmed only by a follow-up of those patients eliminated from analysis by the study criteria.

It was not possible to obtain data to test the comparability of the groups with respect to other variables known to be associated with low birth weight. Among others, these include cigarette smoking in mother and father and education of mother and father.

The incidence of low birth weight as well as other unfavorable findings in this low-risk population suggests a need to explore the determinants of these outcomes in similar select groups. The predictors of obstetric complications in a clinically low-risk population may differ from the standard indicators which have been established for high-risk groups. Such a finding would have significant implications for the delivery of obstetric services by nurse-midwives whose care is confined to the low-risk patient.

In summary, the findings of the study warrant the acceptance of certified nurse-midwives for the care of the clinically low-risk maternity patient.



Further evaluation studies of the extension of the role of the nurse-midwife to dealing with high-risk prenatal patients will define the clinical limitations of a successful nurse-midwifery service.

The expanded use of nurse-midwives in the hospital setting has profound implications for the delivery of health services to the maternity population. As care of the normal patient is assumed by the nurse-midwives, physicians will be free to concentrate on high-risk cases. Nurse-midwives may begin to meet the demand for family-centered maternity care. Furthermore, the characteristics and quality of care administered by the nurse-midwife may be especially responsive to certain needs of the population. Finally, nurse-midwives may facilitate a more logical distribution of maternal and infant care providers in that certified nurse-midwives might manage the low-risk aspects of care for all patients, leaving physicians free to attend to the high-risk elements of care.

The authors wish to acknowledge the assistance of Jerry E. Parish and Minta Uzodinma, C.N.M.

MARY KNOWS FETAL MONITORS INSIDE OUT,

and their importance to you and your patient.

Mary Viski, one of many fine people at Corometrics, has thirty years electronics wiring experience. She's been with us since we began. Through our in-house education program, Mary learned the value of fetal monitoring to others. We know it's important to have people like Mary who know what they're doing. And you can rely upon us, because we rely upon Mary.

Ortho-Novum 1/80 □ 21

Each tablet contains 1 mg norethindrone and 0.08 mg mestranol TRADEMARK

a history of good patient acceptance

low incidence of breakthrough bleeding

Less than 2% overall experience in 3,464 women over 34,068 cycles.

low incidence of spotting

Less than 3% overall experience in 3,464 women over 34,068 cycles.

low dropout rate

Only 3.6% of women in clinical studies dropped out because of adverse reactions. Serious as well as minor conditions have been reported following the use of oral contraceptives. These conditions include thromboembolic disease. The physician should remain alert to the earliest manifestation of any symptoms of serious disease and discontinue oral contraceptive therapy when appropriate. The physician should be fully aware of the complete Prescribing Information for this product.

highly effective

Ortho-Novum 1/80 □ 21 is a highly effective, well-balanced oral contraceptive. Moreover, it is packaged in the unique, crush-proof DIALPAK* Tablet Dispenser to help reduce the chance of patient failure. Also available in a 28-day DIALPAK Tablet Dispenser.

See prescribing information on following page

*TRADEMARK

Ortho-Novum 1/80 □ 21

TRADEMARK

Each tablet contains 1 mg norethindrone and 0.08 mg mestranol

a history of good patient acceptance

Ortho-Novum 1/80□21 and Ortho-Novum 1/80□28

Description: Each ORTHO-NOVUM 1/80□21 Tablet contains 1 mg of the progestational substance, norethindrone, together with 0.08 mg of the estrogenic compound, mestranol.

Each lavender ORTHO-NOVUM 1/80□28 Tablet contains 1 mg of the progestational substance, norethindrone, together with 0.08 mg of the estrogenic compound, mestranol. Each green tablet contains inert ingredients.

Actions: ORTHO-NOVUM 1/80□21 and ORTHO-NOVUM 1/80□28 act through the mechanism of gonadotrophin suppression, i.e., through the estrogenic and progestational actions of the ingredients. Alterations in cervical mucus and in the endometrium may also contribute to the efficacy of ORTHO-NOVUM 1/80□21 and ORTHO-NOVUM 1/80□28.

Special note: Oral contraceptives have been marketed in the United States since 1960. Reported pregnancy rates vary from product to product. The effectiveness of the sequential products appears to be somewhat lower than that of the combination products. Both types provide almost completely effective contraception.

An increased risk of thromboembolic disease associated with the use of hormonal contraceptives has now been shown in studies conducted in both Great Britain and the United States. Other risks, such as those of elevated blood pressure and reduced tolerance to carbohydrates, have been reported and appropriate tests should be conducted to monitor these during oral contraceptive therapy. Liver disease has also been reported, and the physician should be alert to its earliest manifestations.

Long-term administration of both natural and synthetic estrogens in subprimate animal species in multiples of the human dose increases the frequency for some animal carcinomas. These data cannot be transposed directly to man. The possible carcinogenicity due to the estrogens can neither be affirmed nor refuted at this time. Close clinical surveillance of all women taking oral contraceptives must be continued.

Indication: Contraception.

Contraindications: 1. Thrombophlebitis, thromboembolic disorders, cerebral vascular disease, or a past history of these conditions. 2. Markedly impaired liver function. 3. Known or suspected carcinoma of the breast. 4. Known or suspected estrogen-dependent neoplasia. 5. Undiagnosed abnormal genital bleeding. 6. Known or suspected pregnancy.

Warnings: 1. The physician should be alert to the earliest manifestations of thrombotic and thromboembolic disorders, thrombophlebitis, cerebrovascular disorders including hemorrhage, pulmonary embolism and retinal thrombosis. Should any of these occur or be suspected, the drug should be discontinued immediately.

Retrospective studies of morbidity and mortality in Great Britain and studies of morbidity in the United States have shown a statistically significant association between thrombophlebitis, pulmonary embolism and cerebral vascular disease, occlusive or hemorrhagic, and the use of oral contraceptives. There have been three principal studies in Great Britain[1-3] leading to these conclusions and three in this country.[4-7] The estimate of the relative risk of thromboembolism in the study by Vessey and Doll[3] was about sevenfold, while the United States studies found relative risks of 4.4 to 11, meaning that the users are several times as likely to undergo thromboembolic disease without evident cause as non-users.

In May, 1974, the Royal College of General Practitioners in England[8] issued an interim report of its continuing large-scale prospective study comparing a user group to a non-user group. This study in its interim analysis states, "A statistically significant higher rate of reporting of cerebrovascular accidents in Takers is evident, but the numbers are too small to justify an estimation of the degree of risk." The study also reported a higher incidence of superficial and deep vein thrombosis in users as compared to non-users. The risk of superficial and deep vein thrombosis was reported to be lower in women using 50 mcg estrogen preparations.

The Sartwell study[4] indicated that the risk did not persist after discontinuation of administration. Both the Sartwell and the Royal College studies indicated that the degree of risk was not associated with duration of treatment.

In a collaborative American study[5,6] of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the relative risk of thrombotic stroke was 4.1 to 9.5 times greater in users than in non-users. A comparable estimate for hemorrhagic stroke was 2.0.

None of the American studies was designed to evaluate a difference between products. However, the Sartwell study[4] suggested that there might be an increased risk of thromboembolic disease in users of sequential products.

Other retrospective studies[9,10] have reported an increased risk of post-surgery thromboembolic complications in oral contraceptive users. It has been recommended that therapy be discontinued at least one month prior to elective surgery.

2. Discontinue oral contraceptive medication if there is: gradual or sudden partial or complete loss of vision; proptosis or diplopia; onset or aggravation of migraine or development of headache of a new pattern which is recurrent, persistent or severe; papilledema; or any evidence of retinal vascular lesions.

3. Fetal abnormalities have been reported to occur in the offspring of women who have taken progestogens and/or estrogens during pregnancy.[11,12] The safety of ORTHO-NOVUM1/80□21 or ORTHO-NOVUM 1/80□28 in pregnancy has not been demonstrated. Pregnancy should be ruled out before initiating or continuing the contraceptive regimen. Pregnancy should always be considered if withdrawal bleeding does not occur.

4. A small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The long-range effect to the nursing infant cannot be determined at this time.

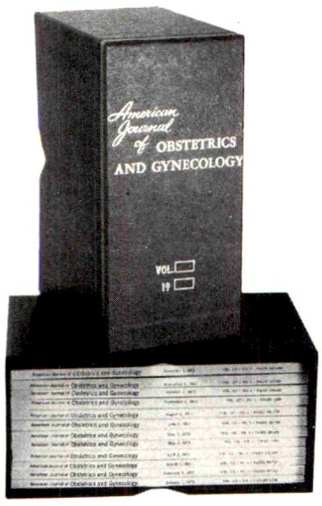
5. Hepatic lesions (adenomas, hepatomas, hamartomas, regenerating nodules, etc.), occasionally fatal, have been reported in women on oral contraceptives. Such lesions may present as an abdominal mass or with the signs and symptoms of an acute abdomen. These lesions should be considered if the patient has abdominal pain or evidence of intra-abdominal bleeding. This has been reported in short-term as well as long-term users of oral contraceptives.

Precautions: 1. A thorough history and physical examination should be performed before prescribing oral contraceptives and periodically during their administration and should include special reference to breasts and pelvic organs, including Papanicolaou smear since estrogens have been known to produce tumors, some of them malignant, in five species of subprimate animals. 2. Endocrine and possibly liver function tests may be affected by treatment with ORTHO-NOVUM 1/80□21 or ORTHO-NOVUM 1/80□28. Therefore, if such tests are abnormal in a patient taking ORTHO-NOVUM 1/80□21 or ORTHO-NOVUM 1/80□28, it is recommended that they be repeated after the drug has been withdrawn for two months. 3. Under the influence of estrogen-progestogen preparations, pre-existing uterine fibromyomata may increase in size. 4. Because these agents may cause some degree of fluid retention, conditions which might be influenced by this factor, such as epilepsy, migraine, asthma, cardiac or renal dysfunction, require careful observation. 5. In breakthrough bleeding, and in all cases of irregular bleeding per vaginam, nonfunctional causes should be borne in mind. In undiagnosed bleeding per vaginam, adequate diagnostic measures are indicated. 6. Patients with a history of psychic depression should be carefully observed and the drug discontinued if the depression recurs to a serious degree. 7. Any possible influence of prolonged ORTHO-NOVUM 1/80□21 or ORTHO-NOVUM 1/80□28 therapy on pituitary, ovarian, adrenal, hepatic or uterine function awaits further study. 8. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. The mechanism of this decrease is obscure. For this reason, diabetic patients should be carefully observed while receiving ORTHO-NOVUM 1/80□21 or ORTHO-NOVUM 1/80□28 therapy. 9. The age of the patient constitutes no absolute limiting factor, although treatment with ORTHO-NOVUM 1/80□21 or ORTHO-NOVUM 1/80□28 may mask the onset of the climacteric. 10. The pathologist should be advised of ORTHO-NOVUM 1/80□21 or ORTHO-NOVUM 1/80□28 therapy when relevant specimens are submitted. 11. Susceptible women may experience an increase in blood pressure following administration of contraceptive steroids. 12. Cholestatic jaundice has been reported in users of oral contraceptives. If this occurs ORTHO-NOVUM 1/80□21 or ORTHO-NOVUM 1/80□28 should be discontinued. This condition is more likely to occur in patients who have experienced cholestatic jaundice of pregnancy. Patients with a history of cholestatic jaundice of pregnancy should be carefully observed during ORTHO-NOVUM1/80□21 or ORTHO-NOVUM 1/80□28 therapy.

Adverse reactions observed in patients receiving oral contraceptives: A statistically significant association has been demonstrated between use of oral contraceptives and the following serious adverse reactions: thrombophlebitis, pulmonary embolism, cerebral thrombosis and hemorrhage, gallbladder disease.

Although available evidence is suggestive of an association, such a relationship has been neither confirmed nor refuted for the following serious adverse reactions: neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis, hepatic lesions with or without intra-abdominal bleeding.

The following adverse reactions are known to occur in patients receiving oral contraceptives: nausea, vomiting, gastrointestinal symptoms (such as abdominal cramps and bloating), breakthrough bleeding, spotting, change in menstrual flow, amenorrhea during and after treatment, edema, chloasma or melasma, which may persist, cholestatic jaundice, migraine, rash (allergic), mental depression, change in weight (increase or decrease), breast changes: tenderness, enlargement and secretion, changes in cervical erosion and cervical secretions, suppression of lactation when given immediately post-partum, rise in blood pressure in susceptible individuals.



Although the following adverse reactions have been reported in users of oral contraceptives, an association has been neither confirmed nor refuted: anovulation post-treatment, which tends to occur more frequently in women with a history of menstrual disorders, premenstrual-like syndrome, changes in libido, changes in appetite, cystitis-like syndrome, headache, intolerance to contact lenses, nervousness, dizziness, fatigue, backache, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruptions, itching, vaginitis.

The following laboratory results may be altered by the use of oral contraceptives: hepatic function—increased sulfobromophthalein retention and other tests; coagulation tests—increase in prothrombin, Factors VII, VIII, IX and X; decrease in anti-thrombin III; increase in platelet aggregability; thyroid function—increase in PBI, and butanol extractable protein-bound iodine and decrease in T^3 uptake values; metyrapone test; pregnanediol determination.

Jersey Shore Medical Center

SYMPOSIUM & WORKSHOP

in Electronic Fetal Monitoring

DATE
February 28 and 29, 1976

PLACE
Cherry Hill Inn
Rte. 38 and Haddonfield Rd.
Cherry Hill, New Jersey

PROGRAM CHAIRMAN

Nubar G. O. Tchilinguirian, MD, FRCS(C), FACOG
Coordinator, Department of Obstetrics and Gynecology: Jersey Shore Medical Center, Fitkin Hospital; Neptune, New Jersey

This two-day symposium and workshop is designed to provide the practicing obstetrician, perinatologist, neonatologist and nurse with practical and up-to-date techniques of electronic and biochemical monitoring for evaluation of the fetus and neonate. A guest faculty of international experts in the field of perinatal medicine will discuss the following topics:

- understanding the design of a fetal monitor
- interpretation and pathophysiologic significance of heart rate patterns
- role of fetal scalp pH sampling for evaluation of the fetus
- role of the nurse in a community hospital
- significance of variability changes in FHR and the impact of OB anesthesia on FHR variability
- oxytocin challenge test and its modern interpretation
- value of the alert system in intensive care fetal monitoring
- advances in electronic monitoring of the neonate
- economics of fetal monitoring; diagnosis and treatment of fetal distress

Individual teaching and interpretation of fetal monitoring patterns is included in the program.

REGISTRATION INFORMATION

Maximum registration has been established at 200 for this workshop. PRE-REGISTRATION is necessary. DEADLINE FOR REGISTRATION IS FEBRUARY 20, 1976.

For further information, contact:
Fetal Monitoring Symposium Coordinator,

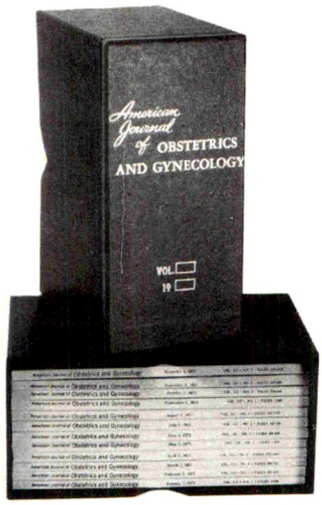
Breast self-examination:



KEY ROLE OF THE PHYSICIAN

item:	**Breast cancer is a major concern of American women, according to a recent Gallup study conducted for the American Cancer Society.**
item:	**Although aware that early discovery improves the chances of cure, and that BSE can lead to early discovery, *fewer than 1 in 5* women practice BSE, and *only half* have an annual breast examination by a physician.**
item:	**Only 35% of all women polled reported that a *physician* had ever raised the subject of breast self-examination, and only 24% had received instruction from the physician on how to do it. Even among women who regularly see a gynecologist, only 34% had been instructed on BSE.**
item:	***But,* among women who received personal instruction from their physicians, the overwhelming majority *(92%)* practiced BSE during the preceding year.**

The Gallup study revealed that, far more important than increasing awareness of breast self-examination, is the problem of inducing women to practice it regularly. The physician plays a key role in this—by teaching women the correct technique, and instilling in them the confidence that will assure their continued practice of BSE.

The American Cancer Society gives major emphasis to breast cancer through research and a vast array of public educational materials, designed to give women life-saving information about the disease. Our latest approach is via a pioneering television film starring Jennifer O'Neill, "Breast Cancer: Where We Are." Where we *will* be in a few years will certainly hinge on our joint efforts.

OB/GYN

COMPREHENSIVE GROUP HEALTH CARE PLAN

(Winston-Salem, N. C.)

A new prepaid group health plan (Multi-specialty) is being developed for employees of R. J. Reynolds Industries, Inc., and board-qualified OB/GYN specialists are needed:

This represents an opportunity to practice under ideal conditions in modern new facilities and excellent hospitals in a unique concept in the Southeast.

Winston-Salem is located in the Piedmont section of North Carolina and is within reasonable driving distances to the Atlantic Ocean and Blue Ridge Mountains. The city is noted for its cultural, recreational and college environments.

Salary commensurate with experience. Liberal fringe benefits including paid vacation, CME, retirement, life insurance and health coverage. Relocation expenses paid.

Send curriculum vitae including salary requirements, to:

E. Reid Bahnson, Medical Director

Winston-Salem Health Care Plan, Inc.
P.O. Box 2959
Winston-Salem, N. C. 27102

An Equal Opportunity Employer, m/f

One or two OB/GYN specialists wanted immediately for new, 120 bed hospital in Northern Wisconsin community of 10,000. Great water sports, fishing, and hunting abound in this Lake Superior vacation area. Good schools and new office space available adjacent to hospital. Contact: Kenneth Morrow, M.D., (715) 682-8146 after 7:00 p.m. or Lowell Miller (715) 682-4563.

Abnormal uterine bleeding: progesterone replacement... to oppose unopposed estrogen

Estrogen replacement therapy... a frequent cause of abnormal uterine bleeding

Administration of estrogen for the relief of menopausal symptoms is a frequent cause of irregular bleeding or spotting during the menopause, and the most common cause of uterine bleeding after the menopause. Bleeding may occur when long-term administration of estrogen causes overstimulation of the endometrium.

It cannot be assumed, however, that uterine bleeding in a woman on estrogen replacement therapy is due solely to the exogenous estrogen. The existence of a pathologic condition—benign or malignant—should always be considered, thoroughly explored, and ruled out. It is generally agreed that any woman taking estrogen who complains of abnormal uterine bleeding should undergo a careful physical examination including a Pap test, followed by curettage of the uterine cavity.

A close look at the influence of estrogen and progesterone on the endometrium

In the normal proliferative endometrium (left), the epithelium contains rather flat, nonciliated cells with small microvilli, and scattered, uniform ciliated cells. Regrowth of the surface epithelial cells proceeds vigorously throughout the proliferative phase of the cycle. (X2250)

Under the continued and unopposed influence of estrogen (center), there is a striking increase in the number of ciliated cells and in the abundance and size of the microvillous processes on the nonciliated cells. (X1600)

During the normal secretory phase (right), the presence of progesterone causes the secretory cells to become more complex, and the microvilli to increase in number. Scattered droplets are visible on the surface of some of the nonciliated cells and are attached to the tips of some microvilli. (X2500)

overa replacement oppose unopposed estrogen

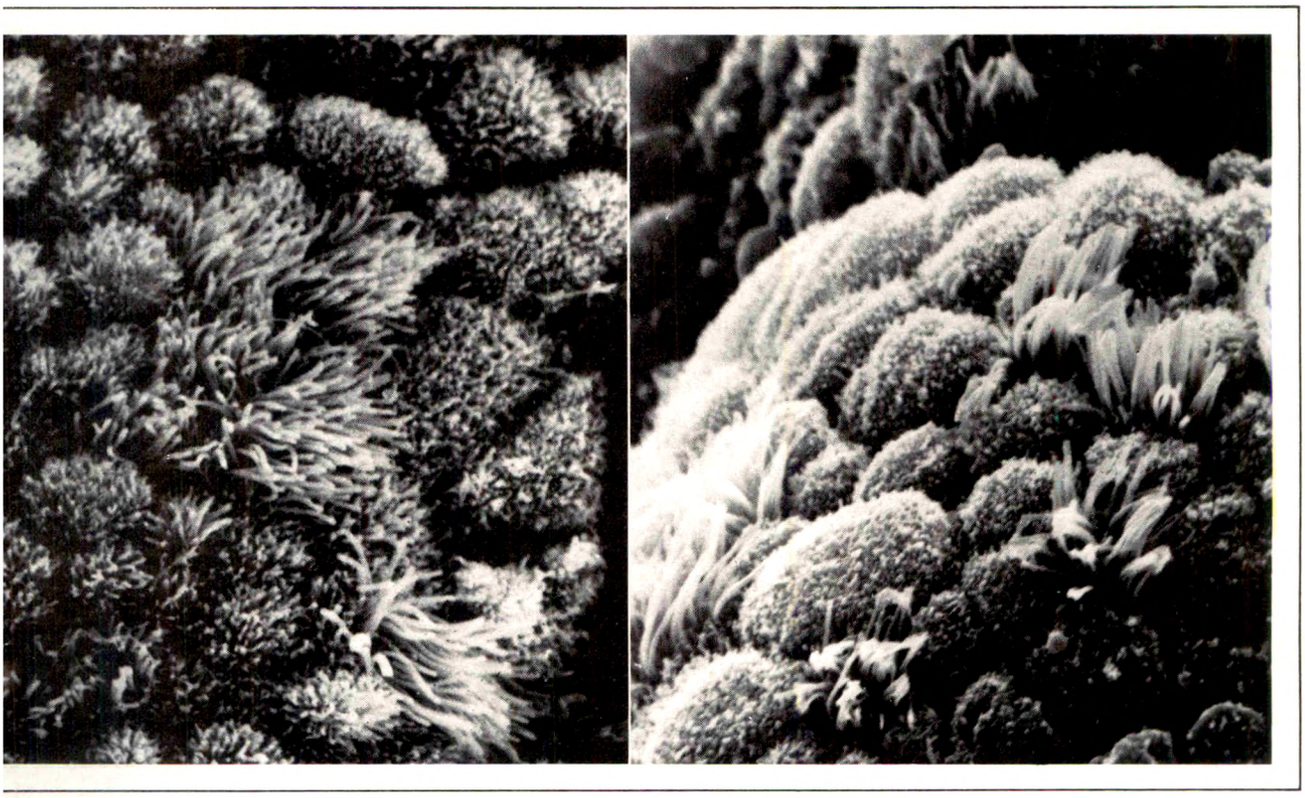
ıen the unopposed action of exogenous estro- ı is responsible for abnormal uterine eding in the menopausal or postmenopausal ient, administration of Provera® edroxyprogesterone acetate), 5 mg - 10 mg ly for 5-10 days, may be all that eeded to control or regulate bleeding. vera, an orally active derivative of gesterone, transforms the estrogen-primed lometrium into a secretory endometrium. eding and rapid shedding of the lometrium occur following cessation of gestin therapy.

ecautions and ntraindications

ıvera appears to be devoid of significant rogenic activity; however, andro- ıic effects have been noted with the drug.

ring progesterone therapy, thrombophlebitis l pulmonary embolism have been reported. r this reason, such therapy is contra- licated in women with a history of these idents. Progesterone therapy is also contraindicated in the presence of liver dysfunction or disease, known or suspected malignancy of breast or genital organs, undiagnosed vaginal bleeding, and missed abortion. Because a decrease in glucose tolerance may occur during Provera therapy, diabetic patients should be followed closely. Patients with a history of psychic depression should be carefully observed and if serious depression occurs, Provera should be discontinued.

To control abnormal uterine bleeding in the absence of organic pathology



Provera® 10 mg Medroxyprogesterone Acetate Tablets, U.S.P., Upjohn

To control abnormal uterine bleeding in the absence of organic pathology

Provera® 10 mg Medroxyprogesterone Acetate Tablets, U.S.P., Upjohn

Description and actions: Medroxyprogesterone acetate is a derivative of progesterone. Administered orally or parenterally to women with adequate endogenous estrogen it transforms proliferative endometrium into secretory endometrium.

Indications: Provera Tablets are indicated in secondary amenorrhea and abnormal uterine bleeding due to hormonal imbalance in the absence of organic pathology such as fibroids or uterine cancer.

Contraindications: Thrombophlebitis, thromboembolic disorders, cerebral apoplexy or patients with a past history of these conditions. Liver dysfunction or disease. Known or suspected malignancy of breast or genital organs. Undiagnosed vaginal bleeding. Missed abortion. Known sensitivity to medroxyprogesterone acetate.

Warnings: 1. Immediately discontinue administration should any of the following thrombotic disorders occur or be suspected: thrombophlebitis, cerebrovascular disorders, pulmonary embolism, retinal thrombosis. **2.** Beagle dogs treated with medroxyprogesterone acetate developed mammary nodules, some of which were malignant. Although nodules occasionally appeared in control animals, they were intermittent in nature, whereas the nodules in the drug treated animals were larger, more numerous, persistent, and there were some breast malignancies with metastases. Their significance with respect to humans has not been established. **3.** Discontinue medication pending examination if there is sudden partial or complete loss of vision, or if there is a sudden onset of proptosis, diplopia or migraine. If examination reveals papilledema or retinal vascular lesions, medication should be withdrawn. **4.** Detectable amounts of progestin have been identified in the milk of mothers receiving the drug. The effect of this on the nursing infant has not been determined. **5.** Usage in pregnancy is not recommended because of data indicating a possible association between administration of progestins early in pregnancy and congenital heart defects in the offspring. **6.** Three major studies in Great Britain and one in this country have shown a statistically significant association between thrombophlebitis, pulmonary embolism, cerebral thrombosis and embolism and the use of oral contraceptives. It has been estimated that users are several times as likely to undergo thromboembolic disease without evident cause as nonusers. The American study indicated that the risk did not persist after discontinuation and it was not enhanced by long continued administration.

Precautions: A pretreatment physical exam should include special reference to breast and pelvic organs and a Papanicolaou smear. This drug may cause some degree of fluid retention; therefore, observe carefully patients with conditions influenced by fluid retention such as epilepsy, migraine, asthma, and cardiac or renal dysfunction. In breakthrough bleeding, and other irregular bleeding per vaginum bear in mind nonfunctional causes. Perform adequate diagnostic measures in cases of undiagnosed vaginal bleeding. Advise pathologist of therapy when submitting relevant specimens. Carefully observe patients with history of psychic depression and discontinue drug if serious degree of depression recurs. Any possible influence of prolonged therapy on pituitary, ovarian, adrenal, hepatic, or uterine function awaits further study. Decreased glucose tolerance has been observed in a small percentage of patients on estrogen progestin combinations, therefore, carefully observe diabetic patients receiving progestin therapy. Age constitutes no absolute limiting factor, although onset of climacteric may be masked. Because of the occasional occurrence of thrombotic disorders (thrombophlebitis, pulmonary embolism, retinal thrombosis, and cerebrovascular disorders) in patients taking estrogen-progestin combinations and since the mechanism is obscure, the physician should be alert to the earliest manifestation of these disorders.

Adverse reactions: The following have been reported: breast tenderness or galactorrhea in a few instances; an inferential association between the administration of progestins early in pregnancy and the occurrence of congenital malformations (see also Warnings); occasional sensitivity reactions including pruritus, urticaria, edema and generalized rash; acne, alopecia and hirsutism in a few patients; thromboembolic phenomena including thrombophlebitis and pulmonary embolism.

The following adverse reactions have been observed in women taking progestins including medroxyprogesterone acetate: breakthrough bleeding; spotting, change in menstrual flow; amenorrhea; edema, increase or decrease in weight; changes in cervical erosion and secretions; cholestatic jaundice, rash (allergic) with and without pruritus, and mental depression.

A statistically significant association has been demonstrated between use of estrogen-progestin combination drugs and the serious adverse reactions of thrombophlebitis, pulmonary embolism and cerebral thrombosis and embolism. Therefore, patients on progestin therapy should be carefully observed.

Although available evidence is suggestive, a relationship has been neither confirmed nor refuted for the association of the serious adverse reaction of neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been observed in patients receiving estrogen-progestin combination drugs: rise in blood pressure in susceptible individuals; premenstrual-like syndrome, changes in libido; changes in appetite, cystitis-like syndrome, headache; nervousness; dizziness; fatigue; backache, hirsutism; loss of scalp hair; erythema multiforme; erythema nodosum; hemorrhagic eruption; and itching. Therefore, observe patients on progestin therapy carefully.

The following laboratory results may be altered by the use of estrogen-progestin combination drugs: increased sulfobromophthalein and other hepatic function tests; coagulation tests (increase in prothrombin factors VII, VIII, IX and X), metyrapone test; pregnanediol determination; thyroid function tests (increase in PBI, and butanol extractable protein bound iodine and decrease in T^3 uptake values).

How supplied: *2.5 mg* in bottles of 25. *10 mg* in bottles of 25 and 100.

FETUS, PLACENTA, AND NEWBORN

Cardiac output in the fetal lamb: The effects of spontaneous and induced changes of heart rate on right and left ventricular output

ABRAHAM M. RUDOLPH, M.D.
MICHAEL A. HEYMANN, M.D.
San Francisco, California

Right and left ventricular outputs were measured continuously in fetal lambs in utero for 2 to 21 days after implantation of electromagnetic flow transducers around the main pulmonary trunk and ascending aorta. Surface pacing electrodes were implanted on the left and right atria. The intact cervical vagus nerve was stimulated by electrodes implanted around the nerve. Spontaneous increases in fetal heart rate were associated with increases in both right and left ventricular outputs and spontaneous falls in heart rate with reduction in both outputs. There was a linear relationship between fetal heart rate and ventricular outputs. Vagal stimulation reduced fetal heart rate with a consistent and linear fall in ventricular output. Left atrial pacing increased right ventricular output by 15 to 20 per cent but produced a variable response, usually a fall, in left ventricular output. Right atrial pacing resulted in increases in both outputs but the increase in right ventricular output was less than during left atrial pacing at the same rate. The difference in response of ventricular outputs to induced as compared to spontaneous heart rate changes relates to the effects on left and right atrial phasic pressure relationships. These changes probably alter blood flow patterns across the foramen ovale.

MEASUREMENT of cardiac output in fetal animals has been hampered by difficulties in access to the fetus and by the presence of large central shunts in the fetal circulation. Most previous measurements of cardiac output have been made acutely in fetal lambs exteriorized from the uterus, with umbilical-placental flow maintained. The effects of anesthesia, removal of the fetus from the uterus, and surgical manipulation on cardiovascular function have not been assessed fully. It has been shown, however, that exteriorization of the fetus results in a progressive fall in umbilical blood flow.[1] The presence of large shunts through the foramen ovale and ductus arteriosus has precluded the application of methods used in adult animals. Modifications of the Fick[2] and indicator dilution techniques[3] have been used to measure cardiac output in exteriorized fetuses. Recently we described a method for measuring cardiac output in fetal lambs in which catheters had been chronically maintained in utero and

radionuclide-labeled microspheres injected into a lower and upper limb or jugular vein.[4] The microsphere method, as well as the Fick and indicator dilution techniques, have the disadvantage that only single measurements can be made over limited periods of time, and rapid and sequential changes cannot be observed. Assali and associates[5] introduced the use of electromagnetic flowmeters to study ascending aortic and pulmonary trunk flow in fetal lambs. Although they could observe flows continuously, the combined outputs of the left and right ventricles were considerably lower than values reported for fetal lambs in utero.[4] Exteriorization of the fetus, the acute surgical procedure of thoracotomy, and extensive dissection of the great vessels probably influenced cardiovascular function profoundly.

In an attempt to study cardiovascular function in the fetus, in utero, in as undisturbed a state as possible, we have applied electromagnetic flow transducers of the cuff type around the main pulmonary trunk and the ascending aorta of fetal lambs and allowed them to recover from surgery. During continuous observations of right or left ventricular output we noted fluctuations associated with changes in heart rate. We have examined the effects of a spontaneous increase or decrease of heart rate on right and left ventricular output. We also induced changes in heart rate by electrically pacing the left or right atrium and stimulating the vagus nerve and studied the effects of these changes on right and left ventricular output.

Methods and materials

We studied the fetuses of 23 pregnant sheep of Dorset, Hampshire, or mixed strains. The gestational ages of the lambs were known to within 4 to 5 days of the date of conception, and ranged from 112 to 130 days (0.75 to 0.85 gestation).

Instrumentation of the fetus. The ewes were starved for periods varying from 24 to 48 hours prior to the performance of surgery. Strict aseptic precautions were observed throughout all surgical procedures. The mother was blindfolded and lower body analgesia accomplished by low spinal or, more recently, epidural anesthesia with 2 ml. (20 mg.) of tetracaine hydrochloride (Pontocaine). Polyvinyl catheters (I.D. 0.050″, O.D. 0.090″) were inserted into a maternal hindlimb artery and vein and advanced to the descending aorta and inferior vena cava. The ewe was then placed supine and through a midline abdominal incision the uterus was exposed. Sodium pentobarbital was given intravenously to the ewe in amounts of 200 to 300 mg. if she seemed restless or struggled. All fetal surgical procedures were performed with 0.5 per cent lidocaine hydrochloride for local anesthesia. A fetal hindlimb was located and exposed through a small (2 to 3 cm.) uterine incision. Polyvinyl catheters (I.D. 0.038″, O.D. 0.066″) were inserted into an artery and vein and advanced to the descending aorta and proximal inferior vena cava. The limb was returned to the uterus, a polyvinyl catheter (I.D. 0.050″, O.D. 0.090″) placed in the amniotic cavity, and the incision sutured.

A second 5 to 6 cm. incision was made in the uterine wall over the left side of the fetal chest, the left forelimb was extracted through this incision, and a thoracotomy was performed through the third or fourth intercostal space. The pericardium was incised over the pulmonary trunk from the region of the pulmonary valve to the ductus arteriosus, taking care to avoid damaging the vagus nerve. With minimal blunt dissection, the pulmonary trunk was separated from the underlying ascending aorta and aortic isthmus; short lengths of polyvinyl tubing (I.D. 0.030″, O.D. 0.048″) were passed around the vessels selected for instrumentation. A cuff-type electromagnetic flow transducer which had been precalibrated in vitro was placed around the ascending aorta distal to the origin of the coronary arteries to measure left ventricular output, but excluding coronary blood flow, in 10 animals. Transducers with inside diameters of 5 to 7 mm. were required to provide good electrode contact with minimal vessel constriction. In eight animals, transducers with an internal diameter of 8 to 11 mm. were placed around the pulmonary trunk midway between the pulmonary valve and the origin of the pulmonary arteries to measure right ventricular output. In five fetuses, flow transducers were placed around both vessels. In those animals with a transducer around the pulmonary trunk, a polyvinyl catheter (I.D. 0.030″, O.D. 0.048″) was inserted, either directly into the right ventricle or indirectly across the pulmonary valve from the pulmonary trunk, through purse-string sutures in the wall. A catheter (I.D. 0.030″, O.D. 0.048″) was also inserted through a purse-string suture into the left atrium in 14 fetuses. Electrodes for pacing the left or right atrium were prepared by soldering 1 mm. diameter bulbs of platinum to No. 30 Teflon-coated wire and gas sterilized. In all animals two electrodes were sutured on the inner aspect of the pericardium overlying the left atrium so that they lay in contact with the atrium about 1 cm. apart; in five animals an additional two electrodes were applied similarly to the right atrium. The pericardium was not sutured. A No. 8 F. polyvinyl tube with multiple side openings was placed in the left pleural space and the ribs brought together, with care to avoid angling or distorting the position of the transducers; in some

instances it was necessary to excise a short segment of rib. In some fetuses, polyvinyl catheters (I.D. 0.038″, O.D. 0.066″) were placed into the exposed axillary artery and vein; then the muscle and skin were sutured. The neck was exposed through either the same or a separate small uterine incision in some animals and the left vagus nerve and trachea dissected. Two electrodes consisting of 3 to 4 mm. lengths of platinum wire soldered to No. 30 Teflon-coated wire were applied around the vagus nerve about 1 cm. apart. A polyvinyl catheter (I.D. 0.038″, O.D. 0.066″) with multiple side holes was inserted through a purse-string suture into the trachea and advanced until the tip lay within the thorax. The skin and uterine incisions were sutured and all the catheters and electrodes led to the left flank of the ewe. The flow-transducer cables were passed through small incisions (1 cm.) in the abdominal wall, and the catheters and electrodes were led through a cannula inserted through the skin and into the peritoneal cavity. The catheters and electrodes were protected by a Teflon cloth pocket sewn to the skin on the flank. The catheters were filled with heparin solution and sealed with metal plugs. One million units of penicillin G and 500 mg. of Kanamycin were administered to the sheep on the day of surgery and each day thereafter. Half the total amount was injected into the amniotic cavity catheter and the remainder into the maternal vein catheter.

Recordings. The mother was allowed to recover from the surgery and measurements were made daily while the sheep stood quietly in a stall. Phasic and mean flows were measured with Statham SP 2202 electromagnetic flowmeters. The flows measured with the precalibrated transducers and this flowmeter were accurate to within 5 per cent. The electrical zero was checked repeatedly and showed only minor daily variations from zero flow recorded during the diastolic phase of the cardiac cycle. Pressures were measured continuously from the fetal arterial and amniotic cavity catheters in all animals and from the right ventricular, tracheal, left atrial, and inferior vena caval catheters in the animals in which they were inserted. All pressures were measured with $P_{23}Db$ (Statham) pressure transducers. At the onset of each observation period a fetal femoral arterial blood sample was obtained for measurement of Pco_2, Po_2, and pH with a radiometer blood-gas analyzer with appropriate electrodes. All pressure and flow recordings were made on a Beckman direct-writing recorder. Fetal heart rate was monitored continuously with a cardiotachometer triggered from either the fetal arterial pressure or the electromagnetic flow signal. In some studies beat-to-beat stroke volume

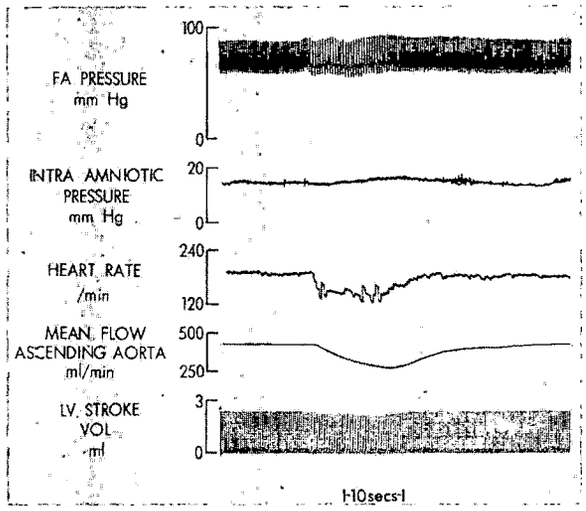

Fig. 1. Response of the fetal circulation to a 12 second long spontaneous fall in fetal heart rate; fetal femoral arterial *(FA)* and intra-amniotic pressures, heart rate, mean flow in the ascending aorta, and left ventricular *(LV)* stroke volume are shown.

was recorded by integrating the velocity signal from the flowmeter with a Beckman type 9873B integrator.

The pressures and flows were recorded continuously for varying periods of 15 minutes to 5 hours each day. Electrical pacing studies were started after permitting the animals to recover for at least 2 days after surgery. After obtaining control recordings for about 15 to 30 minutes, the left or right atrial electrode was stimulated at the resting heart rate and with frequencies increasing by 15 per minute to a maximum rate of 315 or 330 per minute. The stimuli were applied with a Grass 588 stimulator and an SIU5 stimulus isolation unit. The stimulation was applied at each rate until flows and pressures reached a new constant level; then it was stopped and pressures and flows allowed to return to control before the next stimulation at a higher rate was applied. In those animals with left and right atrial pacing electrodes, we sometimes alternated the pacing of each atrium at the same rate. On occasion the stimulation produced so much artifact in the flow signal that it was not possible to measure flow accurately; this was most often noted on the first few days after surgery and these observations were discarded. The stimuli consisted of 1 to 1.5 msec. impulses of 3 to 8 V. The voltage required to effect capture of the heart rate usually increased after a few days, but we were able to maintain effective pacing even 2 to 3 weeks after surgery. Vagal stimulation also was applied with the Grass stimulator and impulses of 3 msec. duration at 8 to 15 V. were applied at a frequency of 15 per second. The stimulation was maintained until a

steady level of pressures and flows was accomplished. During vagal stimulation it was noted that intrathoracic pressure as measured by the tracheal catheter increased in all animals; the magnitude of the increase varied in different fetuses from 2 to 3 mm. Hg to as much as 10 to 12 mm. Hg. In some fetuses a stable ventricular output was not achieved as intermittent expiratory movements with elevations of pressure of 10 to 20 mm. Hg occurred. In order to eliminate the effects of these respiratory changes on ventricular output, we administered intravenous succinylcholine chloride in doses of 2 mg. per kilogram directly to the fetus. This amount did not have any effect on resting heart rate, blood pressure, or ventricular outputs, nor did it alter the response to pacing the left or right atrium, or the circulatory changes associated with spontaneous variations of heart rate. The succinylcholine eliminated spontaneous respiratory movements and prevented the rise of intrathoracic pressure and the intermittent expiratory movements during vagal stimulation.

Results

Pressures, ventricular output, and heart rate were recorded on the first day after surgery and almost every day thereafter until fetal death or abortion occurred. Most intrauterine deaths were related to infection. All measurements reported were obtained when the fetuses had descending aortic $Po_2 > 20$ torr, $Pco_2 < 45$ torr, and $pH > 7.35$. There was no sig-

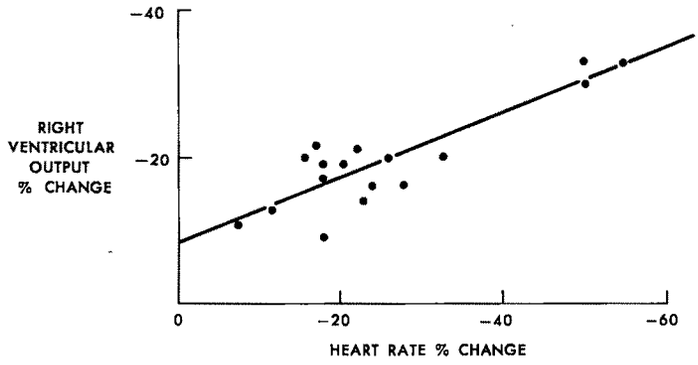

Fig. 5. The relationship between the percentage decreases from resting of right ventricular output and heart rate during electrical stimulation of the intact left vagus nerve is demonstrated.

nificant change in resting heart rate and aortic, left atrial, right ventricular, inferior vena caval, or amniotic cavity pressures after the first day of observation. In the six early studies, right ventricular output increased rapidly between the first and fifth days, but showed minor changes thereafter; in later studies, there was no significant change in flow after the first 2 days. There was also no difference in the spontaneous variation in flow associated with heart rate changes, nor in the responses to atrial pacing or vagal stimulation. We have therefore pooled the information obtained at various intervals after surgery. In analyzing the spontaneous variations in flow and heart rate, we measured the percentage increase or decrease from the resting level at the time of maximal change of heart rate. Similarly, during vagal stimulation and atrial pacing we measured the percentage change of left and right ventricular output and related it to the percentage change of heart rate.

Spontaneous changes in heart rate. Spontaneous increases in heart rate of greater than 10 per cent above resting level were invariably associated with an increase in both right and left ventricular outputs. The duration of the increased heart rate varied from 10 seconds to several minutes, and the increased output was maintained as long as the heart rate was elevated. In some instances the increased heart rate was associated with initiation of fetal respiratory movements, but episodic changes were observed even after respiratory movements were inhibited by muscular relaxation with succinylcholine. The increase in heart rate was often, but not always, associated with an elevation of aortic blood pressure. The rise of ventricular output consistently was related to the heart rate increase, whether or not fetal respiratory movements or a rise of blood pressure occurred.

Spontaneous decreases in heart rate of more than 10 per cent of resting level resulted in a fall in right and

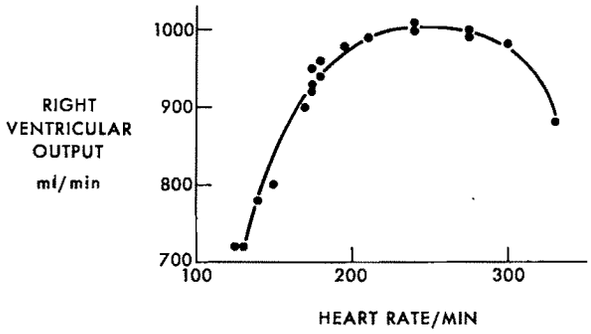

Fig. 6. The relationship between right ventricular output and heart rate in one fetus is shown. A marked rise in output occurs as the rate rises from 125 to 200 per minute. Above a rate of 300 per minute output falls.

left ventricular outputs. The reductions in heart rate were of 10 to 100 seconds duration and the flow was decreased during the whole period. These changes usually occurred independent of changes in amniotic cavity pressure, respiratory activity, or arterial pressure (Fig. 1). In several instances there was an associated increase in fetal arterial pressure and in intratracheal, left atrial, and inferior vena caval pressures in the first 3 to 5 seconds (Fig. 2). Administration of succinylcholine eliminated the respiratory and venous pressure changes but did not influence the flow response to reduction in heart rate.

There was a linear relationship between the percentage changes in heart rate and in right and left ventricular outputs. Fig. 3 shows the variation in right ventricular output (ordinate) associated with changes in heart rate (abscissa). The relationship is described by the equation $Y = 0.6X$ and the correlation coefficient is 0.83. Alteration of left ventricular output (ordinate) in relation to changes in heart rate (abscissa) is shown in Fig. 4. The relationship is described by the equation $Y = 0.74X$ and the correlation coefficient is 0.92.

The inferior vena caval and left atrial pressures were

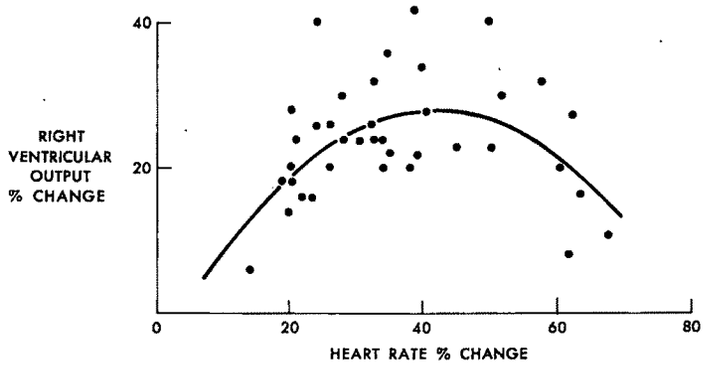

Fig. 7. The relationship between the percentage increases from resting of right ventricular output and heart rate during electrical pacing of the left atrium in 13 fetuses is demonstrated.

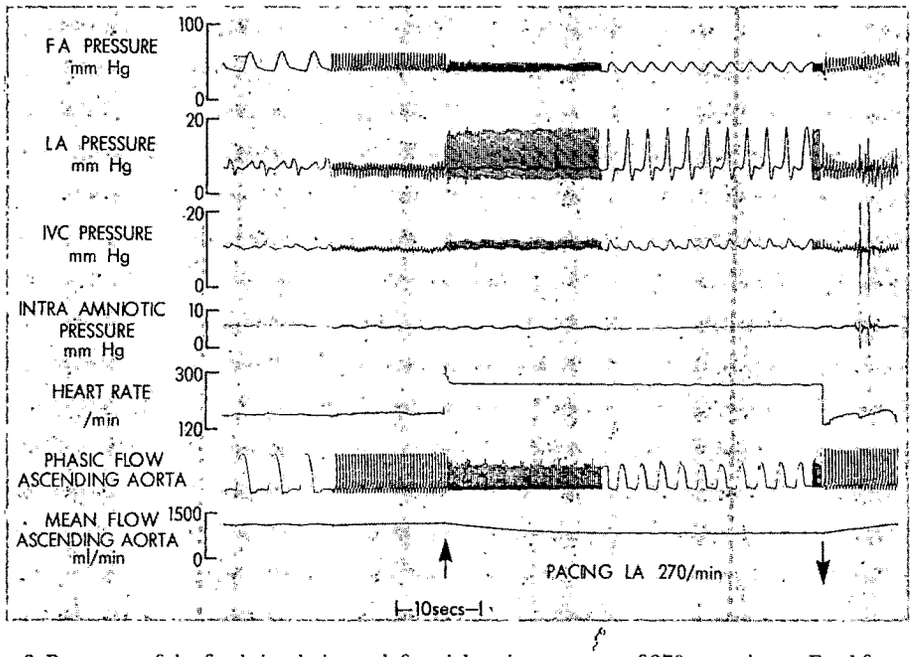

Fig. 8. Response of the fetal circulation to left atrial pacing at a rate of 270 per minute. Fetal femoral arterial *(FA)*, left atrial *(LA)*, inferior vena caval *(IVC)* and intra-amniotic pressures, heart rate, and phasic and mean flow in the ascending aorta are shown.

measured simultaneously in 14 fetuses. Pressure was measured in the proximal inferior vena cava in preference to the right atrium, since left atrial filling is derived largely from the inferior vena cava directly through the foramen ovale in the fetus. A mean pressure difference of 2 to 3 mm. Hg was recorded between the inferior vena cava and the left atrium (Fig. 12, *A*). There was no change in the mean pressure difference nor in the phasic pressure relationship between the vena cava and the left atrium during spontaneous changes in heart rate.

Cervical vagal stimulation. In these studies the intact vagus nerve was stimulated, so that cardiac slowing could have resulted directly from efferent fiber stimulation or through afferent fibers passing to cerebral vasomotor centers. Vagus nerve stimulation produced an elevation in arterial pressure which was not avoided by succinylcholine administration. Increases in tracheal and venous pressures associated with vagal stimulation were inhibited by succinylcholine. Vagal stimulation adequate to cause a reduction in heart rate produced a consistent fall in ventricular output. When vagal escape occurred the recovery of heart rate was associated with a parallel rise in flow. There was a linear relationship between the heart rate (abscissa) and right ventricular output (ordinate) as seen in Fig. 5. This is expressed by the equation $-Y = -0.4X - 8.5$, and the correlation coefficient is 0.86. The fact that the line intercepts with the flow axis on the negative side of zero suggests that

other factors, in addition to reduction of heart rate, influence right ventricular output during vagal stimulation. Vagal stimulation studies were conducted only in one animal in which left ventricular output was measured; similar changes were observed.

Left and right atrial pacing. The effects of left atrial pacing were studied in all the fetuses, but right atrial pacing studies were performed in only five animals to evaluate the differences in responses. Left atrial pacing resulted in a consistent increase in right ventricular output. In most of the studies, resting heart rate ranged between 160 and 180 per minute. Right ventricular output increased as rate was raised to 240 to 270 per minute, by an average of 15 to 20 per cent of the resting flow, maintained a plateau to rates of 300 to 315 per minute, and then fell with further increases of rate. A typical example of this response is shown in Fig. 6. The percentage increase in right ventricular output is related in a curvilinear manner (second-order regression) to the percentage increase in heart rate above resting levels, as shown in Fig. 7.

The effects of left atrial stimulation on left ventricular output were quite variable. In most studies, an increase in heart rate was associated with a progressive fall in left ventricular output. At rates of 270 to 330 per minute, left ventricular output usually fell by 50 to 60 per cent of resting levels (Fig. 8). In some instances, however, there was a small increase of left ventricular output of about 10 per cent at pacing rates of 210 to 240 per minute, but flow fell as rate was increased further. In view of the variable responses of left ventricular output to left atrial pacing at the same heart rate in different animals, no correlation could be defined. In the five animals in which flow transducers were placed on both the ascending aorta and the pulmonary trunk, the selective effects of left atrial pacing on left and right ventricular outputs were clearly demonstrated. Left ventricular output either fell, or increased minimally, while right ventricular output always increased (Fig. 9). If left ventricular output did increase slightly, right ventricular output increased much more.

We compared the effects of right and left atrial pacing in five fetuses. Right ventricular output consistently increased with both left and right atrial pacing, but the rise was always greater with left atrial pacing (Fig. 10). Similarly, left ventricular output rose slightly or fell during left atrial pacing, but increased during right atrial pacing. When the heart was paced at rates similar to resting rate, left atrial pacing usually produced a fall, but right atrial pacing caused a small rise, in left ventricular output (Fig. 11).

Fetal arterial pressure either increased slightly or did not change when pacing rate was slightly higher than resting rate (Fig. 11); with further increases, systolic pressure fell markedly, while diastolic pressure was maintained (Figs. 8 and 9).

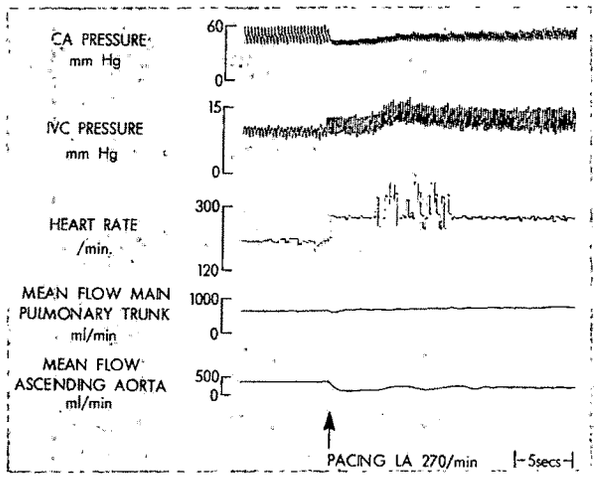

Fig. 9. Response of the fetal circulation to left atrial pacing at a rate of 270 per minute; fetal carotid arterial *(CA)* and inferior vena caval *(IVC)* pressures, heart rate, and mean flow in the main pulmonary trunk and ascending aorta are shown.

Left atrial and inferior vena caval pressures during atrial pacing. Inferior vena caval mean pressures were 2 to 3 mm. Hg higher than those in the left atrium in undisturbed fetuses. Left atrial pacing produced a reduction in the mean pressure difference to 0 to 1 mm. Hg and caused variable alterations in the phasic pressure contours. At lower pacing rates, small changes in left atrial and inferior vena caval pressures were observed (Fig. 11) but at high rates a very prominent a wave developed; this was more prominent in the left atrium than in the inferior vena cava (Figs. 8 and 9). The pressure contours differed during selective left and right atrial pacing in the same fetus (Fig. 10).

Rapid recordings of left atrial and inferior vena caval pressures were made using two carefully matched transducers with identical amplification. Inferior vena caval pressure exceeded that in the left atrium during all phases of the cardiac cycle in the resting fetus (Fig. 12, *A*). During left atrial pacing, however, left atrial pressure exceeded inferior vena caval pressure during some phase of the cardiac cycle, even though mean pressure usually was slightly higher in the inferior vena cava (Fig. 12, *B*). Right atrial pacing produced less striking changes in phasic pressure contours than left atrial pacing (Fig. 12, *C*).

Comment

The development of a model for measuring right and left ventricular output by chronic implantation of

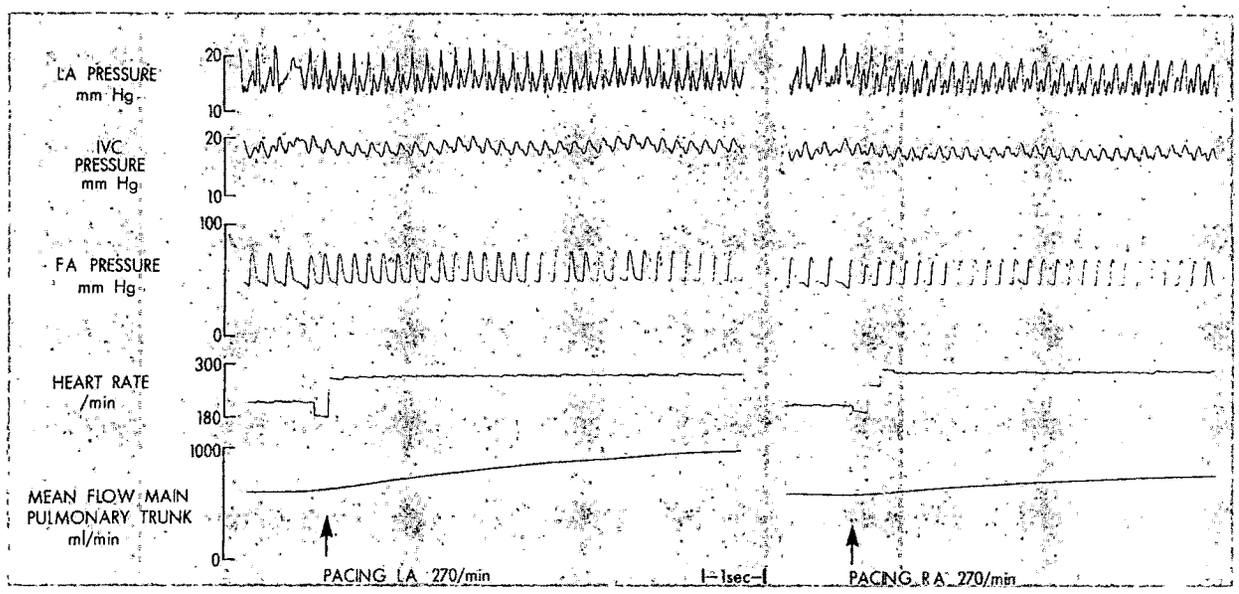

Fig. 10. Response of the fetal circulation, in the same fetus, to left atrial *(LA)* and right atrial *(RA)* pacing at a rate of 270 per minute; fetal left atrial *(LA)*, inferior vena caval *(IVC)*, and femoral arterial *(FA)* pressures, heart rate, and mean flow in the main pulmonary trunk are shown.

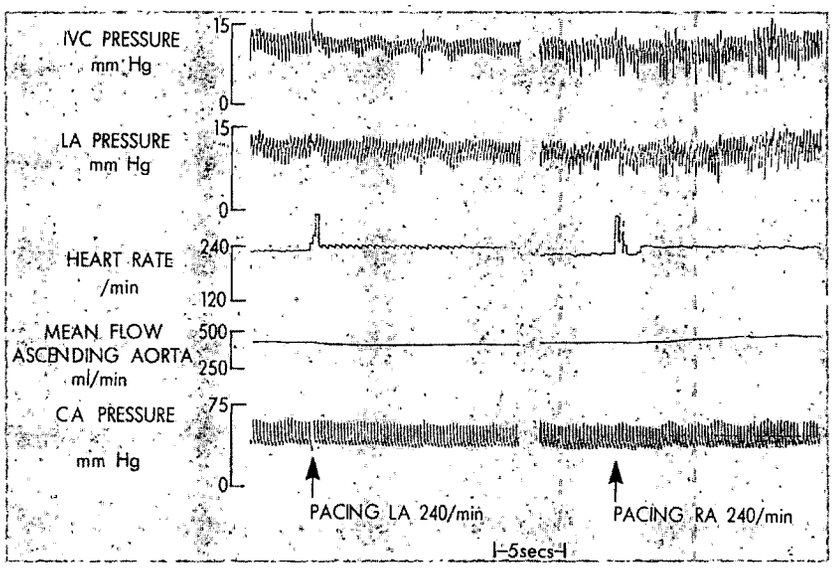

Fig. 11. Response of the fetal circulation in the same fetus to left atrial *(LA)* and right atrial *(RA)* pacing at a rate of 240 per minute; fetal inferior vena caval *(IVC)*, left atrial *(LA)*, and carotid arterial *(CA)* pressures, heart rate, and mean flow in the ascending aorta are shown.

electromagnetic flow transducers, has afforded the opportunity to examine instantaneous hemodynamic responses in the relatively undisturbed lamb in utero. The importance of permitting an adequate period of recovery after surgery is underscored by our observation that cardiac output is reduced during surgery and for several hours thereafter. Although right ventricular output was reduced for 2 to 5 days in our earlier preparations,[6] with improvement of technique, both right and left ventricular output recovered within 24 to 48 hours. This is supported by the finding that the measurements of cardiac output are similar to those obtained by the radionuclide-labeled microsphere technique in fetal lambs 2 to 3 weeks after minor surgery to place catheters in peripheral vessels.[7, 8] Other physiologic functions are disturbed in the fetus for several days after surgery; nitrogen metabolism may be altered[9] and corticosteroid secretion

increased.[10] It is possible that there may be some circulatory changes beyond the first day after surgery, but the fact that all the responses we have examined have been similar in the first few days to those observed 2 to 3 weeks after surgery, has suggested that the cardiovascular system is relatively normal.

We do not know why spontaneous changes in fetal heart rate occur. Some episodes of tachycardia are associated with the onset of fetal respiratory movements and are probably related to changes in electrocortical activity.[11] However, many episodes are not associated with fetal respiratory activity, and tachycardia may not occur with respiratory movements. The frequent association of hypertension suggests that the episodes may be due to hypothalamic discharge, since the cardiovascular manifestations are similar to those observed with stimulation of electrodes placed in the hypothalamus of fetal lambs.[12]

Spontaneous bradycardia was not related to uterine activity in our studies, as no changes in amniotic cavity pressure were observed. Some of the episodes of slowing were associated with increased intratracheal pressures. It is possible that fetal grunting raised intrapleural pressure, resulting in decreased venous return, reduced cardiac output, and bradycardia, as occurs postnatally with the Valsalva maneuver. Blocking the respiratory pressure changes by muscular paralysis with succinylcholine did not, however, prevent the episodes of slowing. The changes could be associated with episodic vagal discharge, initiated centrally or reflexly.

Whatever the cause of the spontaneous variations in heart rate, right and left ventricular output invariably showed similar directional changes. These observations have important clinical implications, since it is possible to assess the magnitude of changes in cardiac output from the alterations of heart rate from resting levels. A reduction in cardiac output will result in a fall in umbilical blood flow with impaired placental gas exchange, or a decrease in fetal body flow with inadequate oxygen supply to the tissues.[13] Thus assessment of fetal heart rate and its changes provides a convenient measure of cardiovascular adequacy.

The effects of vagal stimulation on cardiac output are of considerable interest, since parasympathetic influence on the heart precedes sympathetic nervous activity.[14] The bradycardia associated with hypoxia largely is due to a baroreflex response to hypertension induced by peripheral vasoconstriction.[13] Although the reduction of cardiac output associated with vagal stimulation is produced mainly by the decrease in heart rate, our studies suggest that other mechanisms may also be involved. It is possible that vagal stimulation has

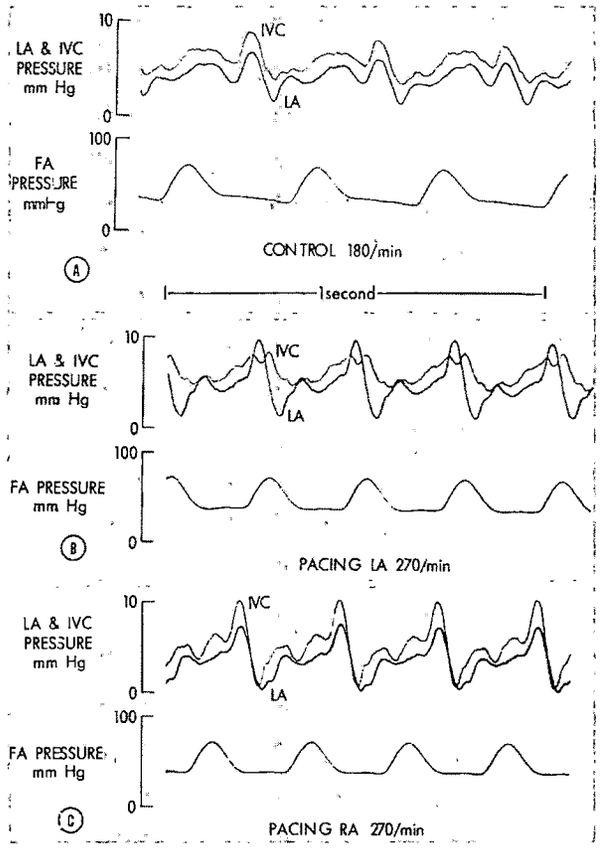

Fig. 12. Fetal left atrial *(LA)*, inferior vena caval *(IVC)*, and femoral arterial pressures are shown: *(A)* during a control period with a heart rate of 180 per minite; *(B)* during left atrial *(LA)* pacing at 270 per minute; and *(C)* during right atrial pacing at 270 per minute.

a direct depressant action on the myocardium, but the finding could be explained by parasympathetic-induced peripheral vasoconstriction. The increased afterload on the ventricles resulting from an increase in vascular resistance could reduce stroke volume.

The marked reduction in cardiac output associated with bradycardia in the fetus implies that the fetal heart has a limited ability to increase stroke volume. This is in striking contrast to the adult animal, in which stroke volume adjusts to changes in heart rate over a wide range thus maintaining a relatively constant cardiac output.[15] The restriction in stroke volume response to cardiac slowing could be due to immaturity of fetal myocardial development and lack of adequate sympathetic innervation to the ventricles.[6]

The effects of electrical pacing of the atria in the fetus were at variance with observations in adult animals. Douglas and associates[16] found no difference in the effects of left or right atrial pacing in adult dogs, even in the presence of small to moderate-sized atrial septal defects. We found consistently that right ven-

tricular output increased during pacing, but the rise was greater with left than with right atrial stimulation. Left ventricular output increased during right atrial pacing, but fell, or increased minimally, during left atrial pacing. The limitation of ventricular output response when the atrium which provides its inflow is paced, could be explained by an interference with effective filling. Since, in the fetus, both atria have a dominant a wave atrial systole may be very important in filling the ventricles in end-diastole. The relationship of the atrial contraction to ventricular pressure may be altered so that it does not provide as effective presystolic filling, and thus the volume of blood ejected by the ventricle will be reduced. Although this mechanism could explain the differences in the responses of the output of the right and left ventricles, it is more likely that they are related to variations in phasic pressure relationships between the left atrium and the inferior vena cava and right atrium. We have shown that the inferior vena caval pressure is normally higher than that in the left atrium throughout all phases of the cardiac cycle in the fetus; blood therefore flows through the foramen ovale into the left atrium. With left atrial pacing, the left atrial pressure may exceed that in the inferior vena cava during some periods, thus tending to close the foramen ovale, and interfere with left atrial filling and left ventricular output. The diversion of blood to the right atrium and through the tricuspid valve would favor right ventricular output. We favor this hypothesis, since we have shown that when left atrial pressure is raised in the fetus by increasing pulmonary blood flow by means of acetycholine infusion, there is a considerable reduction in the passage of inferior vena caval blood across the foramen ovale.[17]

These observations of the effects of atrial pacing on ventricular output in the fetus are important because they point out that atrial arrhythmias could have profound influences on the intracardiac distribution of flow in the fetus. Furthermore, they underscore the fact that physiologic responses in the adult are not necessarily applicable to the fetal circulation.

Development of a special electrode for continuous subcutaneous pH measurement in the infant scalp

OTTO STAMM, M.D.
URS LATSCHA, M.D.
PAUL JANECEK, M.D.
ALDO CAMPANA, M.D.
St. Gallen, Switzerland

Using a combined special glass electrode it is possible to monitor pH ratios and pH variation in the subcutaneous tissue of the infant scalp continuously. Tests on a normal sample of newborn babies immediately after birth showed a significant correlation between tissue pH and capillary blood pH, with the trend of pH variation being broadly similar in both measurement media.

FETAL-SCALP blood sampling[1, 2] has been widely adopted as a means of monitoring the condition of the fetus during labor by intermittent analysis of acid-base components. The usefulness of this method is limited by the fact that no information is available during the interval between two blood samples. It therefore seemed to us desirable to replace the intermittent method by a continuous, quickly readable, and labor-saving method of recording pH.

Material and methods

On the hypothetical assumption that pH ratios in subcutaneous tissue could also provide clinically useful pointers to the child's metabolic situation, a special glass electrode was constructed (Fig. 1), the point of which is inserted into the subcutaneous tissue of the child's scalp and fixed with spiral springs.

Measurement of pH is based on the electrometric principle. The menstruation chain consists of a combined glass electrode with indicator and direct recorder. The chief constructional novelty of our electrode lies in the combination of both electrodes in a spherical mensuration head. This construction, i.e., reduction of the current key to a minimal distance of 2 to 3 mm., makes it possible to eliminate interference potential from muscle-action currents.

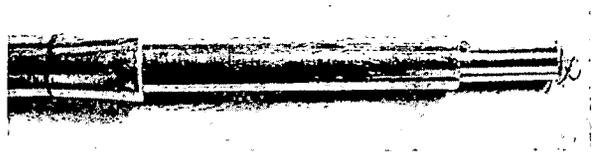

Fig. 1. Special glass electrode for continuous pH measurement in the subcutaneous tissue of the infant scalp.

The accuracy of measurement of the pH electrode described varies during continuous recording over a 2 hour period in standard buffer solution by 0.007 ± 0.002 pH units ($\bar{x}$ ± S.D.).

The investigation under discussion examined the practical applicability of the special probe in the subcutaneous tissue of the scalps of newborn babies. In a sample of 10 children born normally and with an Apgar score of 9/10//10 the electrode point was inserted in the scalp to a depth of approximately 3 mm. immediately after birth and subcutaneous pH recorded continuously over a period of 60 minutes. To clarify the correlation between subcutaneous pH and capillary blood pH, every 5 minutes a sample of heel blood was taken for pH analysis as well.

Results

As can be seen from Figs. 2 and 3, the pH mensuration chain gives relatively interference-free recording curves for pH ratios in subcutaneous tissue. The curve trend in the postpartum phase is similar in all 10 cases and is characterized by a progressive pH increase from

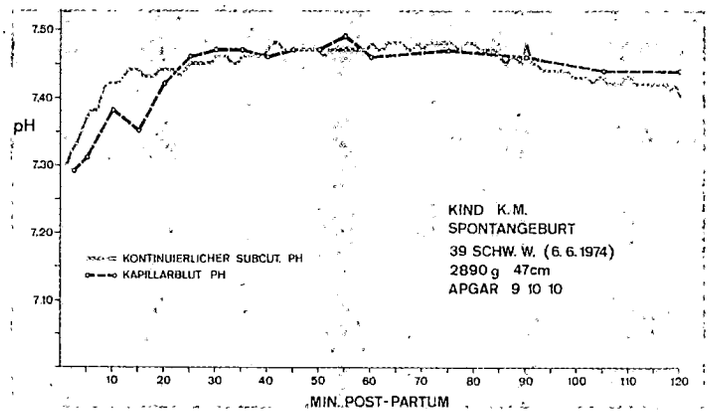

Fig. 4. Child K. M. (same case as in Fig. 3): Graph showing pH trend in subcutaneous tissue and in capillary blood, recorded over a 2 hour period (breakdown of subcutaneous recording curve into 1 minute values.

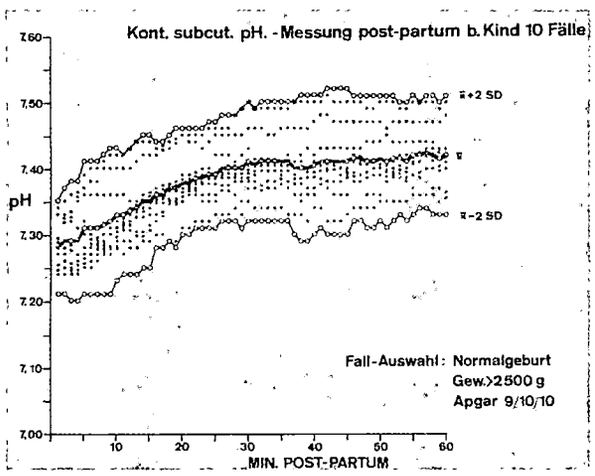

Fig. 5. Subcutaneous pH mean values with double standard deviation in a normal sample (10 children with Apgar score 9/10/10).

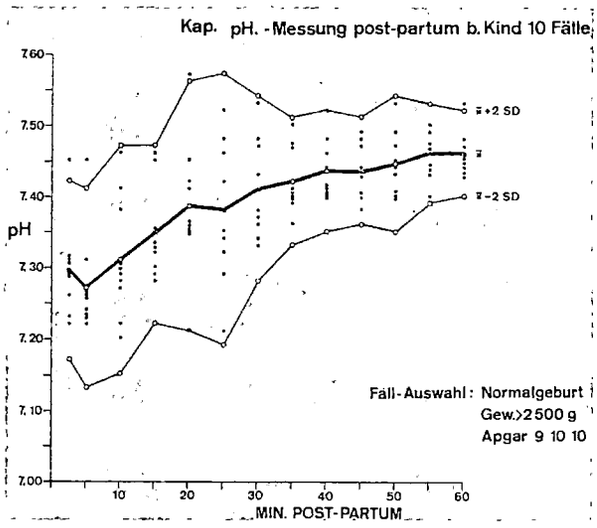

Fig. 6. Capillary blood pH mean values with double standard deviation for the same normal sample as in Fig. 5 (10 children with Apgar score 9/10/10).

$\bar{x}_1$ 7.29 ± 0.04 (immediately post partum) to $\bar{x}_2$ 7.42 ± 0.05 pH (60 minutes post partum).

As has been mentioned already, in each case capillary blood pH was controlled also, at intervals of 5 minutes. The close correlation of pH ratios in both measurement media can be seen in Fig. 4. Basically pH values for the normal sample examined lie in the same pH range, which means that acidosis adjustment in subcutaneous tissue can occur with a delay of approximately 2 to 5 minutes.

For the 10 normal cases mean values with standard deviation were calculated for subcutaneous and for capillary pH. In addition the recording curves were broken down into 1 minute values. The results are shown in Figs. 5 and 6. Mean values in the two measurement media differed by a maximum of 0.04 pH units. The curves follow the same time pattern. The 95 per cent deviation range is less wide in the case of continuous subcutaneous pH recording than in the case of intermittent monitoring of capillary blood pH.

Correlation analysis between subcutaneous pH mean value and capillary blood pH mean value produced a correlation coefficient of $r = 0.965$ ($p < 0.001$).

Maternal endotoxemia, fetal anomalies, and central nervous system damage: A rat model of a human problem

ASHER ORNOY, M.D.
GEOFFREY ALTSHULER, M.B.B.S.
Cincinnati, Ohio

Endotoxemia is a common consequence of the gram-negative urinary tract infections that complicate human pregnancies. Only rarely, however, have the effects of maternal endotoxemia been evaluated by animal experiments or by human investigations. Data of the Collaborative Perinatal Study suggest an association between maternal endotoxemia and fetal central nervous system damage. For these reasons we performed controlled studies of the fetal effects of treatment of pregnant rats, at appropriate gestational ages, with E. coli *endotoxin. We found a maximum 7 per cent incidence of fetal anomalies in the treated animals but no anomalies in controls. Placental light microscopy examinations indicated the mechanism to include Shwartzman-like phenomena. It has been shown by others that neonatal endotoxemia produces periventricular leukomalacia. We obtained an incidence of neuronal necrosis in treated fetuses that was 10 times greater than in control fetuses. It is therefore of importance that additional studies of the pathologic effects of endotoxin be performed.*

IN THE Collaborative Perinatal Study of the National Institute of Neurological Diseases and Stroke, fever with positive urine culture is stated to occur in 1.27 per cent of pregnant white women and in 1.74 per cent of pregnant black women.[14] This complication of pregnancy suggests an occurrence of maternal endotoxemia resulting from the gram-negative organisms that typically cause urinary tract infections. Since pregnant women with fever and bacteriuria give birth to a higher incidence of infants with neurologic defects at 1 year of age than do mothers free of urinary tract infection,[14] it appears that human maternal endotoxemia is associated with fetal central nervous system damage. Endotoxin has been shown to induce placental damage and abortion in experimental animals.[7, 13, 20, 23] Moreover, even a single injection of the active lipopolysaccharide fraction can cause the generalized Shwartzman reaction in pregnant animals.[13, 21]

Kass[8] has reported bacteriuria in 6 to 7 per cent of pregnant women, many of whom delivered premature infants. Following that investigation contradictory results were obtained by other investigators. Kincaid-Smith and Bullen[9] observed a higher percentage of prematurity associated with maternal bacteriuria but Wilson and associates[25] did not.

In a study of chronic bacteriuria of pregnancy Patrick[18] did not find an increased incidence of prematurity or perinatal death but found an increased malformation rate of 5.4 per cent as opposed to 0.8 per cent in her control group. Most of the anomalies were of the central nervous system. Ohba[16] also observed central nervous system anomalies in fetal mice whose mothers had been treated with *E. coli* endotoxin. Other than for these studies there is a lack of critical investigation both in human beings and animals of the association of congenital anomalies with maternal bacteriuria and endotoxemia. We decided to design a study to investigate whether results of an animal experiment support the apparent association between human fetal damage and maternal endotoxemia. We chose the rat arbitrarily and, although aware that strain

differences in results might occur, were not concerned specifically to investigate that possibility.

Materials and methods

White rats of the Sprague-Dawley and Wistar strains were used for the experiment. The animals were mated and the first day of pregnancy assessed by the finding of sperm in vaginal smears. A 0.5 mg. dose of endotoxin (*E. coli* endotoxin, 026-B6, Difco Laboratories, Detroit, Michigan) was initially administered intraperitoneally (i.p.) to the pregnant rats. This dose was too high, being lethal occasionally even after only one dose. A 0.25 mg. dose, injected on day 13 or 14 of gestation, did not kill the animals, but many aborted. We therefore further reduced the dose to 0.15 mg.

Rats were divided into the following groups: Group I, eight pregnant rats injected with 0.15 mg. of endotoxin i.p. on days 14 and 17 of gestation; Group II, 15 pregnant rats receiving the same dose i.p. on days 11, 14, and 17 of gestation (eight rats) or gestational days 10, 13, and 16 (seven rats); Group III, seven pregnant rats injected with 0.15 mg. of endotoxin i.p. on days 8, 10 and 12 of gestation; Group IV, 12 control rats which either were not treated (six rats) or which were given normal saline (six rats) i.p. on gestational days 11, 14, and 17.

All but five rats were killed on gestational day 21, following ether anesthesia. The abdomen was opened and resorption sites and living fetuses were counted. The placentas and attached uterine walls were examined by light microscopy as were the maternal kidneys, adrenal glands, lungs, livers, and spleens. The methods for the light microscopy examination included fixation in Bouin's solution and standard procedures of processing the tissue into paraffin

blocks, 6μ sectioning, and staining with hematoxylin and eosin. Following examination of the fetuses by the sectioning method described by Wilson,[24] transverse sections of the brains through the lateral ventricles at the level of the trigeminal ganglion and sections of the thoracic spinal cord were evaluated for neuronal necrosis. On no occasion did at least one of the examining investigators have foreknowledge as to whether the sections to be evaluated were of the experimental or of the control animals. The finding of three to four necrotic neurons in one section of the diencephalon or one to two in the spinal cord was considered as moderate neuronal necrosis, and the presence of five or more necrotic neurons in the diencephalon or three or more in the spinal cord was considered as severe neuronal necrosis.

Results

Maternal toxicity. Two pregnant rats died during the course of the experiment, one control and one from experimental Group I. Nine rats completely resorbed their litters or aborted: one from Group I, one from Group III, and seven from Group II. The placentas of the resorbed fetuses showed widespread severe ischemic necrosis, occasionally associated with fibrin thrombi. The experimental rats which did not resorb all their fetuses gained more than 100 Gm. of weight during pregnancy, as did the controls. However, two to three hours after each endotoxin injection the animals were lethargic, weak, and uninterested in their environment. These effects lasted less than 24 hours.

Fetuses and placentas. The mean fetal and placental weights on the beginning of day 21 of pregnancy were similar in the experimental and control animals (Table I). The litter average in Groups I and II was lower than in the controls and the resorption rates, excluding the animals that resorbed all their litter, were 16.4 and 20.4 per cent, respectively (Table I). The resorption rate in experimental Group III rats was only 5.3 per cent (Table I).

The placentas of all experimental animals showed severe pathologic changes: decidual necrosis, necrosis of glycogen cells (clear cells) and quasisyncytium (junctional zone damage), congestion of the labyrinth with occasional ischemic areas, and balloon degeneration of epithelial cells of the yolk sac placentas (Tables II to V). In the controls, slight placental damage was

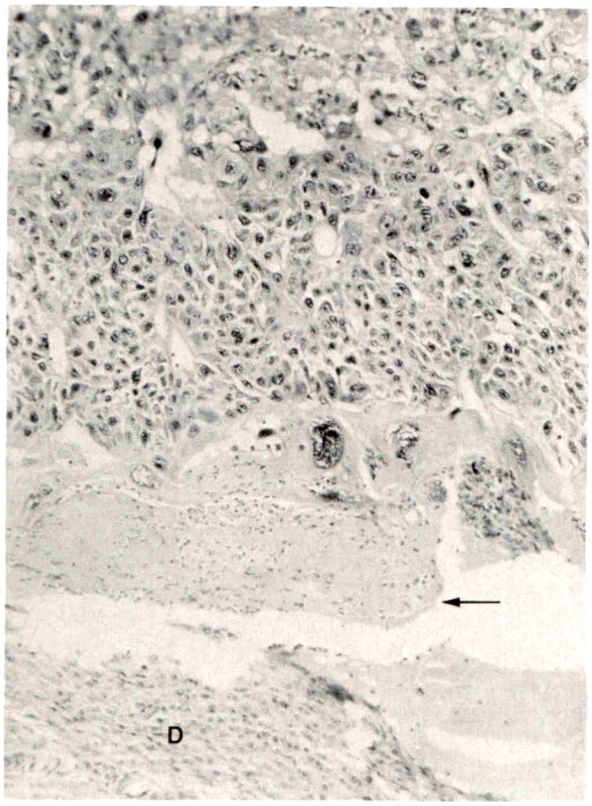

Fig. 1. Placental floor. Note the fibrin thrombus in a maternal vessel (arrow) overlying the decidua *(D)*. (Hematoxylin and eosin; original magnification ×160.)

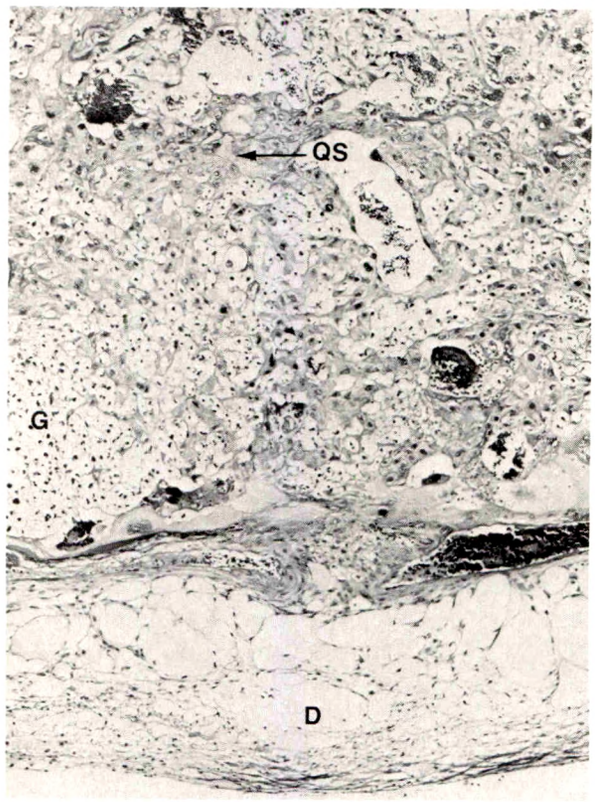

Fig. 2. Placenta floor, junctional zone, and labyrinth. Note the severe acute infarction of the decidua *(D)*, the glycogen cells *(G)*, and the quasisyncytium *(QS)*. (Hematoxylin and eosin; original magnification × 70.)

present in two animals (Table II). Maternal organs of control rats were normal except in one rat in which extramedullary hematopoiesis in liver and spleen, bronchitis, and bronchiolitis were present.

In the animals from the first experimental group (Table III), the placentas had severe lesions: moderate or severe maternal floor infarction occasionally associated with fibrin thrombi, severe necrosis of glycogen cells, ischemia, and congestion of the labyrinth (Figs. 1 and 2). In two rats of experimental Group I, yolk sac lesions were present—ballooning of the yolk sac epithelial cells (Figs. 3 and 4) with leukocytic infiltration beneath the epithelium (Table III).

The most severe placental lesions were found in the experimental Group II animals (Table IV). Fibrin thrombi in decidual vessels were more frequently observed, and in some animals occasional fibrin thrombi were additionally found in the labyrinth. The yolk sac placental damage, although similar to that of experimental Group I, was more severe. Placental damage (including yolk sac lesions) was prominent even in experimental Group III. In this last group one mother had microscopical evidence of pneumonia (Table V).

No disseminated fibrin thrombi were found in the organs examined from the rats of all three experimental groups. In only two rats were rare, early fibrin thrombi present. These were located in renal veins.

No gross anomalies were found in the 106 control fetuses. None of the 56 Group I fetuses was malformed (Tables I and III). Five out of 74 Group II fetuses were malformed (Tables I and IV): three had hydrocephaly (Fig. 5), one had microcephaly, and one had multiple anomalies—abnormal small head, severe brain dysplasia (Figs. 6 and 7), microphthalmia, and anophthalmia and agenesis of the left urogenital ridge. Five of the 71 Group III fetuses were malformed (Tables I and V): three had hydrocephaly, one of these also had unilateral hydronephrosis, and one had a very small left lateral ventricle. Placentas in litters with malformed fetuses were more severely damaged, including also severe yolk sac lesions, than those of litters with fetuses free of anomalies.

Moderate or severe neuronal necrosis was present in

more than 50 per cent of the Groups II and III experimental fetuses but was relatively rare in Group I experimental fetuses and in the control (Table II, Fig. 8).

In a total of five experimental fetuses subcutaneous, abdominal, and.or thoracic hemorrhages were observed (Tables III, IV, and V).

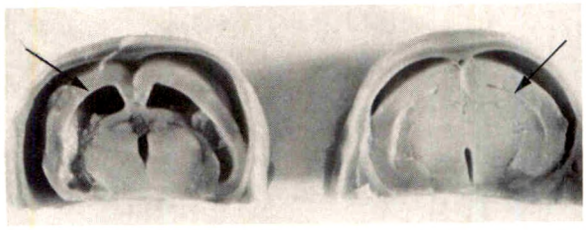

Fig. 5. Coronal sections of fetal heads. Arrows point to the lateral ventricles. Note the difference between hydrocephaly and a normal brain.

Comment

Several years have elapsed since the development of the limulus coagulation test for the detection of endotoxemia.[10] Methodologic problems still exist in the utilization of the test and, perhaps partly because of this, there has been limited clinical and laboratory study of endotoxemia in pregnancy.

In clinical neonatology placental examination is rarely used for the diagnosis and study of congenital disease[2] and in the many animal studies that have been performed with various teratogenic agents, morphologic placental changes also have seldom been evaluated. This is regrettable since, both in clinical medicine[1] and in laboratory investigation, morphologic placental studies have been shown to elucidate many aspects of the pathogenesis of congenital disease.

In the present experimental study, although we did not produce ischemic lesions in the organs of the mother or fetus, we consistently produced severe ischemic placental lesions with repeated doses of endotoxin. Treatment at the appropriate early developmental phase was productive of fetal anomalies in five of 74 Group II and in five of 71 Group III fetuses. Control rats, however, were free of fetal anomalies.

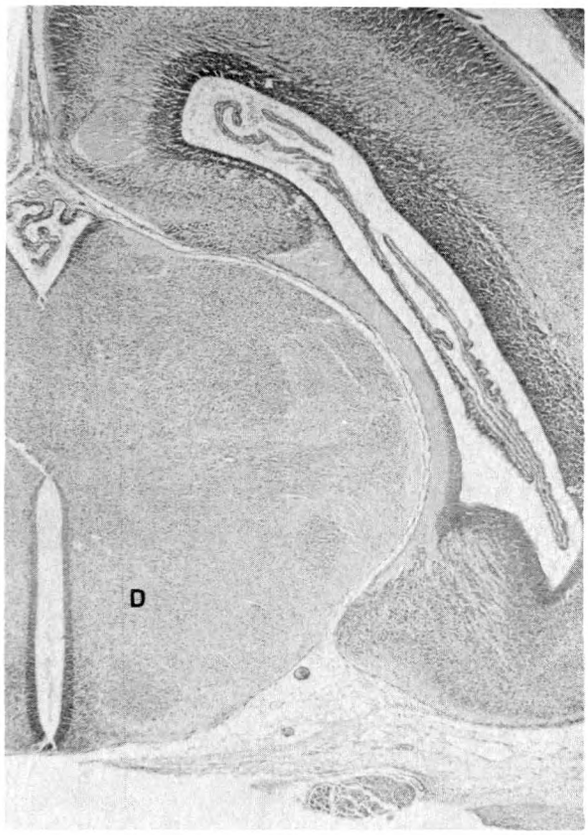

Fig. 6. Coronal section through a normal fetal brain at the level of the trigeminal ganglion. *D* = diencephalon. (Hematoxylin and eosin; original magnification × 40.)

Endotoxins are known to cause abortions in rabbits, mice, and rats [13, 21, 23] as well as in human subjects. Extensive study of endotoxin animal experimental models has been performed in the investigation of "toxemia of pregnancy"[14] but there has been a lack of application of this model to the investigation of a possible association between endotoxemia and fetal malformation.

In our experiments the rate of endotoxin production of anomalies (maximally 7 per cent) was lower than that generally obtained with many other teratogenic agents.[24] We consider that the mechanism of teratogenesis with endotoxin includes fetal hypoxia resultant from endotoxin-induced severe placental ischemia as well as possible malnutrition or metabolic and other derangements. Extensive hemorrhages have been produced in chicken and mice fetuses subjected to hypoxia.[6, 22] Thus it may be that the widespread hemorrhages in five of our experimental fetuses result from fetal hypoxia. Fetal hypoxia, a proved teratogen in many species,[6, 22] is presumably one of the major consequences of severe placental lesions. Rat embryos are relatively resistant to hypoxia, the incidence of hypoxia-induced anomalies being lower in them than in other species. [6, 24] All of our treated fetuses could be correlated at least with severe damage of the maternal floor of the placenta (Table II). Moreover, in all mothers that produced malformed fetuses, the yolk sac placenta was also severely damaged. This suggests an association between yolk sac abnormalities and fetal anomalies, an occurrence which has been demonstrated by other investigators.[24]

There is disagreement as to the pathogenesis of the placental lesions in experimental endotoxemia in terms of whether or not a Shwartzman phenomenon is operative.[7, 13, 20] Our endotoxin-treated animals always suffered ischemic necrosis of the placental floor, often with fibrin thrombi and with ischemic lesions elsewhere in the placenta. These changes are characteristic of the Shwartzman phenomenon. We consider that the placental lesions, when induced at the appropriate time of gestation, may well be the cause of some of the fetal anomalies. Ischemic placental damage has been found after administration of high doses of vitamin D_2[16] and of estrogen[17] to pregnant rats. Decreased weight and skeletal anomalies were found in the fetuses.

Our light microscopy studies provided evidence that the fetal lesions obtained were not significantly attributable to maternal or fetal infections. In two instances of Group III, however, maternal pneumonia, deciduitis, and chorioamnionitis were present. Since there were no light microscopy findings of infection in the associated fetuses we included these animals in the study. It is possible that fetal shock induced by fetal endotoxemia may cause neuronal necrosis. We did not find disseminated intravascular coagulation or light microscopy signs of fetal shock. Furthermore, a lack of intrauterine fetal growth retardation makes it difficult to explain the mechanism of the neuronal necrosis as being attributable to shock.

Because our control animals were free of morphologically significant placental lesions and of fetal anomalies, it is reasonable to infer that the pathogenesis of fetal damage included placentally mediated damage. We are aware of a great number of reports of maternal pyrexia as a teratogenic agent.[3, 4] Although in our methodology we did not measure the maternal temperature, we recognize that endotoxemia is well known to cause hyperpyrexia and that the latter causes fetal damage mainly manifest within the central nervous system and the skeleton.[3, 4] A direct transplacental effect of endotoxin may be operative. To date, however, a lack of investigations prelcudes knowledge

Fig. 7. Coronal section through a dysplastic brain at the level of the trigeminal ganglion. (Hematoxylin and eosin; original magnification × 40.)

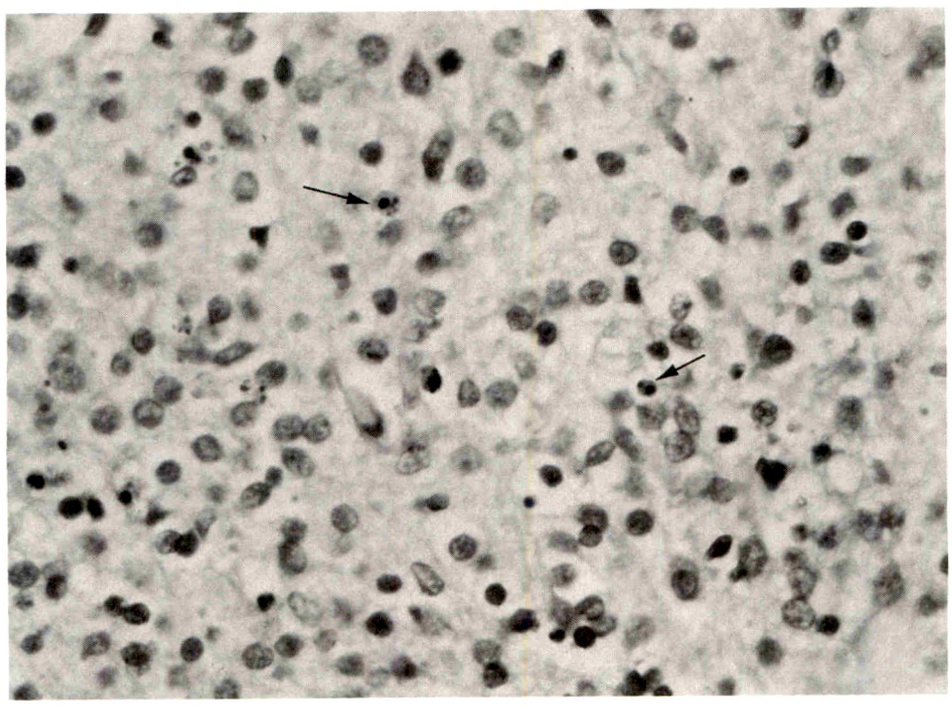

Fig. 8. Coronal section through the diencephalon. There are many necrotic neurones (arrows). (Hematoxylin and eosin; original magnification × 640.)

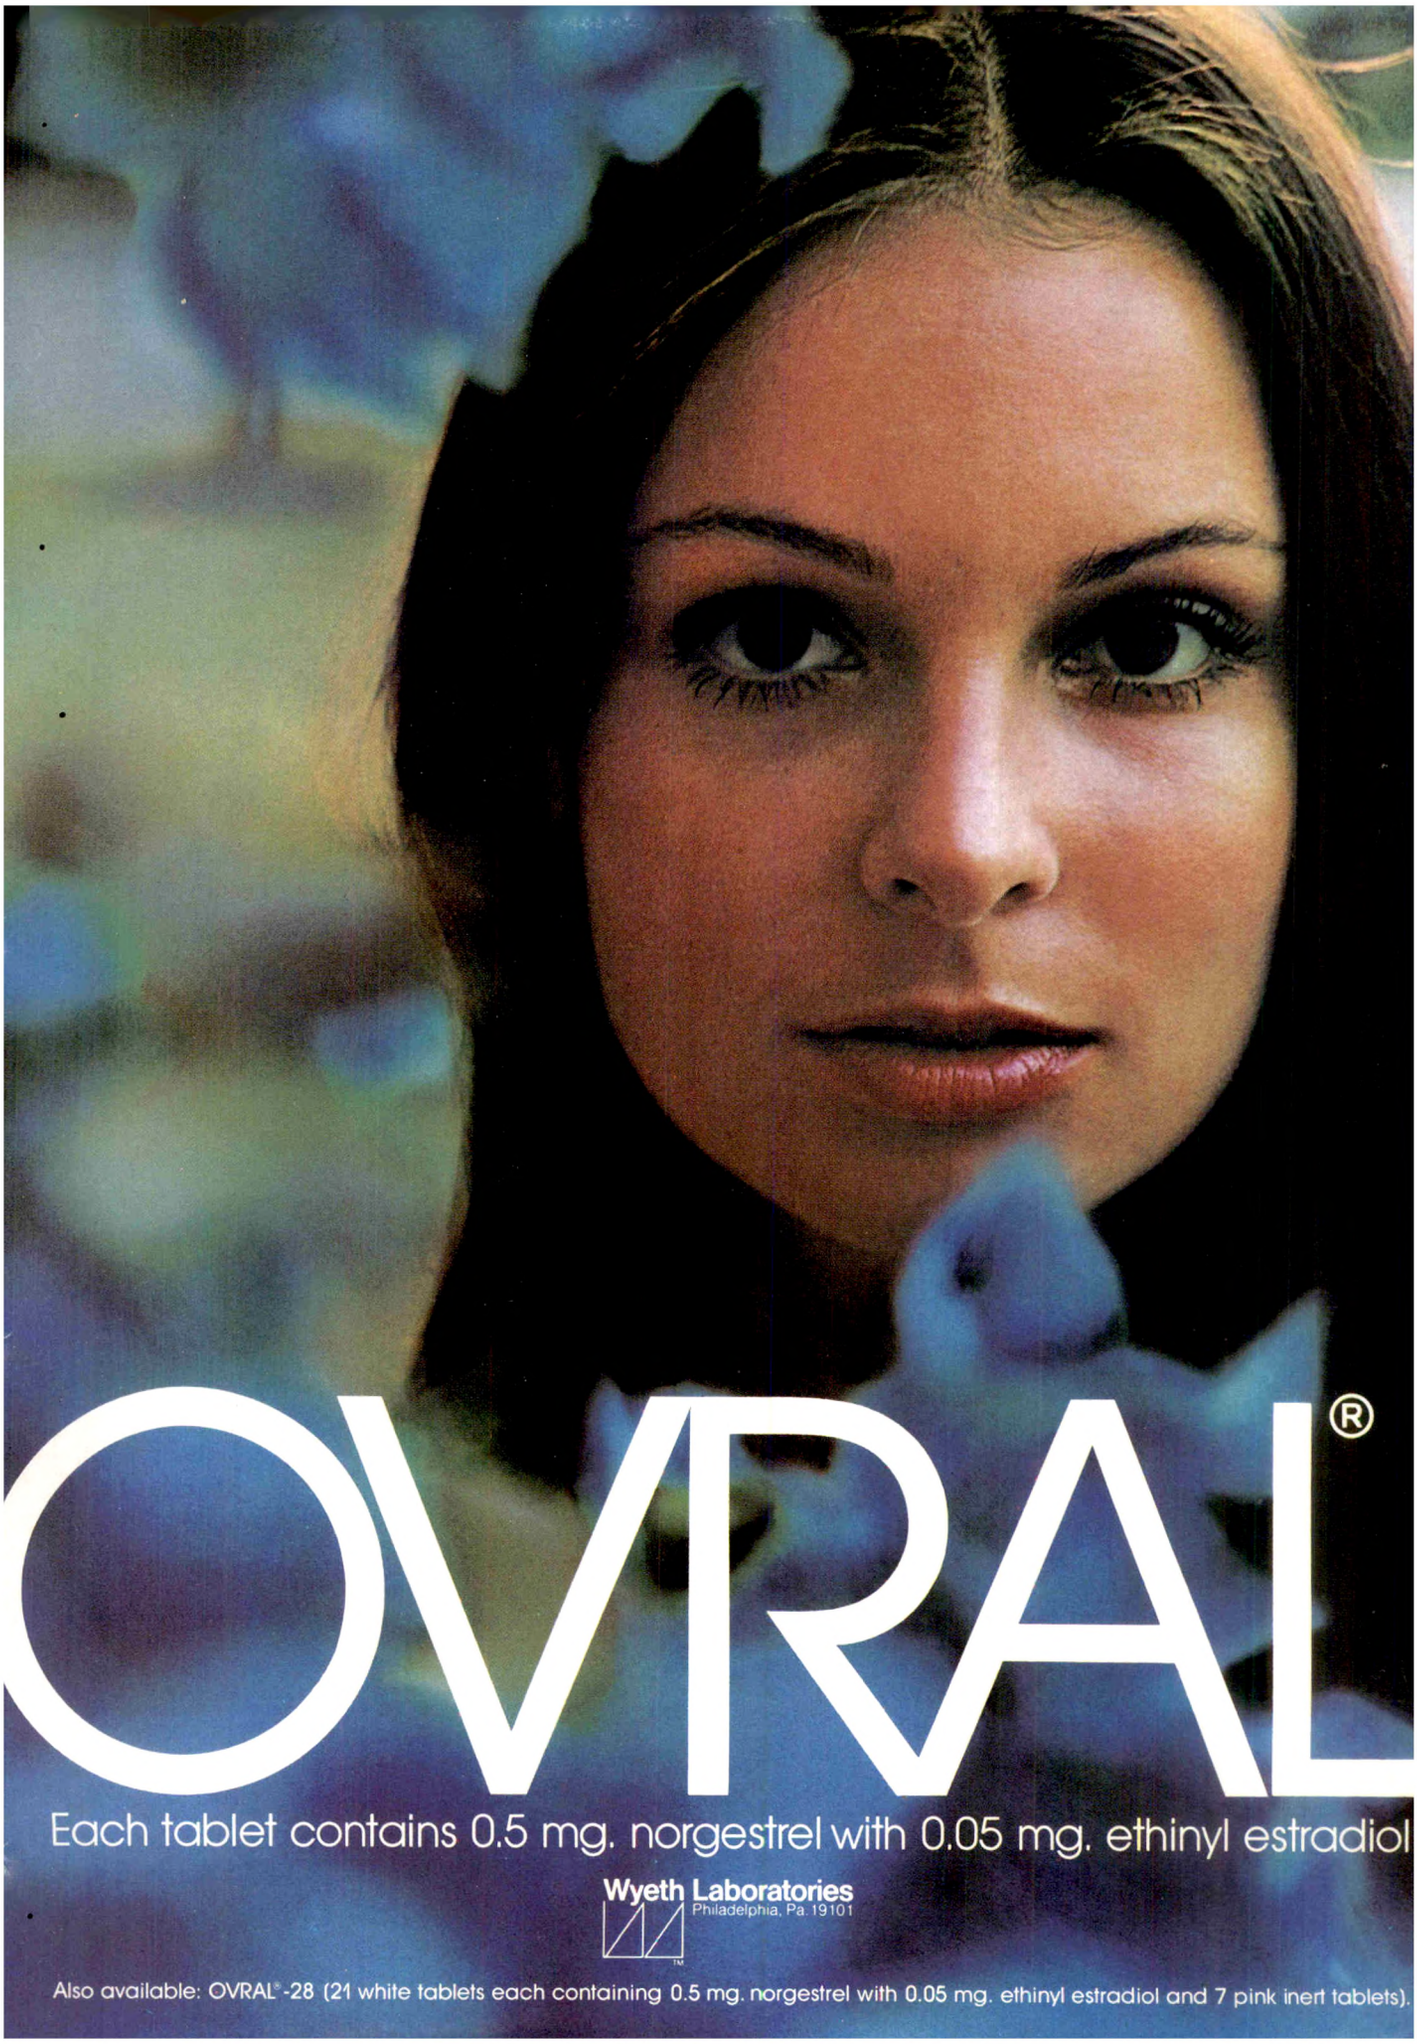
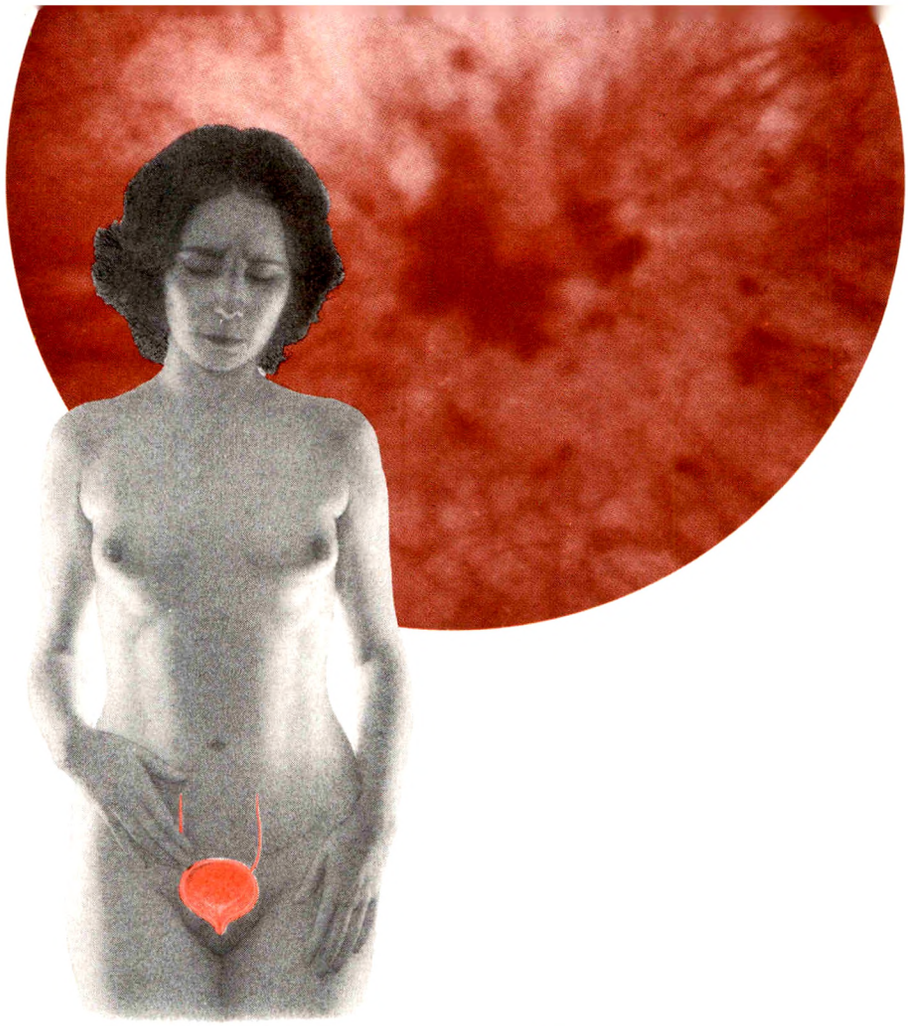
of whether endotoxin is able to cross the rat and the human placenta.



Several years ago Perrin and Landing[19] indicated that human perinatal infection, notably with gram-negative organisms, is often associated with lesions of the periventricular white matter. Gillies and associates[5] have demonstrated hydrocephalus *ex vacuo* and neonatal telencephalic leukoencephalopathy in the brains of newborn kittens treated intraperitoneally with endotoxin. Throughout our study it was apparent that there was a correlation between endotoxin treatment and fetal neuronal necrosis. A moderate to marked degree of neuronal necrosis was often found in the brains of many experimental Group II and experimental Group III fetuses but such lesions were relatively rare in the brains of control fetuses (Table II). Of additional interest is the fact that our findings of a pattern of hydrocephaly, microcephaly, brain dysplasia, microphthalmia, and anophthalmia are comparable with those of Patrick,[18] who reported "dorsal midline fusion defects" in human infants born to mothers who suffered chronic bacteriuria.



Thiersch,[23] in systematic studies of various bacterial endotoxins in pregnant rats, found placental damage but rarely any fetal anomalies. The methodology of that investigation was considerably different from ours inasmuch as the majority of the fetuses were evaluated after a few days of exposure to this insult. It is remarkable that maternal endotoxemia, a common complication of pregnancy, has been accorded such little investigation.

The authors express appreciation to Dr. Josef Warkany, their catalyst and consructive critic. Thanks are due to M. Muzzy and R. Lal for their skilled technical assistance.

OVRAL®
Each tablet contains 0.5 mg. norgestrel with 0.05 mg. ethinyl estradiol
Wyeth Laboratories
Philadelphia, Pa. 19101
Also available: OVRAL®-28 (21 white tablets each containing 0.5 mg. norgestrel with 0.05 mg. ethinyl estradiol and 7 pink inert tablets).

Double trouble: Acute painful cystitis

FOR THE PAIN

Early relief of painful symptoms such as burning and pain often associated with urgency and frequency.

FOR THE PATHOGENS

Effective control of susceptible pathogens such as *E. coli, Klebsiella-Aerobacter, Staph. aureus, Proteus mirabilis* and, less frequently, *Proteus vulgaris.*

Appropriate antibacterial therapy: Up to 3 days' therapy with Azo Gantrisin, 4 to 6 tablets *Stat.*, then 2 tablets *q.i.d.;* then 11 days with Gantrisin (sulfisoxazole) may be considered.

Relieve the pain while you eliminate the pathogens

Azo Gantrisin®

(0.5 Gm sulfisoxazole and 50 mg phenazopyridine HCl)

Before prescribing, please consult complete product information, a summary of which follows.

Indications: In adults, urinary tract infections complicated by pain (primarily cystitis, pyelitis and pyelonephritis) due to susceptible organisms (usually *E. coli, Klebsiella-Aerobacter, Staphylococcus aureus, Proteus mirabilis,* and, less frequently, *Proteus vulgaris*) in the absence of obstructive uropathy or foreign bodies.

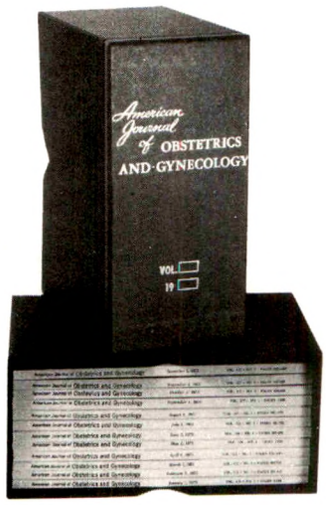
Important Note: Carefully coordinate *in vitro* sulfonamide sensitivity tests with bacteriologic and clinical response. Add aminobenzoic acid to culture media for patients already taking sulfonamides. Increasing frequency of resistant organisms currently is a limitation of the usefulness of antibacterial agents including the sulfonamides. Blood levels should be measured in patients receiving sulfonamides for serious infections, since there may be wide variations with identical doses; 12 to 15 mg/100 ml is considered optimal for serious infections; 20 mg/100 ml should be the maximum total sulfonamide level, as adverse reactions occur more frequently above this level.

Contraindications: Children below age 12; sulfonamide hypersensitivity; pregnancy at term and during nursing period. Contraindicated in glomerulonephritis, severe hepatitis, uremia, and pyelonephritis of pregnancy with gastrointestinal disturbances, because of phenazopyridine HCl component.

Warnings: Safe use in pregnancy has not been established. Teratogenicity potential has not been thoroughly investigated. Deaths from hypersensitivity reactions, agranulocytosis, aplastic anemia and other blood dyscrasias have been reported; clinical signs such as sore throat, fever, pallor, purpura or jaundice may be early indications of serious blood disorders. Complete blood counts and urinalysis with careful microscopic examination should be performed frequently during sulfonamide therapy.

Precautions: Use with caution in patients with impaired renal or hepatic function, severe allergy, bronchial asthma and in glucose-6-phosphate dehydrogenase-deficient individuals. In the latter, hemolysis may occur. Maintain adequate fluid intake to prevent crystalluria and stone formation.

Adverse Reactions: *Blood dyscrasias:* Agranulocytosis, aplastic anemia, thrombocytopenia, leukopenia, hemolytic anemia, purpura, hypoprothrombinemia and methemoglobinemia. *Allergic reactions:* Erythema multiforme (Stevens-Johnson syndrome), skin eruptions, epidermal necrolysis, urticaria, serum sickness, pruritus, exfoliative dermatitis, anaphylactoid reactions, periorbital edema, conjunctival and scleral injection, photosensitization, arthralgia and allergic myocarditis. *Gastrointestinal reactions:* Nausea, emesis, abdominal pains, hepatitis, diarrhea, anorexia, pancreatitis and stomatitis. *C.N.S. reactions:* Headache, peripheral neuritis, mental depression, convulsions, ataxia, hallucinations, tinnitus, vertigo and insomnia. *Miscellaneous reactions:* Drug fever, chills, toxic nephrosis with oliguria and anuria, polyarteritis nodosa and L.E. phenomenon. Due to certain chemical similarities with some goitrogens, diuretics (acetazolamide and thiazides) and oral hypoglycemic agents, sulfonamides have caused rare instances of goiter production, diuresis and hypoglycemia.
Cross-sensitivity with these agents may exist.



Dosage: Usual adult dosage for acute, painful phase of urinary tract infections is 4 to 6 tablets initially, then 2 tablets four times daily for up to 3 days. If pain persists, causes other than infection should be sought. After relief of pain has been obtained, continued treatment of the infection with Gantrisin (sulfisoxazole) may be considered.

Note: Patients should be told that the orange-red dye (phenazopyridine HCl) will color the urine soon after ingestion.

How Supplied: Tablets, each containing 0.5 Gm sulfisoxazole and 50 mg phenazopyridine HCl—bottles of 100 and 500.

Not too many patients have an "iron will." That's why Abbott hematinics are easy to take.

Comfort minimal chance of gastric upset, thanks to the controlled-release iron (105 mg. Elemental Iron) which can be taken even on an empty stomach.

Convenience 500 mg. of Vitamin C, to enhance iron absorption, is combined with iron and B-Complex* in a single tablet.

Cooperation thanks to the once-a-day dosage.

Iberet-500
Hematinic Supplying Controlled-Release Iron with Vitamin C and *B-Complex (contains no folic acid)

Iberet-Folic-500® ℞
Controlled-Release Iron with Vitamin C and B-Complex including Folic Acid

Please see opposite page for Brief Summary.

ABBOTT

509106

Iberet®-500

One Filmtab® tablet a day supplies:

Controlled-Release Iron

Ferrous Sulfate,
(equivalent to
elemental iron—105 mg.) .. 525 mg.

Plus High Potency Vitamin C

Vitamin C
(as Sodium Ascorbate) .... 500 mg.

Plus the B-Complex
(contains no folic acid)

Niacinamide ..... 30 mg.
Calcium Pantothenate ..... 10 mg.
Vitamin B_1
(Thiamine Mononitrate)..... 6 mg.
Vitamin B_2 (Riboflavin) ..... 6 mg.
Vitamin B_6
(Pyridoxine Hydrochloride) .. 5 mg.
Vitamin B_{12}
(Cyanocobalamin) ..... 25 mcg.

INDICATIONS: For conditions in which iron deficiency occurs concomitantly with deficient intake or increased need for the B-complex vitamins (contains no folic acid).

Iberet-Folic-500® ℞

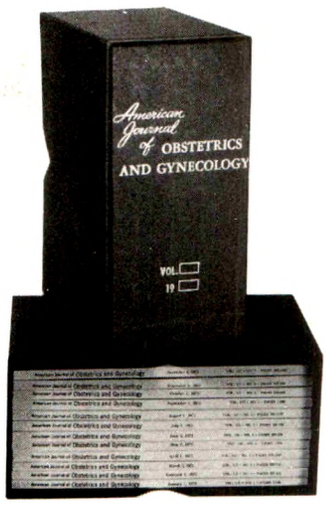
One Filmtab tablet a day supplies the same formula as Iberet-500 plus:

Folic Acid .....800 mcg.

INDICATIONS: In non-pregnant adults, for the treatment of iron deficiency and prevention of concomitant folic acid deficiency where there is an associated deficient intake or increased need for the B-complex vitamins. Also indicated in pregnancy for the prevention and treatment of iron deficiency where there is a concomitant deficient intake or increased need for B-complex vitamins (including folic acid).

CONTRAINDICATION: Pernicious anemia.

WARNINGS: Folic acid alone is improper therapy in the treatment of pernicious anemia and other megaloblastic anemias where vitamin B_{12} is deficient.



PRECAUTION: Where anemia exists, its nature should be established and underlying causes determined. Iberet-Folic-500 contains 800 mcg. of folic acid per tablet. Folic acid especially in doses above 1.0 mg. daily may obscure pernicious anemia, in that hematologic remission may occur while neurological manifestations remain progressive.

ADVERSE REACTIONS: The likelihood of gastric intolerance is remote. If such should occur, the tablet may be taken after a meal. Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

509106

Gradumet—Controlled-release dose form, Abbott.
Filmtab—Film-sealed tablets, Abbott.

An important advance in estrogen replacement therapy

Mead Johnson introduces

Estrace®
(estradiol)

1-mg. and 2-mg. scored tablets

- the primary estrogen of the human ovary
- synthesized in free form (not esterified, not conjugated)

overall, 95% of patients studied gained adequate or complete relief of their symptoms[1]

Estrace (estradiol) was given to 369 estrogen-deficient women for periods ranging up to a year or more (average of six months); 319 of these women received an initial dosage of 1 or 2 mg. per day and were evaluated for efficacy. *Complete disappearance* of hot flushes was experienced by 227 (76%) of 298 women, of sweating by 131 (80%) of 164 women, of tingling by 62 (94%) of 66 women, and of genital atrophy by 44 (88%) of 50 women. In general, 95% of the patients evaluated experienced either adequate or complete relief of their symptoms. Remarkably, in 77% of the patients, symptoms were controlled without need to adjust the initial dosage—usually 2 mg. daily. (Dosage after adjustment ranged from 1 mg. to 3 or 4 mg. a day.)[1]

estradiol frequently desired

Physicians for years have desired to use estradiol, the major human ovarian hormone, as the basis for oral estrogen replacement therapy. Since 1953, several studies have reported that oral administration of estradiol, in 1 to 2 mg. doses, provided varying degrees of relief of menopausal symptoms.[2–4] One study[4] showed that the optimum estrogenic effect was obtained with 2 mg. daily.

In a preliminary investigation, Martin, *et al.*,[5] 1972, reported on a single-blind study of 71 women given four different estrogenic preparations. A formulation of micronized estradiol was selected by more women than any other preparation. In fact, twice as many selected micronized estradiol than conjugated equine estrogen.* Yen, *et al.*,[6] showed that micronized estradiol (Estrace®) given orally is readily absorbed, metabolized in part to estrone, and is biologically active.

With micronized estradiol there is no need for special coatings which may hamper tablet absorption and no "barnyard" aftertaste—problems sometimes seen with conjugated equine estrogens.

*Because the micronized estradiol formulations may differ, these data are not necessarily applicable to Estrace.

estradiol... orally effective

The technique of micronization has opened up the oral route to natural human estrogen replacement with Estrace. Reduced particle size of the estradiol in Estrace makes effective gastrointestinal absorption possible. Onset of action is rapid, with marked increases in levels of circulating estradiol and estrone; concomitant decreases in serum concentrations of FSH and LH are sustained over a 24-hour period.[6]

Estrace apparently creates a reservoir of physiologically active estrogen that is available to the cells on an "as needed" basis.[6] And because estradiol can be assayed in plasma, Estrace can provide objective[6] as well as clinical evidence[1] of ready availability and biologic activity.

well accepted by patients[1]

In the 369 patients previously described, the incidence of estrogen-induced side effects with Estrace was relatively low. Incidence of nausea was remarkably low—only 2% of patients before dosage adjustment. Some patients who had complained of this problem while on conjugated equine estrogens reported its complete disappearance on changing to Estrace. Whereas before dosage adjustment 24% experienced breast tenderness, 31% edema, 18% (of 151 with intact uteri) bleeding, and 4% weight gain, only about 2% of the 369 patients dropped out because of side effects.[1]

A few instances of significant gynecologic disease became apparent during clinical investigations.[1] Endometrial hyperplasia was discovered in seven patients, all of whom had previously received estrogen therapy for one to three years prior to entering the study. One patient was reported to have carcinoma *in situ* and another showed adenocarcinoma of the endometrium. In clinical practice, the physician should be alerted to the potential of thrombotic disorders and be prepared to discontinue medication immediately if they occur. Because of variations in normal endogenous hormone production, certain patients may exhibit signs of excessive estrogenic stimulation. Adverse reactions generally associated with estrogen administration may occur and these are listed in the brief summary. Prior to initiation of treatment with Estrace or any other estrogenic preparation, an adequate physical examination should be given.

For Brief Summary, please see following page.

Estrogen replacement therapy moves forward...

Estrace® (estradiol)

the major human estrogen micronized for oral effectiveness

Indications: Estrace® (17β-Estradiol) is indicated for relief of endogenous estrogen deficiency and associated menopausal symptoms.

Contraindications: Estrace® is contraindicated in patients with 1) markedly impaired liver function; 2) known or suspected carcinoma of the breast, except those cases of progressing disease not amenable to surgery or irradiation occurring in women who are at least 5 years postmenopausal, or in men in whom castration is not feasible; 3) known or suspected estrogen dependent neoplasia, such as carcinoma of the endometrium; 4) undiagnosed abnormal genital bleeding; 5) thrombophlebitis, thromboembolic disorders, cerebral apoplexy, or with a past history of these conditions; and 6) pregnancy.

Warnings: The physician should be alert to the earliest manifestations of thrombotic disorders (thrombophlebitis, cerebrovascular disorders, pulmonary embolism and retinal thrombosis). If these occur or are suspected the drugs should be discontinued immediately. Discontinue medication pending examination if there is a sudden onset of proptosis, diplopia, or migraine. If examination reveals papilledema or retinal vascular lesions, medication should be withdrawn. Estrogens may be excreted in the mother's milk and an estrogenic effect upon the infant has been described. The long range effect on the nursing infant cannot be determined at this time. Hypercalcemia may occur in as many as 15% of breast cancer patients with metastases and this usually indicates progression of bone metastases. This occurrence depends neither on dose nor on immobilization. In the presence of untoward effects such as progression of the cancer or hypercalcemia, estrogen medication should be stopped. A statistically significant association has been reported between maternal ingestion during pregnancy of diethylstilbestrol and the occurrence of vaginal carcinoma developing years later in the offspring. Whether such an association is applicable to all estrogens is not known at this time. In any event, estrogens are not indicated for use during pregnancy.

Precautions: Because normal endogenous hormone production varies individually, certain patients may be unusually responsive to estrogenic therapy and may respond with undesirable manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, edema, etc. Because of estrogen induced salt and water retention, these drugs should be used with caution in patients with epilepsy, migraine, asthma, cardiac or renal disease. Patients with a history of psychic depression should be carefully observed and the drug discontinued if the depression recurs to a serious degree. In the event that any unexplained or excessive vaginal bleeding would occur while on estrogen therapy, nonfunctional causes should be borne in mind. The drug should be discontinued and a thorough investigation made as to the cause, being certain to rule out the possibility of malignancy. Pre-existing uterine fibromyomata may increase in size while using this product, therefore, patients should be examined at regular intervals while receiving estrogenic therapy. Women with a strong family history of cancer, recurrent chronic cystic mastitis, or abnormal mammograms should be administered estrogens with caution. Because of a possible decrease in glucose tolerance, diabetic patients should be followed closely. Because estrogens influence the metabolism of calcium and phosphorus, they should be used with caution in patients with certain metabolic bone diseases that are associated with hypercalcemia or in patients with renal insufficiency. The pathologist should be advised of estrogen therapy when relevant specimens are submitted. Because of the effects of estrogens on epiphyseal closure, they should be used judiciously in young patients in whom bone growth is not complete. A pre-treatment physical examination should include special reference to breast and pelvic organs as well as a Papanicolaou smear since estrogens have been known to produce tumors, some of them malignant, in five species of animals. When large doses of estrogens are used, urinary stress incontinence may occur in nonpregnant females. Prolonged high doses of estrogens will inhibit anterior pituitary functions. This should be borne in mind when treating patients in whom fertility is desired. Continuous use of estrogens will result in prolonged stimulation of the endometrium and breast. In order to avoid this, oral estrogens should be administered cyclically in the menopausal or hypogonadal patient. The age of the patient constitutes no absolute limiting factor, although treatment with estrogens may mask the onset of the climacteric. Certain endocrine and liver function tests may be affected by treatment with estrogens. If such tests are abnormal in a patient taking these drugs it is recommended that they be repeated after the drug has been withdrawn for two months. Any possible influence of prolonged estrogen therapy on pituitary, ovarian, adrenal, hepatic, or uterine function awaits further study.

Adverse Reactions: A statistically significant association has been demonstrated between use of estrogen-progestin oral contraceptives and the following serious reactions: Thrombophlebitis, pulmonary embolism, and cerebral thrombosis. Although available evidence is suggestive of an association, such a relationship has been neither confirmed nor refuted for the following serious reactions: coronary thrombosis and neuro-ocular lesions (e.g. retinal thrombosis and optic neuritis). The following adverse reactions are known to occur in patients receiving estrogens: nausea, vomiting, anorexia, gastrointestinal symptoms (such as abdominal cramps or bloating), edema, breakthrough bleeding, spotting or withdrawal bleeding, breast tenderness and enlargement, change in body weight (increase or decrease), headache, increased cervical mucus, allergic rash, loss of libido and gynecomastia in the male, reactivation of endometriosis, aggravation of migraine headaches, hepatic cutaneous porphyria becoming manifest, cholestatic jaundice, rise in blood pressure in susceptible individuals, mental depression, cystitis-like syndrome, loss of scalp hair, erythema nodosum, hemorrhagic eruption, premenstrual-like syndrome, changes in libido, changes in appetite, nervousness, dizziness, fatigue, backache, erythema multiforme, itching, possible diminution in lactation when given immediately post-partum, irritability, and malaise.

Important Notes: An increased risk of thromboembolic disease associated with the use of oral contraceptives containing estrogens and progestins has now been conclusively established. Retrospective studies have shown a statistically significant association between thrombophlebitis, pulmonary embolism, and cerebral thrombosis and embolism and the use of these drugs. There have been three principal studies in Great Britain[1-3] and one in the United States[4] leading to this conclusion. As a result of these studies, it has been estimated that users of oral contraceptives containing estrogens are 4 to 7 times more likely than nonusers to develop thromboembolic disease without evident cause. The American study also indicated that the increased risk did not persist after discontinuation, nor was it enhanced by long continued administration. Although the American study was not designed to evaluate a difference between products, it did suggest that there might be an increased risk of thromboembolic disease in users of sequential products. Confirmation of this finding requires further study. In a more recent analysis of data derived from several national adverse reaction reporting systems,[5] British investigators concluded that the risk of thromboembolism, including coronary thrombosis, is directly related to the dose of estrogen used in oral contraceptive products. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. Nevertheless, in view of this study, as well as others that have demonstrated a positive relationship between estrogens and thromboembolism, it would seem prudent and in keeping with basic therapeutic principles, to utilize, whenever feasible, the smallest effective dose of estrogen in treating patients. Risks associated with certain other known adverse reactions, such as elevated blood pressure, liver dysfunction, and reduced tolerance to carbohydrate, have not as yet been quantitated. Long term administration of both natural and synthetic estrogens in subprimate animal species in multiples of the human dose increases the frequency for some animal carcinomas. These data cannot be transposed directly to man. The possible carcinogenicity due to the estrogens can neither be confirmed nor refuted at this time. Close clinical surveillance of all women taking estrogens must be continued. It has been reported in a recent study done in the United States[6] that the maternal ingestion of diethylstilbestrol during pregnancy appears to increase the risk of vaginal adenocarcinoma developing years later in the offspring exposed.

Epidem. 90:365-380, (November) 1969. (5) Inman, W.H.W., Vessey, M.P., Westerholm, B., Engelund, A., Thromboembolic Disease and the Steroidal Content of Oral Contraceptives. Brit. Med. J., 25th April, 1970. (6) Herbst, et al. — Adenocarcinoma of the Vagina — New England Journal of Medicine, Vol. 284, Number 16 (April 22, 1971).

Dosage and Administration: Treatment is usually initiated with a dose of 1 or 2 mg. daily of micronized estradiol. Dosage may be adjusted to control the presenting symptoms depending on the response of the individual patient; the minimal effective dose for maintenance therapy should be determined by titration. To avoid continuous stimulation of the reproductive tract and breasts, cyclic therapy is recommended. The usual regimen consists of three weeks on drug followed by one week off drug. Some patients may require a slightly shorter estrogen-free interval (4-6 days) to prevent recurrence of menopausal symptoms. Withdrawal bleeding of unusual amount or duration should be investigated.

How Supplied: Estrace® 1 mg; lavender scored tablets, NDC 0087-0755-01, bottles of 100. Estrace® 2 mg; turquoise scored tablets, NDC 0087-0756-01, bottles of 100.

Case of ovarian tumors—both the right and the left being removed at the same operation

JOHN LIGHT ATLEE

The New York Journal of Medicine and the Collateral Sciences, vol. 1, pp. 168-170, 1843

168 Atlee's *Case of Removal of Ovarian Tumors.* [Sept.

ART. III.—*Case of Ovarian Tumors—both the right and the left being removed at the same operation*, by JNO. L. ATLEE, M. D., of Lancaster, Pa. [Communicated by letter to the Editor, by J. M. FOLTZ, Esq., Surgeon U. S. Navy.]

Lancaster, Pa., August 1, 1843.

MY DEAR DOCTOR—A few days ago I was invited by my old friend, Dr. JNO. L. Atlee, of this city, to accompany him on a visit to the patient from whom he removed, seven weeks ago, *two ovarian tumors*. As the operation of removing both diseased ovaria had never been previously performed, I felt much interest in seeing the case. We found the patient waiting to accompany her surgeon on a morning drive, agreeably to previous arrangement; but the Doctor was prevented doing so, in consequence of unforeseen professional engagements. The lady, who is under thirty years of age, and has never been married, had suffered from ascites for the last three years; and for this disease, she had been tapped four times, the ovarian tumors having remained undetected until after the third *paracentesis*. Convinced that these enlarged ovaria were the cause of the dropsy, Dr. A. proposed their removal, to which the heroic patient consented.

An incision about nine inches in length, in the course of the linea alba, and commencing at the pubes, was made into the abdominal cavity. The left ovarian tumor was found attached merely by the round ligament, which floated free in the abdomen; while the tumor on the right side, adhering about two-thirds of its extent to the brim of the pelvis and the omentum, required some careful dissection in its removal. They were both removed without any copious hæmorrhage; and this large wound, which was brought together by the interrupted suture, is now, seven weeks after the operation, completely united, with the exception of the lower extremity, where the ligatures upon the round ligaments still remain. As not an unfavorable symptom has thus far been presented, the patient may be safely pronounced out of all danger incident to this terrible and unprecedented operation.

Although the removal of diseased ovaria had its advocates in the last century, the operation (*vide Good's Study of Medicine*) having been actually done, and successfully too, in 1776, by L'Aumonier, surgeon-in-chief of the hospital of Rouen; yet, in consequence of its condemnation by such high authority as the names of De Haen and Morgagni, it became so completely neglected, that when Dr. McDowell, of Kentucky, reported three cases in which he had operated successfully, it was discredited by the Medico-Chirurgical Review; but this opinion was doubtless due in part to certain improbabilities connected with the details.

Professor N. Smith, of Yale College, reported, in 1822, in the American Medical Recorder, an interesting case of the successful extirpation of an ovarian tumor. In 1826, Dr. David L. Rodgers, of New York, performed the same operation; and so successful was the issue, that "in six weeks from the period of the operation, her catamenia had returned, and her health entirely recovered." This operation has been done no less than five times by Dr. Clay, of Manchester, and each time,

John L. Atlee of Lancaster, Pennsylvania, revived the operation of ovariotomy, pioneered by Ephraim McDowell. This, one of his earliest cases, was the first successful removal of both ovaries, one of which weighed 1¼ pound and the other weighed ¾ pound. Following a historical account of the operation of oophorectomy, Atlee wrote, "I have thus briefly summed up a history of the operations for diseased ovaria, under the belief that these cases, combined, tend to establish a new principle in surgery, viz, the comparative safety of making large openings into the cavity of the abdomen. . . . The successful result, generally speaking, attending the extirpation of enlarged ovaria, would seem, however, to show that operations within the abdomen are, by no means, so fatal as the profession have been led to believe. . . ." From 1843 to 1883, he performed oophorectomy about 78 times with 64 recoveries. This mortality rate of only 18 per cent was remarkable for its time, but by the end of the century the mortality rate for the operation had decreased to 1 per cent. In addition to having a busy general practice, Atlee served as professor of anatomy and physiology at Franklin and Marshall College and was one of the founders of the American Medical Association.

COMMUNICATIONS IN BRIEF

This section is suitable for reporting cases, results of therapeutic trials, and descriptions of new procedures or instruments. Reports should be limited to seven hundred words and two references. Use of an illustration or table requires a proportionate reduction in total words.

Peritoneal-cutaneous fistula secondary to a perforated Dalkon shield

LAURA SLAUGHTER, M.D.
DAVID J. MORRIS, M.D.
Women's Hospital, Los Angeles, California

THE FOLLOWING case report is presented as an unusual manifestation of a perforated Dalkon shield.

M. B., A 25-year-old black woman, gravida 5, para 4, therapeutic abortion 1, had a Dalkon shield inserted 6 weeks post partum in June, 1972. The insertion was extremely painful and she requested immediate removal but agreed to a 3 week trial period. During this interval she experienced spotting and cramping which subsided completely by her next appointment. At that time, she was informed after routine pelvic examination that the device was no longer present and she was given oral contraceptives. In the interim prior to admission she had an abortion in January, 1973, was treated for gonococcal salpingitis on August 14, 1973, and had at least four documented visits to a family-planning clinic for birth control pills. On September 21, 1974, she was seen in the emergency room because a 3 by 3 cm. infraumbilical mass which had been present for over a year had suddenly become painful and drained purulent material. A 1 cm. abscess was incised and drained; bacteroides was cultured from the abscess site. Despite these measures, the abscess continued to drain and she was seen on three subsequent occasions. Finally, on December 2, 1974, the abscess cavity, which was now 2 by 2 cm., yielded a black, single-knotted string. A flat plate and lateral x-ray disclosed a Dalkon shield just beneath the abdominal wall. At surgery, the Dalkon shield was found encircled by omentum and fibrous tissue in a 4 x 3 cm. mass. The string led from the peritoneal cavity through the abdominal wall to just beneath the skin and is represented as a radiolucent tract on lateral x-ray (see Fig. 1). The abscess was confined to the abdominal wall.

Reprint requests: Laura Slaughter, M.D., Room L-946, Women's Hospital, 1240 Mission Rd., Los Angeles, California 90033.

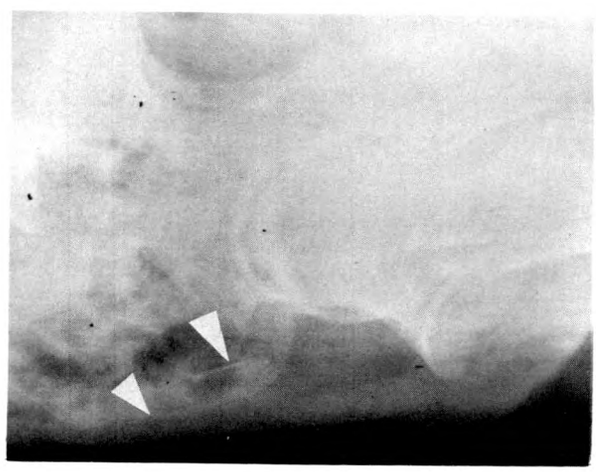

Fig. 1. Lateral x-ray.

Whitson, Israel, and Bernstein,[1] in a recent report on intrauterine Dalkon shields, noted that the majority of cases occurred in multiparas with a standard size device in the puerperium and were associated with a significant chronic adhesive reaction necessitating removal. They carefully outlined a workup for the localization of IUD's suspected to have perforated. This case and others reporting multiple IUD insertions[2] emphasize to the clinician that the absence of IUD strings must not be assumed to represent expulsion per vagina and demands further investigation to rule out perforation.

Maternal midtrimester sepsis in association with the intrauterine contraceptive device: Early histopathologic findings

E. D. BIGGERSTAFF, M.D.
M. T. MENUTTI, M.D.
J. F. YETTER, M.D.
R. E. ROGERS, M.D., F.A.C.O.G.*

Departments of Obstetrics and Gynecology and Pathology, Madigan Army Medical Center, Tacoma, Washington

MATERNAL midtrimester sepsis in association with the shield-type intrauterine contraceptive device (IUD) has now been reported by several authors.[1-4] The mechanisms by which this infection occurs and is disseminated are unknown. The clinical presentation is unusual in that there are often symptoms of generalized infection, a "flu-like" syndrome, with absent or mild symptoms and signs of localized pelvic infection. The case reported here is similar to those previously described, but is presented because of the somewhat unusual microscopic findings.

A 24-year-old white woman, gravida 1, para 0, ABO, presented at 16 weeks' gestation with a shield-type IUD in place and a 12 hour history of chills and fever. She had no other complaints. General physical examination revealed a temperature of 104.6° F. rectally, a blood pressure of 110/60 mm. Hg and a pulse of 120, but was otherwise unremarkable. Pelvic examination confirmed a 14 to 16 week size intrauterine pregnancy. The uterus was mildly tender, and the fetal heart tones were 200 b.p.m. After appropriate laboratory studies and bacterial cultures were obtained, therapy with antibiotics and pitocin was begun.

The fetus, placenta, and IUD were passed vaginally and a curettage was performed. Postoperatively, the patient responded rapidly to continued antibiotic therapy and there were no complications. Maternal blood and placental cultures grew *E. coli*.

Histopathologic examination of the specimen revealed extensive bacterial colonization on the maternal side of the membranes (Fig. 1). Microscopic sections of the placenta and fetal organs were unremarkable.

The mechanism by which severe maternal sepsis occurs in association with an intrauterine pregnancy and a shield-type IUD has been speculated on by the authors reporting previous cases. Because of the rapid clinical deterioration due to septicemia when signs of severe localized pelvic infection were often absent, Christian[1] felt that there might be a mechanical factor which allowed vascular dissemination of bacteria at a time when the infection might be otherwise locally contained. In those cases in which the microscopic examination of the pregnancy has been described, well-established chorioamnionitis and placentitis were most often noted.

Reprint requests: Edward D. Biggerstaff, M.D., Department of Obstetrics and Gynecology, Madigan Army Medical Center, Tacoma, Washington 98431.

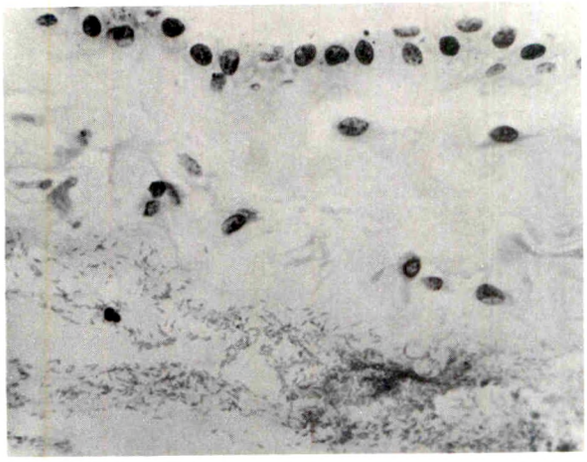

Fig. 1. Amnion, demonstrating epithelial surface (above) and numerous gram-negative bacilli (below). A single polymorphonuclear leukocyte is present. (Hematoxylin and Eosin; ×416).

We believe that the case reported here represents an earlier example of this clinical problem than those generally reported. The finding of large numbers of bacteria on the maternal side of the membranes, without amnionitis or placentitis, is unusual. One might speculate that this could explain the dissemination of bacteria into the maternal vascular system, resulting in severe maternal septicemia prior to the development of the classical signs and symptoms of septic abortion. This is only speculation and in no way attempts to explain how this phenomenon occurs with the IUD. We feel, however, that the histologic findings in this case are consistent with the clinical course seen in this patient and perhaps of other similar reported cases.

Gonadal dysgenesis in two siblings

PHILIP R. FLEISHMAN, M.D.
MELVIN BERLIN, M.D., F.A.C.O.G.
MILTON M. DANA, M.D., F.C.A.P.

Departments of Medicine (Dr. Fleishman), Obstetrics and Gynecology (Dr. Berlin), and Pathology (Dr. Dana), Southside Hospital, Bay Shore, New York

ONE OF THE most fascinating and yet poorly handled entities in medicine is gonadal dysgenesis. X-Y gonadal dysgenesis presents the clinician with a complete challenge. Embryology, genetics, anatomy, endocrinology, physiology, pharmacology, and psychology are all intimately necessary in diagnosing and treating this disorder. In order to recognize the dysgenetic patient we must have a high suspicion level with each case of amenorrhea.

The complete absence of a functioning gonad always, and irrespective of chromosomal pattern, results in the development of the müllerian duct system. This was shown by the experimental work of Jost. By removing the fetal gonads of mice at an early stage in intrauterine life, Jost produced animals with female genitalia regardless of the gonadal sex.

We are now finding more cases of gonadal dysgenesis appearing in the medical literature with increasing evidence that X-Y gonadal dysgenesis is an X-linked recessive or male-limited autosomal dominant condition. This paper adds two cases of pure gonadal dysgenesis in siblings.

Case 1. A 15-year-old phenotypic female was first seen for amenorrhea. She was the product of a 9 month gestation with a birth weight of 5 pounds, 5 ounces. There were two siblings, one older sister with amenorrhea and a normal younger brother. The patient's height was 63 inches, arm span 62 inches, pubis-to-floor measurement 32 inches, weight 133 pounds, blood pressure 130/70 mm. Hg. There was no suggestion of breast development and no axillary or pubic hair. The labia, clitoris, and vagina were normal, with an infantile uterus and cervix. Firm band-like structures were palpated in place of adnexal tissue on careful bimanual examination.

A buccal smear yielded two Barr bodies per 100; human pituitary gonadotropin 96 μ; intravenous pyelogram, negative. 17-OH and ketosteroids were normal. Karyotyping of peripheral blood lymphocytes demonstrated a 46 X-Y pattern and no evidence of mosaicism with examination of 20 metaphase figures.

At laparotomy a small infantile uterus with normal-appearing tubes were found. Two small, white, fibrous, streak gonads were removed. The patient is presently being cycled with Premarin 1.25 mg. and Provera 10 mg., with satisfactory breast development and the realization that she will develop as a healthy female but will be unable to bear offspring unless ovarian transplants become available.

Reprint requests: Dr. Milton M. Dana, Director of Laboratories, Southside Hospital Montauk Highway, Bayshore, New York 11706.

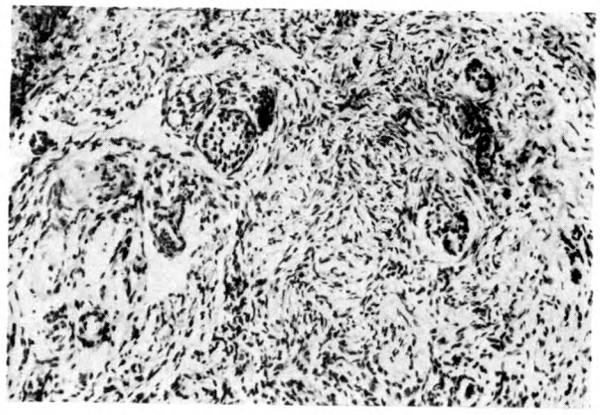

Fig. 1. Case 1. Undifferentiated gonadal tissue with epithelial inclusions. (Hematoxylin and eosin; ×200.)

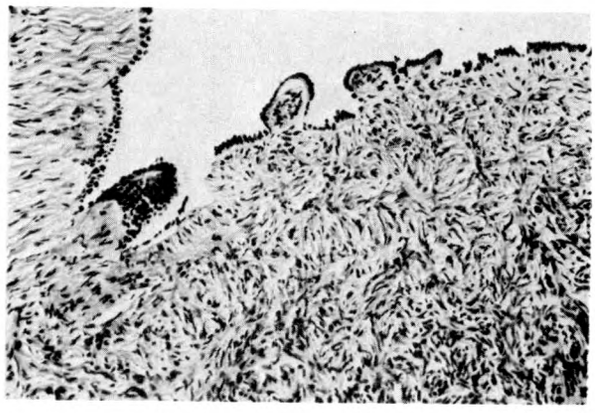

Fig. 2. Case 2. Compact and undifferentiated gonadal tissue partially covered by surface epithelium. (Hematoxylin and eosin; ×200.)

Histologic examination of the removed gonads revealed a compact fibrous stroma devoid of ovarian follicles or seminiferous tubules. Rare groups of Leydig-like cells and a few small celomic-type epithelial inclusions were seen (Fig. 1).

Case 2. The 23-year-old sibling of the patient described in Case 1 presented herself at the office after her sister had surgery. She had initially been seen at age 15 for amenorrhea and her condition was diagnosed as "Turner's agenesis." She was taking estrogens and progestens to produce cyclic bleeding and was told that she might have children if given "fertility pills."

Physically, she is an attractive, large-boned, thin, phenotypic female, 64 inches tall. Her external genitals were female, with sparse axillary and pubic hair and breasts of small estrogenized type. Her vagina was 8 cm. and the uterus and cervix were of small adolescent type.

In place of adnexa, firm streak-like areas were palpated bilaterally. 17-OH and ketosteroids were normal. A buccal smear yielded one to two Barr bodies per 100 cells. An IVP was normal. Karyotyping of peripheral blood lymphocytes

demonstrated a 46 X-Y pattern and no evidence of mosaicism with examination of 20 metaphase figures.

Histologic examination of the removed gonads revealed a compact fibrous stroma devoid of any epithelial structures (Fig. 2).

Siblings with pure gonadal dysgenesis are presented, typically appearing with a history of primary amenorrhea. The diagnosis was established in the younger of the siblings initially, thus stressing the importance of cytogenetic studies in all cases of primary amenorrhea. The reported significant familial incidence of dysgenetic gonads suggests a need to study all siblings. Once the X-Y pattern is found, the experience as reported in the literature to date makes the decision for treatment relatively easy, i.e., removal of all streak gonads once the presence of a Y chromosome is established.[1, 2] Fortunately, no tumors were found in our patients. The uncertainty of sexual identification exists with the older of the two siblings because of misinformation afforded the patient initially.

Pregnancy following 29 cycles of clomiphene citrate therapy: A case report

CHARLES M. MARCH, M.D.
ROBERT ISRAEL, M.D.
DANIEL R. MISHELL, JR., M.D.

Section of Reproductive Biology, Department of Obstetrics and Gynecology, Women's Hospital/University of Southern California Medical School, Los Angeles, California

DESPITE extensive experience with clomiphene citrate (Clomid), controversy remains regarding dosage, duration of therapy, and the use of alternative or additional methods of treatment. The product information brochure limits its use to dosages no greater than 100 mg. per day for 5 days and for no more than three ovulatory cycles.

This paper reports the successful induction of ovulation followed by pregnancy after 29 courses of treatment with clomiphene citrate.

Reprint requests: Dr. Charles M. March, Section of Reproductive Biology, Department of Obstetrics and Gynecology, Women's Hospital/University of Southern California School of Medicine, 1240 N. Mission Rd., Los Angeles, California 90033.

U. H., a 26-year-old nulligravida, was referred to the Endocrine-Infertility Clinic in September, 1970, because of infertility for 6 years and oligomenorrhea since her menarche at age 12. Contraceptives had never been used. She had gained 40 pounds in 7 months and was amenorrheic since February, 1970. In July, 1970, she underwent an appendectomy with lysis of multiple blood-tinged, intra-abdominal perirectal cysts. The uterus, tubes, and ovaries were described as normal.

Complete physical examination was within normal limits except for obesity. She was neither hirsute nor virilized. CBC, electrolytes, renal and liver function tests, FBS, 2 hour PP, T_3, T_4, VDRL, urinalysis, cervical cytology, and chest x-ray were within normal limits.

Clomiphene citrate, 50 mg. daily for 5 days, was administered on the fifth day of intramuscular progesterone–induced bleeding. A serum progesterone level 17 days after the last clomiphene tablet was 4.0 ng. per milliliter, consistent with ovulation. A fractional postcoital test in a subsequent cycle was normal. Hysterosalpingography and diagnostic laparoscopy with chromopertubation were also normal.

The same clomiphene dose resulted in presumably ovulatory cycles on 13 successive occasions. Treatment was interrupted for 1 month when asymptomatic, 6 cm., bilateral, ovarian cysts developed. These cysts spontaneously resolved before treatment was resumed. Despite clomiphene therapy, ovulation did not occur in February, 1972. Withdrawal bleeding was again induced and clomiphene citrate, 100 mg. per day for 5 days, was prescribed, resulting in presumptive ovulation. In November the 100 mg. dose of clomiphene failed to induce ovulation and therapy consisting of 150 mg. per day for 5 days was begun. Hematologic studies, electrolytes, and liver and renal function tests remained normal throughout clomiphene therapy. Each of 12 cycles at this dosage was ovulatory and conception occurred in February, 1974.

The pregnancy progressed uneventfully until August 26, 1974, when premature labor began. She spontaneously gave birth to a 3-pound, 9 ounce male infant, whose subsequent growth and development have been normal.

Clomiphene citrate, gonadotropins, and bilateral ovarian wedge resection are the measures used most commonly to treat anovulatory infertility. Because of complications, expense, inconvenience, and a high incidence of multiple gestations, gonadotropin therapy is warranted only in a highly selected group of patients and must be accompanied by daily monitoring of estrogen levels.

Goldzieher[1] summarized the results of wedge resection in 1,079 cases collected from 187 references: postoperatively, regular menstrual cycles occurred in six to 95 per cent (mean 80 per cent) of patients and pregnancy in 13 to 89 per cent (mean 63 per cent). The widely divergent results are secondary to patient selection, the presence of additional infertility factors, variations in surgical technique, and occasional intra- and postoperative complications.

In a recent report from our clinic in which an individualized, graduated, treatment regimen of clomiphene citrate was used to induce ovulation until pregnancy occurred, there was an ovulation rate of 91.4 per cent and an over-all pregnancy rate of 38.1 per cent.[2] When patients with other infertility factors were eliminated, however, the corrected pregnancy

rate was found to be 85.7 per cent. It is our belief that clomiphene citrate therapy is preferable to treatment by wedge resection because: (1) a major operative procedure is avoided, (2) peritubal and periovarian adhesions frequently occur after wedge resection, and (3) the recurrence of anovulatory cycles following wedge resection is common.

When clomiphene citrate successfully corrects the ovulatory defect, but pregnancy does not occur, two alternative methods of treatment have been recommended: combined clomiphene citrate–gonadotropin therapy and bilateral ovarian wedge resection. The former adds the risks of gonadotropin therapy and the latter substitutes potentially hazardous surgical therapy. The pregnancy rate following ovulation induced by these two methods has not been shown to be greater than that following ovulation induced by clomiphene citrate.

The limitation of clomiphene citrate to an arbitrary number of apparently ovulatory cycles is not warranted in the absence of other infertility factors. If a patient ovulates, but does not conceive, cyclic clomiphene treatment should be continued. In this way patients may become pregnant with greater safety than after having a laparotomy and removal of functional ovarian tissue. As illustrated by this case report, when clomiphene citrate successfully induces ovulation, treatment should be continued until conception occurs. In this patient, treatment for more than 2 years had no deleterious effects and was followed by a successful pregnancy.

Ovarian malignancy subsequent to a Le Fort operation

NOROHITO SUDO, M.D.
THEODORE GOLDBERG, M.D.
SANFORD SALL, M.D.

Gynecologic Malignancy Service of the Department of Obstetrics and Gynecology, New York Medical College, New York, New York

THE LE FORT colpocleisis is well known to gynecologists as a reliable procedure for the surgical repair of uterine prolapse. Although the operation has been modified in several ways, the technique includes the denuding of rectangular areas of similar size on the anterior and posterior walls of the vagina and suturing these mucosal edges together and opposing the denuded surfaces so that drainage canals are created laterally, permitting the egress of uterine or cervical secretions. This procedure is usually restricted to those patients who are postmenopausal, are no longer interested in sexual activity, or have medical complications for which a rapid, noninvasive procedure is desirous.

The major disadvantages of this procedure are that (1) intercourse is limited and (2) the facility for evaluation of postmenupausal bleeding is compromised. Postmenopausal bleeding subsequent to this procedure poses difficulty in diagnosis and often predisposes the gynecologist to suboptimal procedures, as well as hazardous delay.

Dilatation and fractional curettage of the uterus may be precluded by vaginal obliteration and an abdominal hysterectomy may be required for diagnosis and treatment. In those cases with endometrial carcinoma, proper staging and review of histologic material was not carried out prior to surgery, compromising the patient's prognosis. In those cases where "breakdown" of the colpocleisis was successful and adequate diagnostic procedures were performed, the patient may be exposed to the risks of bladder and rectal injury.

At New York Medical College–Metropolitan Medical Center, we recently encountered one patient who presented with complaint of postmenopausal bleeding 3 years following a Le Fort procedure.

J. G., a 56-year-old woman, gravida 3, para 3-0-0-3, whose last menstrual period was in 1965, was admitted on September 22, 1974, for evaluation of postmenopausal bleeding. Her past surgical history included a Le Fort colpocleisis in 1971 for uterine prolapse and cystorectocele. She had been well until June, 1974, when she noted small amounts of intermittent vaginal bleeding. She was seen in the gynecology clinic on July 26, 1974. Pelvic examination revealed no abnormalities other than an obliterated vagina; the Pap smear was Class II, showing mild atrophic atypia.

The patient was admitted for a fractional dilatation and curettage. The cervix was approached by gradual dilatation of the right lateral drainage canal with lubricated Hegar dilators, as well as scalpel dissection of resistant fibrous bands. The previous surgery was not disrupted. The cervix was grasped, traction was applied, and fractional dilatation and curettage and cervical punch biopsies were performed. The pathology report revealed small amounts of moderately differentiated adenocarcinoma. Evaluation of metastatic sites of disease was negative. Our impression at that time was Stage Ia, Grade 2, endometrial carcinoma. Laparotomy revealed a 5 by 5 cm. left adnexal mass with papillary seeding on the Fallopian tubes, the uterus, and the right ovary. There was diffuse seeding of tumor over the serosal surfaces of the small intestine and omentum. The liver, spleen, and kidneys were normal. A total abdominal hysterectomy and bilateral salpingo-oophorectomy and omentectomy were performed. Extirpation of the cervix was not hindered by the prior Le Fort procedure. The bulk of the tumor was removed, leaving diffuse small metastatic

Hanson and Keetel[3] (1969)	D&C, breakdown not mentioned	Endometrial carcinoma	ICR
Sudo, Goldberg, and Sall (1975) 1/74	D&C, no breakdown	Ovarian carcinoma	TAH-BSO + external teletherapy

*Intracavitary radium.

deposits. Surgical clips were placed in areas of larger metastatic concentrations. The pathology report revealed papillary adenocarcinoma of the left ovary. Postoperative cobalt-60 teletherapy was initiated on October 22, 1974 delivering 3,000 r to the whole abdomen in 4 weeks, given through AP-PA portals, blocking the kidneys posteriorly. This was followed by 2,000 r to the whole pelvis.

Pelvic malignancy following a Le Fort operation has been reported in only four instances, all of which have been endometrial in origin (Table I). There are no reported cases of carcinoma of the cervix.[3] This is the first reported case of ovarian malignancy following a Le Fort colpocleisis.

Benign melanosis of the vagina and cervix

YOSHIAKI TSUKADA, M.D.

Department of Pathology, Roswell Park Memorial Institute, Buffalo, New York

Melanotic lesions of the vagina and cervix, benign or malignant, are rare. The majority of such lesions should be regarded as malignant until proved otherwise,[1] but there are occasional benign cases. This report illustrates a case of benign melanosis of the vagina and cervix in a 46-year-old woman which remained unchanged in a 13 year follow-up.

This 46-year-old black woman, gravida 4, para 2, abortus 2, was referred to this institute 13 years ago because of discoloration of the vaginal mucosa. She had had irregular and heavy menstruation for the last 6 years and had been under the care of a physician, who noted the discoloration recently. On examination at this institute, irregular patches of bluish discoloration were noted on the vagina and portio vaginalis. The vaginal lesion was on the anterior wall, beginning at the right anterior fornix, and involved the upper two thirds of the vaginal canal, measuring about 3 cm. in width. The area was neither raised nor firm and was normal on palpation. The cervical discoloration was noted at the 3 and 9 o'clock positions, each measuring about 0.7 cm.

Reprint requests: Yoshiaki Tsukada, M.D., Department of Pathology, Roswell Park Memorial Institute, Buffalo, New York 14203.

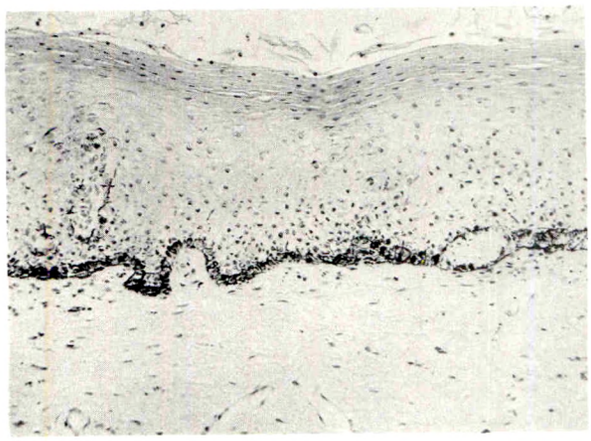

Fig. 1. Photomicrograph of the vaginal mucosa. (Section stained by Fontana stain for melanin; ×220.)

Biopsies of the lesions revealed pigmentation of the basal layer of the squamous epithelium with melanin pigment. Melanocytes with dendrites and melanin pigment were evident among pigmented epithelial cells (Fig. 1). She has been followed at the outpatient clinic and the lesions have not changed. Another biopsy, obtained recently, showed the same histologic feature.

Benign melanotic lesions of the vagina and/or cervix are rare and only few cases have been documented. Nigogosyan, de la Pava, and Pickren[2] studied the vaginal mucosa of 100 random autopsies and found a similar lesion to that of the present case in three cases. All three patients were elderly white women. In one case the pigmentation was extensive. This patient received radiation to the uterus for postmenopausal bleeding 9 months before death. In the other two the pigmented areas were small. In none of the cases were

the lesions recognized clinically. Norris and Taylor[1] described two benign melanotic lesions in the vagina; one resembled a lentigo and the other consisted of melanin-laden cells in the lamina propria. A case of melanin pigmentation of the basal layer of the cervical squamous epithelium was briefly mentioned by Ackerman and Rosai in their *Surgical Pathology* textbook. Other reported cases include pigmented nevus of the vagina and blue nevus of the cervix.

The present patient was referred to this Institute with suspicion of malignant melanoma of the vagina. Biopsy of the lesions, however, revealed melanin pigmentation of the basal layer of the squamous epithelium with scattered melanocytes. This histologic feature corresponds to melanosis of the mucosa found elsewhere. On physical examination the lesions were soft, not raised, and normal on palpation. No ulceration was present. This is in contrast with malignant melanoma of the vagina which is usually nodular, polypoid, or ulcerated, and bleeds easily when touched.[1]

The incidence of melanosis of the vagina and/or cervix is probably higher than one would expect from rarity of reported cases. This is suggested by the fact that Nigogosyan and associates[2] found three such lesions in 100 random autopsies. The lesion of this patient remained stable for 13 years and it is unlikely that it is a precursor of malignant melanoma. Preexisting, concurrent, or later developing melanosis is frequently noted in malignant melanoma of the oral cavity. This phenomenon, however, has not been described in malignant melanoma of the vagina or cervix. The origin of melanocytes in the vagina and cervix is still unsettled but most likely is the neural crest, as suggested by previous investigators.[1, 2]

Chlordiazepoxide withdrawal in the neonate

PAKSHI ATHINARAYANAN, M.D.
SOPHIE H. PIEROG, M.D.
SARVESH K. NIGAM, M.D.
LEONARD GLASS, M.D.

Department of Pediatrics, Jewish Hospital and Medical Center of Brooklyn, Brooklyn, New York

Reprint requests: Sophie H. Pierog, M.D., Department of Pediatrics, Jewish Hospital, 555 Prospect Place, Brooklyn, New York 11238.

THE USE OF addictive drugs during pregnancy has risen sharply over the past decade. In the 1960's heroin was the major drug of abuse leading to the neonatal abstinence syndrome. In more recent years, the use of methadone, barbiturates, and tranquilizers, either alone or in combination, has been observed with increasing frequency. We have recently observed severe signs of withdrawl in twin infants of a mother who used chlordiazepoxide (Librium) throughout pregnancy.

A 33-year-old woman, para 1-0-0-1, who had been treated with chlordiazepoxide, 30 mg. per day for 5 years because of a moderately severe emotional disorder, had her dosage lowered to 20 mg. per day in the twelfth week of the present pregnancy. The use of other psychotropic drugs during pregnancy was denied. After a 36 week gestation, she delivered female monozygotic twins weighing 1,840 grams (Twin A) and 1,590 grams (Twin B), respectively.

The clinical course of both infants was uncomplicated during the first 3 weeks of life. On the twenty-first day, both infants were noted to be irritable, and coarse tremors were observed (more pronounced in Twin B than in Twin A). A diagnostic evaluation for infectious and metabolic disorders was negative, and a presumptive diagnosis of chlordiazepoxide withdrawal was made. Blood drawn from both infants at this time (umbilical cord serum was not available) was sent to Roche Laboratories, where analysis for chlordiazepoxide showed no trace of the drug. Twin B was treated with phenobarbital, 8 mg. per kilogram per day, given in three divided oral doses, while Twin A was swaddled and placed in a quiet environment.

Although there was a temporary improvement in the clinical condition of both infants, severe tremulousness and irritability were noted on day 26. Treatment with intramuscular diazepam, 0.5 mg. every 12 hours, was begun in both infants. Within 48 hours a marked improvement was noted. After 5 days, the dosage of diazepam was tapered and therapy discontinued after 9 days. The further clinical course of both infants remained uneventful.

Benzodiazepine compounds (chlordiazepoxide, diazepam, and oxazepam) are widely used tranquilizers which may cause physical dependence when used in large doses. Abstinence is associated with a clinical syndrome similar to that observed in withdrawal from barbiturates and meprobamate—depression, agitation, loss of appetite, insomnia, and, in some cases, actual convulsions.

Excretion of the drug, which is slow in adults, is markedly delayed in premature infants. Therefore, signs of withdrawal may be significantly delayed after transplacental exposure to the drug has ceased. This is similar to neonatal withdrawal from methadone[1] and long-acting barbiturates,[2] where initial signs of abstinence may be delayed for 2 to 4 weeks after birth.

Although initial signs of neonatal withdrawal from diazepam have been observed as late as 10 days of age, we are not aware of any reports of chlordiazepoxide withdrawal in the neonate.

While the diagnosis in our cases is presumptive

rather than proved, we would nonetheless caution physicians caring for infants of mothers who received benzodiazepine compounds during pregnancy to be alert for a delayed withdrawal syndrome, especially after the infant has been discharged from the newborn nursery. Clinical observations should be correlated with concentrations of the drug in umbilical cord serum and blood of the infant.

CORRESPONDENCE

Progesterone-releasing intrauterine contraceptive device

To the Editors:

I read with great interest the report of Brenner and associates (AM. J. OBSTET. GYNECOL. 121: 704, 1975) on a progesterone-releasing intrauterine contraceptive device.

We tested the same devices by inserting in a randomized fashion 99 T-devices releasing 65 μg of progesterone daily and 99 "placebo" devices obtained under the auspices of the World Health Organization. Since both trials were conducted by similar methods, readers may be interested in our results, with differences in the population and in the habits and attitudes of the patients, which may affect the over-all acceptability pattern, kept in mind. Such local factors may account for the fact that our discontinuation rate was so much lower than that of Brenner and associates.

We inserted devices from January to May, 1973, during menstruation in 198 women, all of whom had regular menses and normal pelvic findings. The patients were followed systematically, and the effectiveness of the devices was computed by the "life-table method" of Tietze.

Our results are shown in Table I.

After insertion, irregular bleeding occurred in 130 patients up to the second follow-up visit (third month). At the one-month checkup, 102 women reported irregular bleeding, while a total of 63 women reported bleeding during the second and/or third month. With exclusion of patients requesting removal, bleeding stopped spontaneously or after treatment with uterotonic agents after one to three weeks. After the third month, only 13 instances of spotting and one instance of bleeding occurred.

It should be mentioned that the devices were not immediately removed at the first report of bleeding, Removal was performed only in women who continued bleeding at least three weeks following unsuccessful treatment with uterotonic agents. Removal had to be performed in only seven of 130 patients, six of whom had irregular bleeding during the first three months. With this management, there was a very marked reduction in removal for bleeding as compared with the results reported by Brenner and his co-workers.

The one-year cumulative rate for wearing the devices per 100 women was 83.84; for the progesterone type it was 85.86, and for the placebo device it was 81.82 (with 9 pregnancies). With exclusion of removals for nonmedical reasons, the cumulative wearing rates became: total, 86.37; the progesterone device, 86.87; and the placebo device, 85.86.

The incidence of removal of the device for bleeding may be minimized if the woman is informed that some bleeding is common in the first three months and that it occurs relatively infrequently after the fourth month. A patient, positive, communicative approach on the part of the physician encourages the woman to leave the device in place during the crucial first three months. It may be worth noting that, in the Brenner series and in our series, the incidence of removal for bleeding was greater in women with the progesterone device than in women with the placebo device, the totals being 24 and 12, respectively. Also, the progesterone devices in our series tended to be associated with alteration of the menstrual cycle. We are studying the clinical significance of these phenomena.

Intensive evaluation of 10 of the patients with the progesterone device and 10 of the patients with the placebo device failed to reveal any difference in the serum progesterone levels or in pregnanediol and estriol excretion from the normal values, proving that the progesterone release acts only locally. Also the

Table I. Number of events causing termination for each device

This investigation received financial support from the World Health Organization.

basal temperatures were biphasic. At endometrial biopsy, predecidual changes were found.

To eliminate the relatively high occurrence of initial irregular bleeding which suggests removal, determining the optimal content and rate of progesterone release should provide a combination method having the advantage of both hormonal and local (mechanical and hormonal) acting methods of fertility control.

Sterilization guidelines

To the Editors:

Recent urging of the need for sterilization guidelines, to determine whether requests will or will not be complied with, has been attacked as "male chauvinist control" over the life and reproduction of women and as an infringement of civil rights.

Since it is clear that sterilization as a permanent irreversible removal of the childbearing *option* is to be viewed as a last resort, it should be equally clear that evaluation of motivations and alternatives is necessary and that no request for any elective operation can be mandatorily complied with regardless of data elicited or clinical judgement. A basic medical-surgical principle states that *no* elective irreversible extirpation of structure or function should ever be carried out unless all reversible alternatives have been *genuinely* exhausted. An equally solid medical-surgical principle states that the *least* chemical-physical ministration which achieves a desired goal is preferred to any more extensive ministration. The burden of proof is on any practitioner who violates these principles. We know that an extremely important component of body image, self-image, or ego identity is intact anatomic structure and intact physiologic options. The permanent loss of any human functional option, of which *potential* generativity is a central example, cannot fail to reduce the human sense of self in the loser.

In view of the above, in a person requesting sterilization of any age or parity, with or without past exposure to reversible contraceptive counseling and methods, regardless of the degree of self-hatred, self-contempt, rejection of gender, and self-mutilating motivation elicited on competent interview, and regardless of the degree of high acute stress which might be contaminating the decision (as in current unwanted pregnancy and abortion or imminent emergency cesarean section), to insist that regardless of all such clinical data the request must be complied with *at that time,* in defense of the civil libertarian, democratic freedom of the patient to be sterilized on request, indeed represents the height of professional abdication and irresponsibility and should be opposed by all conscientious clinicians.

NORINYL® 1+50
tablets (norethindrone 1 mg with mestranol 0.05 mg)

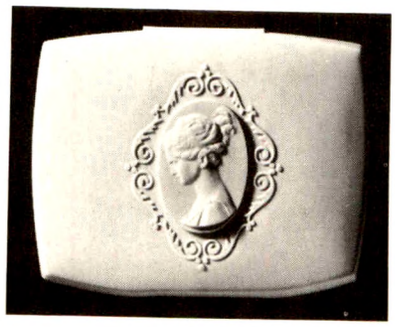
Special Note

Oral contraceptives have been marketed in the United States since 1960. Reported pregnancy rates vary from product to product. The effectiveness of the sequential products appears to be somewhat lower than that of the combination products. Both types provide almost completely effective contraception.

An increased risk of thromboembolic disease associated with the use of hormonal contraceptives has now been shown in studies conducted in both Great Britain and the United States. Other risks, such as those of elevated blood pressure, liver disease and reduced tolerance to carbohydrates, have not been quantitated with precision.

Long term administration of both natural and synthetic estrogens in subprimate animal species in multiples of the human dose increases the frequency for some animal carcinomas. These data cannot be transposed directly to man. The possible carcinogenicity due to the estrogens can neither be affirmed nor refuted at this time. Close clinical surveillance of all women taking oral contraceptives must be continued.

Indications



NORINYL 1+50 and NORINYL 1+80 are indicated for oral contraception.

Contraindications

1. Thrombophlebitis, thromboembolic disorders, cerebral apoplexy, or a past history of these conditions.
2. Markedly impaired liver function.
3. Known or suspected carcinoma of the breast.
4. Known or suspected estrogen dependent neoplasia.
5. Undiagnosed abnormal genital bleeding.
6. Known or suspected pregnancy.

Warnings

1. The physician should be alert to the earliest manifestations of thrombotic disorders (thrombophlebitis, cerebrovascular disorders, pulmonary embolism, and retinal thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. Retrospective studies of morbidity and mortality in Great Britain and studies of morbidity in the United States have shown a statistically significant association between thrombophlebitis, pulmonary embolism, and cerebral thrombosis and embolism and use of oral contraceptives. There have been three principal studies in Britain[1,2,3] leading to this conclusion, and one[4] in this country. The estimate of the relative risk of thromboembolism in the study by Vessey and Doll[3] was about sevenfold, while Sartwell and associates in the United States found a relative risk of 4.4, meaning that the users are several times as likely to undergo thromboembolic disease without evident cause as non-users. The American study also indicated that the risk did not persist after discontinuation of administration, and that it was not enhanced by long continued administration. The American study was not designed to evaluate a difference between products. However, the study suggested that there might be an increased risk of thromboembolic disease in users of sequential products. This risk cannot be quantitated, and further studies to confirm this finding are desirable.
2. Discontinue medication pending examination if there is sudden partial or complete loss of vision, or if there is a sudden onset of proptosis, diplopia or migraine. If examination reveals papilledema or retinal vascular lesions, medication should be withdrawn.
3. Since the safety of NORINYL 1+50 and NORINYL 1+80 in pregnancy has not been demonstrated, it is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule the possibility of pregnancy should be considered at the time of the first missed period.
4. A small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The long range effect to the nursing infant cannot be determined at this time.
5. Hepatic cell adenomas have been reported in women on oral contraceptives. The adenoma may present as an abdominal mass or with the signs and symptoms of an acute abdomen. A bleeding hepatic cell adenoma should be considered if the patient has abdominal pain or evidence of intra-abdominal bleeding.

Norethindrone/mestranol 1+50 combination. From the company that developed norethindrone.

Precautions

1. The pretreatment and periodic physical examinations should include special reference to liver, breasts and pelvic organs, including Papanicolaou smear since estrogens have been known to produce tumors, some of them malignant, in five species of subprimate animals.
2. Endocrine and possibly liver function tests may be affected by treatment with NORINYL 1+50 and NORINYL 1+80. Therefore, if such tests are abnormal in a patient taking NORINYL 1+50 and NORINYL 1+80, it is recommended that they be repeated after the drug has been withdrawn for 2 months.
3. Under the influence of estrogen-progestogen preparations, pre-existing uterine fibromyomata may increase in size.
4. Because these agents may cause some degree of fluid retention, conditions which might be influenced by this factor, such as epilepsy, migraine, asthma, cardiac or renal dysfunction, require careful observation.
5. In breakthrough bleeding, and in all cases of irregular bleeding per vaginam, nonfunctional causes should be borne in mind. In undiagnosed bleeding per vaginam, adequate diagnostic measures are indicated.
6. Patients with a history of psychic depression should be carefully observed and the drug discontinued if the depression recurs to a serious degree.
7. Any possible influence of prolonged NORINYL 1+50 and NORINYL 1+80 therapy on pituitary, ovarian, adrenal, hepatic or uterine function awaits further study.
8. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. The mechanism of this decrease is obscure. For this reason, diabetic patients should be carefully observed while receiving NORINYL 1+50 and NORINYL 1+80 therapy.
9. The age of the patient constitutes no absolute limiting factor, although treatment with NORINYL 1+50 and NORINYL 1+80 may mask the onset of the climacteric.
10. The pathologist should be advised of NORINYL 1+50 and NORINYL 1+80 therapy when relevant specimens are submitted.
11. Susceptible women may experience an increase in blood pressure following administration of contraceptive steroids.

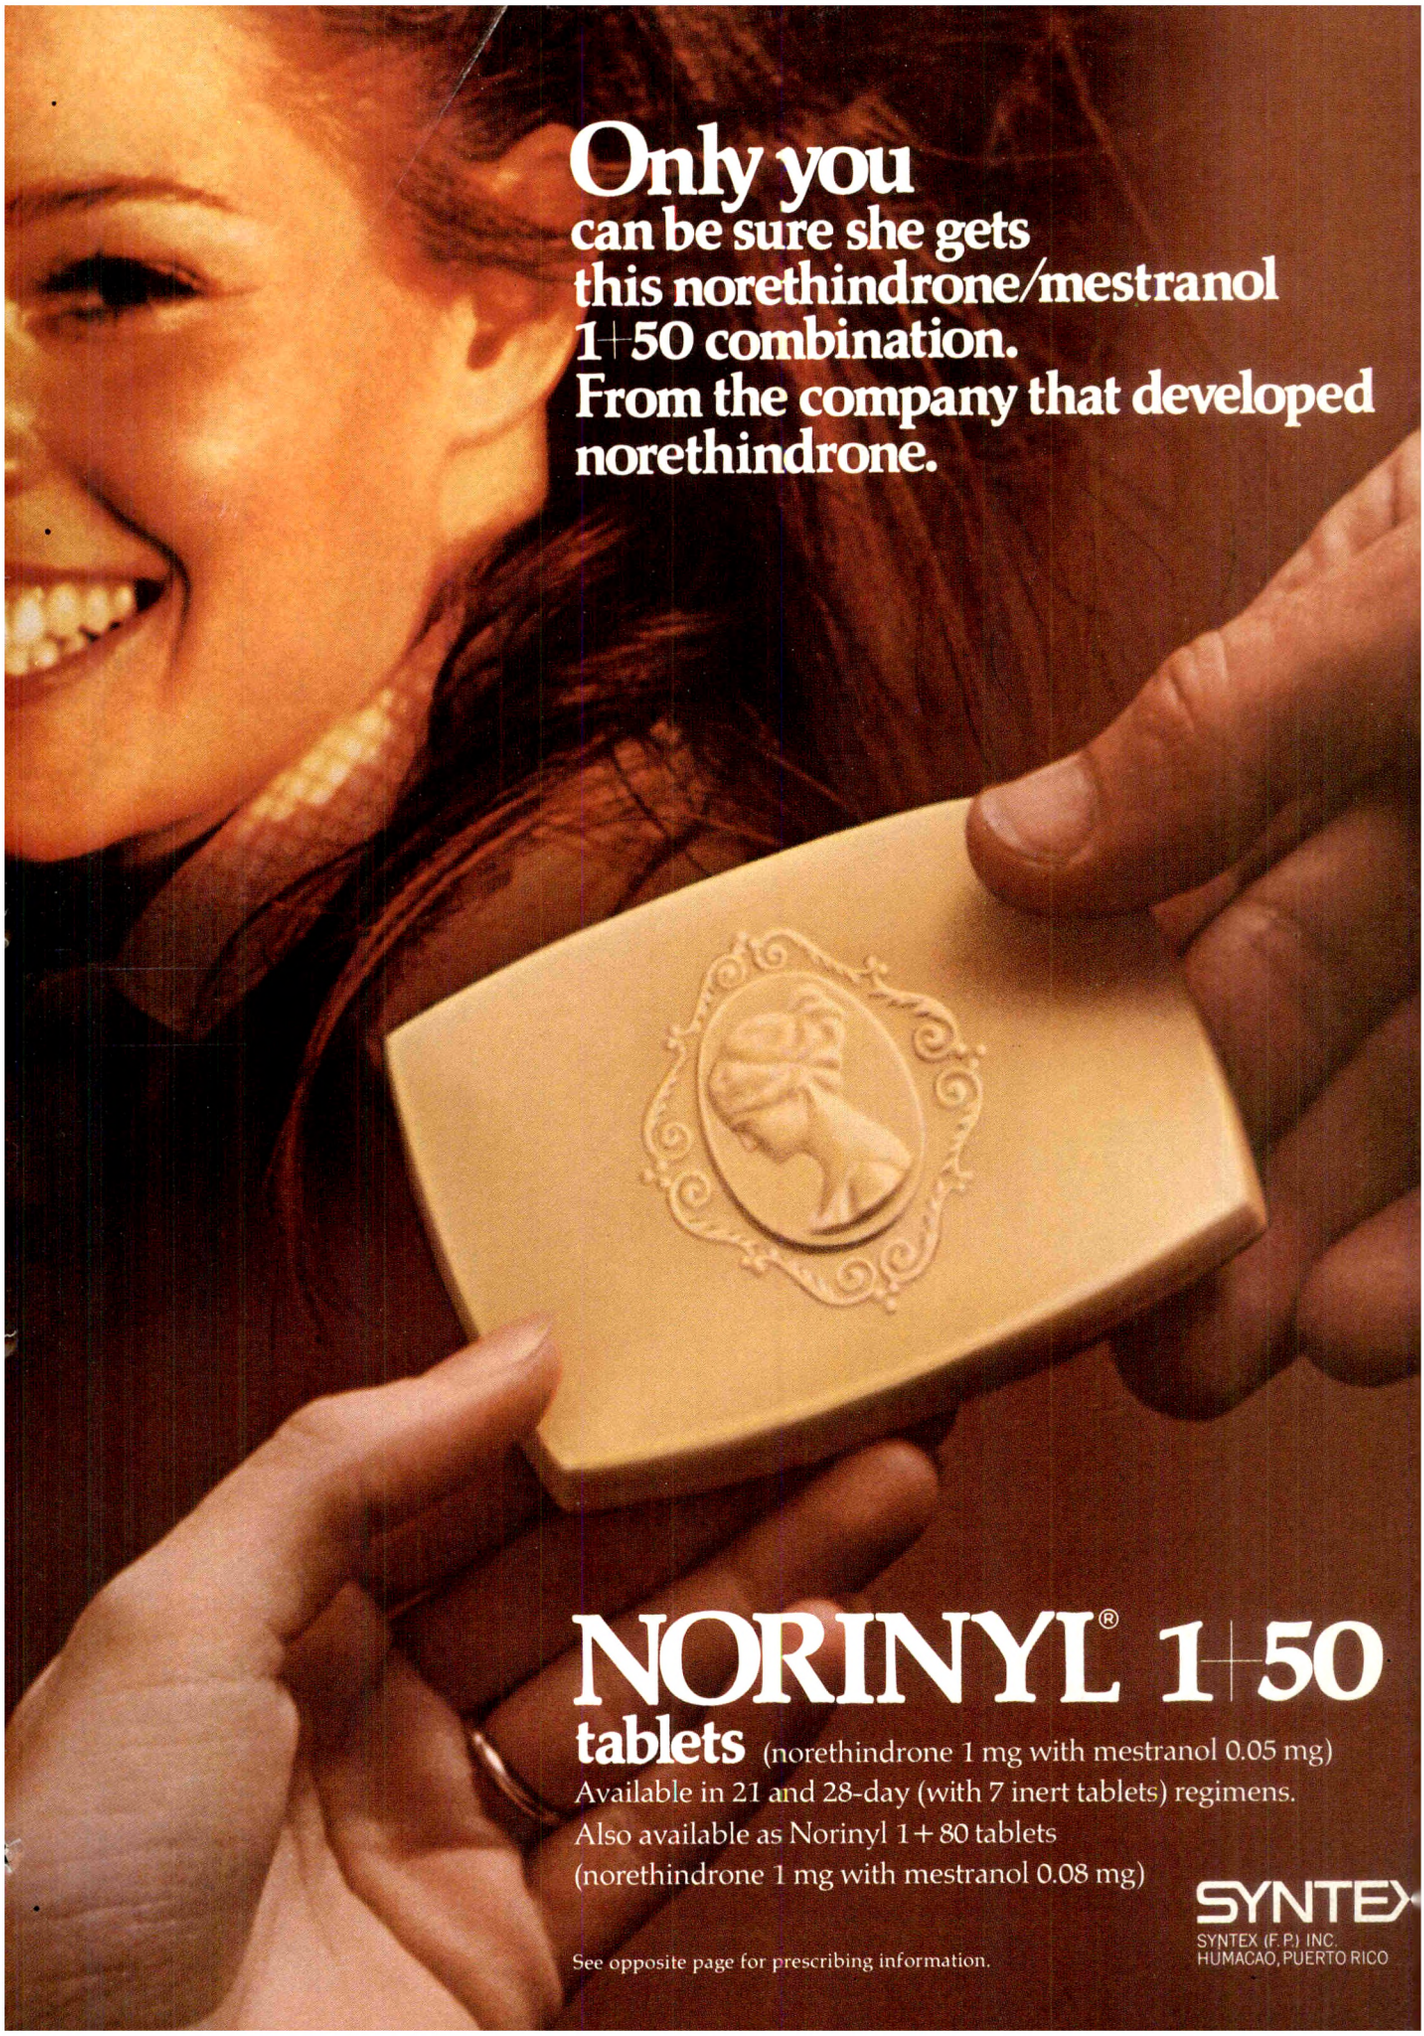
Adverse Reactions Observed in Patients Receiving Oral Contraceptives

A statistically significant association has been demonstrated between use of oral contraceptives and the following serious adverse reactions: thrombophlebitis, pulmonary embolism, cerebral thrombosis.

Although available evidence is suggestive of an association, such a relationship has been neither confirmed nor refuted for the following serious adverse reactions: neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions are known to occur in patients receiving oral contraceptives: nausea, vomiting, gastrointestinal symptoms (such as abdominal cramps and bloating), breakthrough bleeding, spotting, change in menstrual flow, amenorrhea during and after treatment, edema, chloasma or melasma, breast changes: tenderness, enlargement and secretion, change in weight (increase or decrease), changes in cervical erosion and cervical secretions, suppression of lactation when given immediately post-partum, cholestatic jaundice, migraine, rash (allergic), rise in blood pressure in susceptible individuals, mental depression.

Although the following adverse reactions have been reported in users of oral contraceptives, an association has been neither confirmed nor refuted: anovulation post treatment, premenstrual-like syndrome, changes in libido, changes in appetite, cystitis-like syndrome, hirsutism, loss of scalp hair, erythema multiforme, headache, nervousness, dizziness, fatigue, backache, erythema nodosum, hemorrhagic eruption, itching.



The following laboratory results may be altered by the use of oral contraceptives: hepatic function: increased sulfobromophthalein retention and other tests, coagulation tests: increase in prothrombin factors VII, VIII, IX, and X, thyroid function: increase in PBI, and butanol extractable protein bound iodine and decrease in T^3 uptake values, metyrapone test, pregnanediol determination.

Troubled... by symptoms she's reluctant to talk about.

Often enough, your postmenopausal patient may find it "too personal" to mention annoying vaginal dryness and itching – much less to bring up the subject of dyspareunia.

Yet, as your concerned questioning may reveal, this is a common finding in the postmenopausal woman. In many cases there is a simple explanation: atrophic vaginitis, resulting from estrogen deficiency.

And, for most such cases, there is an effective corrective measure. Topical estrogen therapy with PREMARIN Vaginal Cream can help revitalize genital tissue... correct dyspareunia... relieve symptoms of itching, irritation, dryness... help alleviate related complications of frequency, incontinence, or infection... when these conditions are associated with an estrogen deficiency.

Used routinely, PREMARIN Vaginal Cream can help reverse atrophic lesions and rebuild vaginal mucosa, restore texture and vascularity of vaginal epithelium and adjacent genitourinary tissue to a healthier, more infection-resistant state.

PREMARIN®
(CONJUGATED ESTROGENS, U.S.P.)
VAGINAL CREAM

CONTAINS NATURAL ESTROGENS EXCLUSIVELY

(Complete text of package circular.)

PREMARIN® Vaginal Cream
(CONJUGATED ESTROGENS, U.S.P.)
in a nonliquefying base

Description: Each gram contains 0.625 mg. Conjugated Estrogens, U.S.P., in a nonliquefying base.

PREMARIN (Conjugated Estrogens, U.S.P.) is a mixture of estrogens, obtained exclusively from natural sources, occurring as the sodium salts of water-soluble estrogen sulfates blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters.

Actions: PREMARIN Vaginal Cream provides the local estrogenic activity of topical estrogen.

Indications: PREMARIN Vaginal Cream is indicated for the treatment of postmenopausal and senile vulvovaginitis, atrophic vaginitis, pruritus vulvae caused by atrophic changes in the vulval epithelium, dyspareunia associated with an atrophic vaginal epithelium, and for use prior to plastic pelvic surgery in menopausal cases.

Contraindications: PREMARIN Vaginal Cream is contraindicated in patients hypersensitive to its ingredients, and in patients with known or suspected cancer of the breast, or estrogen-dependent neoplasia such as endometrial carcinoma.

Precautions: Diagnostic measures should be taken to eliminate the possibility of neoplasia or gonorrhea.

The use of PREMARIN (Conjugated Estrogens, U.S.P.) Vaginal Cream does not preclude the use of appropriate antimicrobial therapy in the presence of trichomonal, monilial, or bacterial infection.

Overdosage may result in systemic hyperestrogenic effects such as abnormal or excessive uterine bleeding, edema, breast tenderness, or reactivation of endometriosis.

Because of salt and water retention associated with estrogenic anabolic activity, estrogens should be used with caution in patients with epilepsy, migraine, asthma, cardiac, or renal disease.

Certain liver and endocrine function tests may be affected by estrogen administration.

Adverse Reactions: Hypersensitivity reactions, systemic effects such as breast tenderness, and, rarely, withdrawal bleeding.

Dosage and Administration: *Usual dosage:* Intravaginally or topically, 2 to 4 Gm. daily, depending on the severity of the condition. In postmenopausal surgery, therapy is suggested 10 days before and 10 days following intervention.

How Supplied: No. 874 – PREMARIN Vaginal Cream – Each gram contains 0.625 mg. Conjugated Estrogens, U.S.P. (Also contains spermaceti, cetyl alcohol, white wax, glyceryl monostearate, propylene glycol monostearate, methyl stearate, phenylmercuric acetate, sodium lauryl sulfate, glycerin, mineral oil, and certified color.)

Combination package: Each contains Net Wt. 1½ oz. (42.5 Gm.) tube with one calibrated plastic applicator.

Also Available – Refill package: Each contains Net Wt. 1½ oz. (42.5 Gm.) tube. **7443**

The causes of vaginitis are multiple

You can depend on AVC... therapy that combats major vaginal pathogens and provides rapid symptomatic relief.*

***Indications:** Based on a review of AVC by the National Academy of Sciences–National Research Council and/or other information, FDA has classified the indications as follows:

"Probably" effective: For the relief of symptoms of vulvovaginitis where isolation of the specific organism responsible (usually *Trichomonas vaginalis, Candida albicans,* or *Hemophilus vaginalis)* is not possible.

NOTE: When the offending organism is known, treatment with a specific agent known to be active against that microorganism is preferred.

"Possibly" effective: For the treatment of trichomoniasis, vulvovaginal candidiasis, and vaginitis due to *Hemophilus vaginalis* or other susceptible bacteria.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Known sensitivity to sulfonamides.

Precautions/Adverse Reactions: The usual precautions for topical and systemic sulfonamides should be observed because of the possibility of absorption. Burning, increased local discomfort, skin rash or other manifestations of sulfonamide toxicity are reasons to discontinue treatment.

Dosage: 1 applicatorful (about 6 g.) or 1 suppository intravaginally once or twice daily.

Supplied: Cream–4 ounce tube with applicator. Suppositories–Box of 16 with inserter.

BETADINE® Perineal Wash (concentrate) effectively deodorizes as it cleanses

BETADINE Perineal Wash, a welcome advance in personal care, thoroughly cleanses the anogenital area and, at the same time, effectively reduces or eliminates offensive odors. It contains no hexachlorophene, no irritating metallic salts...and is nonstaining and virtually nonirritating to skin and mucosa.

BETADINE Perineal Wash cleanses and deodorizes the perineum: ■ After episiotomy ■ After gynecologic, urologic and anorectal surgery ■ In the presence of incontinence or enuresis ■ In the bedridden or neurologically handicapped ■ Prior to gynecologic, obstetric and urologic examinations ■ During menstruation

Convenient Kit form: Each patient gets an individual kit—an 8 oz. bottle of BETADINE Perineal Wash Concentrate and an 8 oz. calibrated, plastic squeeze dispenser bottle for easy, efficient application.

Gas: one of the frequent complications of surgical aftercare...

Painful gas accumulation in the gut, due to altered intestinal motility, aerophagia and increased salivation, often complicates surgical aftercare.

To help avoid or dispel the acute discomforts of post-op pain in the gut, Phazyme provides simethicone, *"...an effective, safe and simple method of preventing abdominal distention, gas pain and reducing the incidence of ileus."*[1]*

Phazyme's unique dual-phase action releases 20 mg. of specially-activated simethicone initially to the stomach for immediate dispersion of entrapped gas.

The protected inner core delivers an additional 40 mg. of specially-activated simethicone to relieve pain of entrapped gas throughout the lower G.I. tract.

Phazyme also provides 240 mg. of pancreatin directly to the small intestine to help assure normal digestion.

And Phazyme is safe...no systemic effects...no untoward reactions...no contraindications other than known allergy to an ingredient.

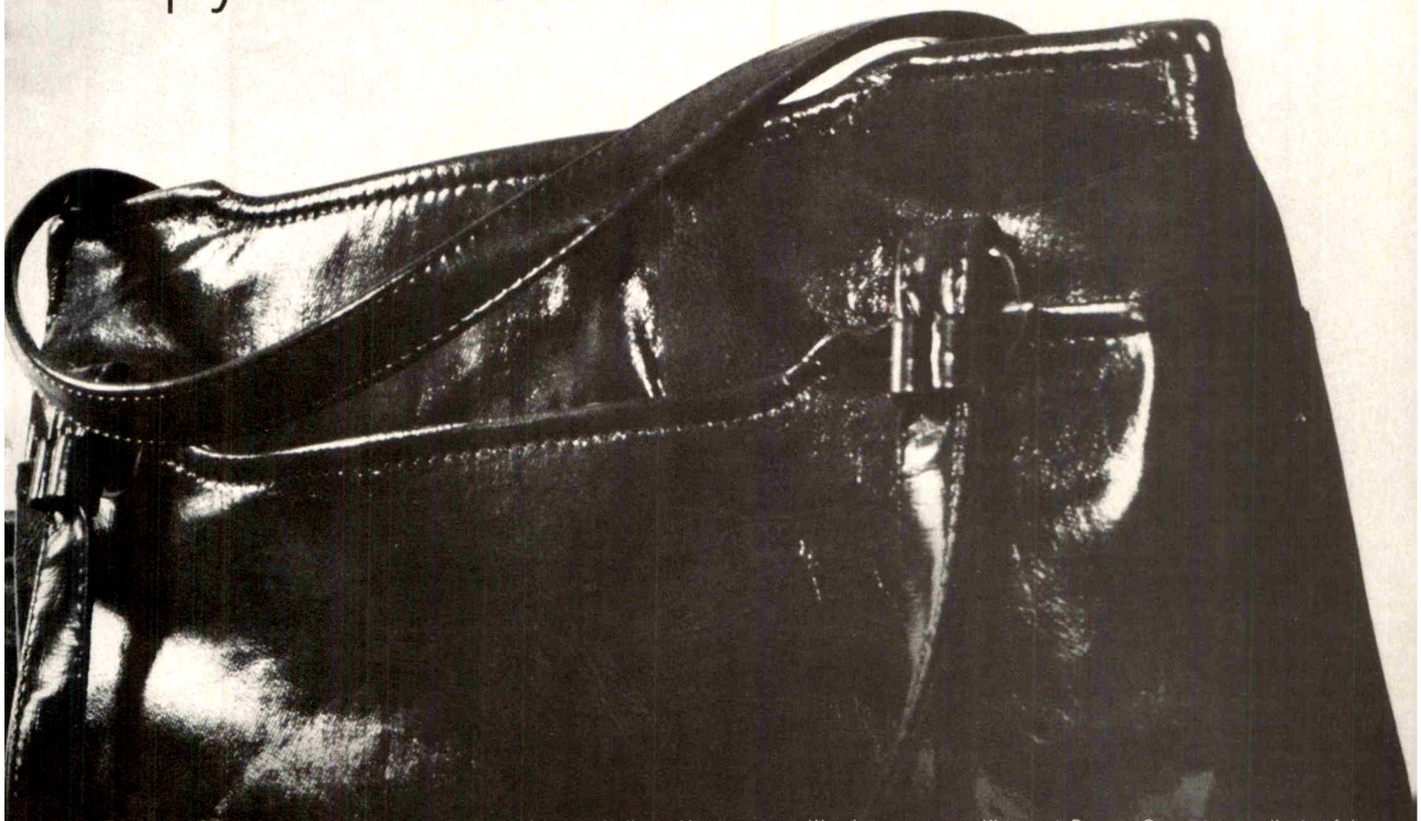
Two reasons your atrophic vaginitis patient will really appreciate ORTHO Dienestrol Cream:

TRADEMARK



(dienestrol 0.01%)

1 Rapid relief of her symptoms – itching, burning, dyspareunia, discharge

© Ortho Pharmaceutical Corporation, 1975

2 Provides economical relief of her symptoms that's easy on her pocketbook...an important consideration if she's on long-term maintenance therapy or a fixed income

ndications: Dienestrol Cream is indicated for the reatment of postmenopausal and senile vulvo-aginitis, atrophic vaginitis, pruritus vulvae caused by atrophic changes in the vulval epithelium, dys-pareunia associated with atrophic vaginal epithe-lium, and for use prior to plastic pelvic surgery in menopausal cases. *Contraindications:* Malignancies or precarcinomatous lesions of the vagina or vulva. A statistically significant association has been re-ported between maternal ingestion during preg-nancy of diethylstilbestrol and the occurrence of vaginal carcinoma in the offspring. The use of diethylstilbestrol or any of its closely related con-geners is contraindicated in pregnancy. *Warning:* Vaginal adenosis has been reported in 30% to 90% of postpubertal girls and young women whose mothers received diethylstilbestrol or a closely related congener during pregnancy. This condition was found most frequently in those cases where DES had been given in early pregnancy (first 12 weeks). The significance of this finding with respect to potential for development of vaginal adenocarci-noma is unknown. Periodic examination of such patients is recommended. *Precautions:* In pruritus vulvae due to infectious conditions, the organism responsible for the infection should be treated with a specific agent. *Dosage:* One or two applicatorsful per day for one or two weeks, then gradually reduced to one-half initial dosage for a similar period. A maintenance dosage of one applicatorful, one to three times a week may be used after restoration of the vaginal mucosa has been achieved. *Supplied:* Available in 2.75 oz. (78 g) tubes with or without ORTHO* Measured-Dose Applicator.

DeVilbiss MINIDOP™ Model 610

The Compact Ultrasonic Diagnostic Instrument for Early Detection and Monitoring of Fetal Life

- Detects fetal life as early as 10 weeks from last menstrual period.
- A single integrated unit, designed to be operated with one hand. Completely portable — powered by two nine-volt batteries.
- Large circular speaker delivers tones with improved amplitude and fidelity.
- Available in two frequency ratings: 5 MG Hz for early detection of fetal life, and 2 MG Hz for precise monitoring of fetal heartbeat during the latter stages of pregnancy.

For a demonstration, or more information, contact your local DeVilbiss representative.

Instructions to authors

Submission of contributions. Manuscripts should in general be sent to a particular Editor according to the following plan: If it is from the southeastern quadrant of the United States or from Canada, or if it has been presented before one of the official sponsoring societies, to Dr. Brewer; if from the northeastern quadrant (including Ohio), or if it is a Clinical Opinion or a Letter to the Editors, to Dr. Zuspan; if from the north central states, any of the United States west of the Mississippi, Hawaii, Alaska, or abroad, to Dr. Quilligan.

All articles published in this Journal must be contributed to it exclusively. Articles previously published in another language are not acceptable.

It is assumed by the Editors that articles emanating from a particular institution are submitted with the approval of the requisite authority, **including all matters pertaining to human studies.** Articles dealing with human experimentation cannot be accepted unless the experiment was approved by the author's local Human Experimentation Committee.

Statements and opinions expressed in the articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or publisher and the Editor(s) and publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the publisher guarantee, warrant, or endorse any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

Manuscripts. Manuscripts should be typewritten on one side of the paper only, with double spacing and liberal margins. The original and one copy of the manuscript are required. References should be placed at the end of the article and should conform to the style of the Cumulated Index Medicus, viz., name of author, article title, name of periodical, volume, page, and year. Authors are encouraged to limit references to *16, except* for Communications in Brief, limited to *2,* Current Investigation and Clinical Opinion, limited to *6,* and Current Developments for which there is *no* limit. Illustrations accompanying manuscripts should be numbered, provided with suitable legends, and marked lightly on the back with the author's name. Authors should indicate on the manuscript the approximate position of tables and text figures.

Tables should be typed on separate sheets of paper, not in the text, with one table to a page. They should be numbered in sequence and each must be referred to at an appropriate point in the text. Captions of the tables should be brief, yet indicate clearly the purpose or content of each table. Rows and columns in the table should precisely define the nature of the data in each. Abbreviations in tables should be used as little as possible and if abbreviations are used they should be explained in a footnote to the table.

An abstract of 50 to 150 words, to be published as an introduction, should accompany each manuscript and should be typed on a separate sheet of paper.

A footnote should be included which gives the name and complete mailing address of the person to whom reprint requests and correspondence should be sent.

A Guide to Writing for the American Journal of Obstetrics and Gynecology may be obtained from the Publisher on request.

Illustrations. A reasonable number of halftone illustrations will be reproduced free of cost to the author, but special arrangements must be made with the Editors for color plates, elaborate tables, or extra illustrations. Original drawings or graphs should be drawn with black India ink. Typewritten or freehand lettering is not acceptable. All lettering must be done professionally. Do not send original art work, x-ray films, or ECG tracings. Glossy print photographs are preferred, for good black and white contrast is essential.

Announcements. Announcements of meetings must be received by Dr. Brewer at least 2½ months prior to the time of the meeting. Such announcements should concern major meetings and other significant activities. Announcements of symposia or seminars for which fees are charged are not published in the scientific pages of the Journal but may be submitted for paid advertisements, if desired.

Letters to the Editors: A brief Letter to the Editors commenting upon some article which has appeared in the Journal will be considered for publication. The writer of the original article will have an opportunity to reply to unfavorable comments. A brief case presentation of special interest in the form of a Letter to the Editors will also be considered for publication. All such letters should be sent to Dr. Zuspan.

Books. Books received will be listed in the Journal. They should be sent to Dr. Gerbie.

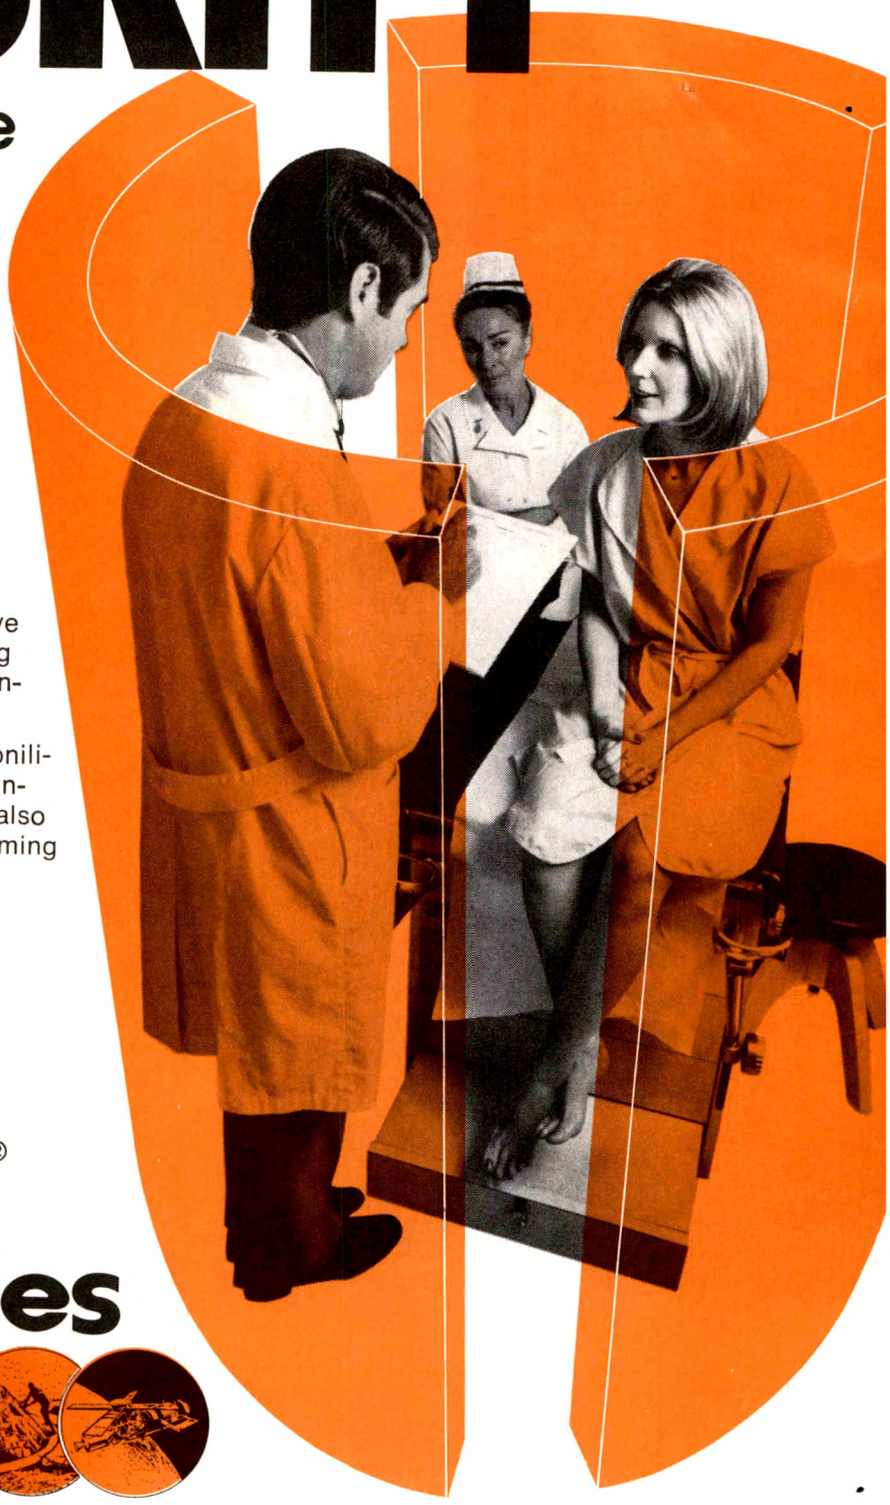
Reprints. Reprints of articles must be ordered from the Publishers, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63141, who will send their schedule of prices. Individual reprints of an article must be obtained through the author.

ANTISEPTIC SECURITY

in Ob/Gyn practice

Prompt, broad-spectrum action of BETADINE Microbicides provides topical antiseptic security for patients, physicians and nurses

BETADINE Solution Microbicidal Applicator, the only 8½″ long, disposable antiseptic-impregnated swabstick, is indicated for degerming hard-to-reach sites, such as the cervix, vulvovaginal, perineal and anorectal areas



BETADINE Solution, for prepping skin, vagina and perineum, and for general antiseptic use on skin, mucosa and wounds

BETADINE Surgical Scrub, for preoperative scrubbing and for hand and skin degerming (In the rare instance of local irritation or sensitivity, discontinue use in the individual)

BETADINE Douche, for treating vaginal moniliasis, *T. vaginalis* vaginitis and nonspecific infectious vaginitis (*H. vaginalis* vaginitis)... also ideal for routine cleansing, due to its degerming and deodorizing properties

**Institutional (multiple-reader) subscriptions are available to public and private libraries, schools, hospitals, and clinics; city, county, state, provincial, and national government bureaus and departments; and all commercial and private institutions and organizations.

†Personal subscriptions and all student-rate subscriptions must be in the names of, billed to, and paid by individuals. All student-rate requests must indicate training status and name of institution.

Publication order. The semimonthly issues of this Journal form three volumes per year; the index is in the last issue of the volume—in the April 15, August 15, and December 15 issues.

Change of address notice. Six weeks' notice is required to effect a change of address. Kindly give the exact name under which a subscription is entered, the name of this Journal, and the full form of both old and new addresses, including the ZIP code number.

Advertisements. Forms close 25th of second previous month for the 1st of month issue; 15th of preceding month for the 15th of month issue. Advertising rates and page sizes will be given on application. Neither the Editor(s) nor the publisher guarantee, warrant, or endorse any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

Bound volumes. Publishers' Authorized Bindery Service, 4440 West Roosevelt Road, Chicago, Illinois 60624, will quote prices for binding complete volumes in permanent buckram.

Published semimonthly

Subscriptions may begin at any time.

Nearly everybody believed that a very low dose oral contraceptive automatically meant a high incidence of breakthrough bleeding.

11,085 cycles later...

LO/OVRAL®

averaged only 3.9% breakthrough bleeding in total cycles.

Combination oral contraceptive—low estrogen and low progestogen.

Unsurpassed contraceptive effectiveness.

Extremely low incidence of minor side effects.*

Ready acceptance.

Convenient dosage in easy-to-use Pilpak® dispenser.

Low dose oral contraceptive—no other combination is more effective

Despite the fact that LO/OVRAL contains only 0.3 mg. norgestrel and 0.03 mg. ethinyl estradiol, contraceptive effectiveness is comparable to that of higher-dosage combinations. In clinical trials with LO/OVRAL encompassing 1,287 patients for a total of 11,085 cycles, only one pregnancy was reported. By Pearl's formula, this is a pregnancy rate of 0.12 per 100 woman-years' usage.

Minor side effects—even breakthrough bleeding—have been remarkably infrequent

In clinical trials the incidence of breakthrough bleeding in the initial cycle was only nine percent. And even that low incidence decreased to an average of only 3.9 percent as cycles progressed.

Incidence of Breakthrough Bleeding in Premarketing Clinical Trials

Cycle	1	3	6	12	Total Cycles 11,085
Breakthrough Bleeding	9.0%	3.5%	2.7%	2.6%	3.9%

Acceptance has been excellent

The low incidence of minor side effects has resulted in ready acceptance of LO/OVRAL by the great majority of patients. Patient complaints have been infrequent. Only eight percent of women participating in clinical trials discontinued LO/OVRAL because of common side effects.

Steroidal balance and norgestrel make the difference

Although total steroids in LO/OVRAL are reduced by 40 percent, the time-proved progestogen-estrogen ratio of OVRAL** is retained. This, together with norgestrel's distinctive qualities, is largely responsible for the patient comfort and acceptance experienced to date. Unlike other progestogens in current use, norgestrel is non-estrogenic, is apparently not converted to estrogen *in vivo* and closely resembles natural progesterone in its progestogenic activity.

Simple to take

The dosage regimen with LO/OVRAL is convenient and easy to follow: 3 weeks on, 1 week off. The attractive, uncomplicated Pilpak® dispenser helps patients follow the right dosage schedule.

*Serious as well as minor adverse reactions have been reported following the use of all oral contraceptives. The physician should remain alert to their earliest manifestations and in the event of serious adverse reactions should avoid any oral contraceptives. *Special note, contraindications, warnings, precautions and adverse reactions* in the accompanying IN BRIEF should be carefully considered.

**OVRAL® each tablet contains 0.5 mg. norgestrel with 0.05 mg. ethinyl estradiol, Wyeth.

Important information on next page.

Wyeth Laboratories
Philadelphia, Pa. 19101

LO/OVRAL®

each tablet contains 0.3 mg. norgestrel with 0.03 mg. ethinyl estradiol, Wyeth

Low dose oral contraceptive.

IN BRIEF:

SPECIAL NOTE: Oral contraceptives have been marketed in the United States since 1960. Reported pregnancy rates vary from product to product. The effectiveness of the sequential products appears to be somewhat lower than that of the combination products. Both types provide almost completely effective contraception.

An increased risk of thrombotic, thromboembolic and cerebral-vascular disease associated with the use of hormonal contraceptives has been shown in studies conducted in both Great Britain and the United States. Other risks, such as those of elevated blood pressure and reduced tolerance to carbohydrates, have been reported, and appropriate tests should be conducted to monitor these during oral-contraceptive therapy. Liver disease has also been reported, and the physician should be alert to its earliest manifestations.

Long-term administration of both natural and synthetic estrogens in subprimate animal species in multiples of the human dose increases the frequency for some animal carcinomas. These data cannot be transposed directly to man. The possible carcinogenicity due to the estrogens can neither be affirmed nor refuted at this time. Close clinical surveillance of all women taking oral contraceptives must be continued.

INDICATIONS: For oral contraception.

CONTRAINDICATIONS: 1. Thrombophlebitis, thromboembolic disorders, cerebral-vascular disease, or a past history of these conditions; 2. Markedly impaired liver function; 3. Known or suspected carcinoma of the breast; 4. Known or suspected estrogen-dependent neoplasia; 5. Undiagnosed abnormal genital bleeding; 6. Known or suspected pregnancy.

WARNINGS: 1. The physician should be alert to the earliest manifestations of thrombotic and thromboembolic disorders, thrombophlebitis, cerebrovascular disorders including hemorrhage, pulmonary embolism and retinal thrombosis. Should any of these occur or be suspected, the drug should be discontinued immediately.

Retrospective studies of morbidity and mortality in Great Britain and studies of morbidity in the United States have shown a statistically significant association between thrombophlebitis, pulmonary embolism and cerebral-vascular disease, occlusive or hemorrhagic, and the use of oral contraceptives. There have been three principal studies in Great Britain[1-3] leading to these conclusions and three[4-7] in this country. The estimate of the relative risk of thromboembolism in the study by Vessey and Doll[3] was about sevenfold, while the United States studies found relative risks of 4.4 to 11, meaning that the users are several times as likely to undergo thromboembolic disease without evident cause as non-users.

In May, 1974, the Royal College of General Practitioners in England[8] issued an interim report of its continuing large-scale prospective study comparing a user group to a non-user group. This study in its interim analysis states: "A statistically significant higher rate of reporting of cerebrovascular accidents in Takers is evident, but the numbers are too small to justify an estimation of the degree of risk." The study also reported a higher incidence of superficial and deep vein thrombosis in users as compared to non-users.

The Sartwell study[4] indicated that the risk did not persist after discontinuation of administration. Both the Sartwell and the Royal College study indicated that the degree of risk was not associated with duration of treatment.

In a collaborative American study[5,6] of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the relative risk of thrombotic stroke was 4.1 to 9.5 times greater in users than in non-users. A comparable estimate for hemorrhagic stroke was 2.0.

None of the American studies was designed to evaluate a difference between products. However, the Sartwell study[4] suggested that there might be an increased risk of thromboembolic disease in users of sequential products.

Other retrospective studies[9,10] have reported an increased risk of post-surgery thromboembolic complications in oral-contraceptive users. It has been recommended that therapy be discontinued at least one month prior to elective surgery.

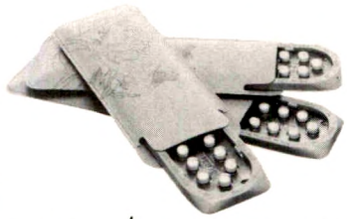
2. Discontinue oral-contraceptive medication if there is: gradual or sudden, partial or complete loss of vision; proptosis or diplopia; onset or aggravation of migraine or development of headache of a new pattern which is recurrent, persistent or severe; papilledema; or any evidence of retinal-vascular lesions. 3. Fetal abnormalities have been reported to occur in the offspring of women who have taken progestogens and/or estrogens during pregnancy.[11,12] The safety of LO/OVRAL® in pregnancy has not been demonstrated. Pregnancy should be ruled out before initiating or continuing the contraceptive regimen. Pregnancy should always be considered if withdrawal bleeding does not occur. 4. A small fraction of the hormonal agent in oral contraceptives has been identified in the milk of mothers receiving these drugs. The long-range effect to the nursing infant cannot be determined at this time. 5. Hepatic lesions (adenomas, hepatomas, hamartomas, regenerating nodules, etc.), occasionally fatal, have been reported in women on oral contraceptives. Such lesions may present as an abdominal mass or with the signs and symptoms of an acute abdomen. These lesions should be considered if the patient has abdominal pain or evidence of intra-abdominal bleeding. Such lesions have been reported in short-term as well as long-term users of oral contraceptives.

PRECAUTIONS: 1. A thorough history and physical examination should be performed before prescribing oral contraceptives and periodically during their administration and should include special reference to breasts and pelvic organs including Papanicolaou smears, since estrogens have been known to produce tumors, some of them malignant, in five species of subprimate animals. 2. Endocrine and possibly liver-function tests may be affected by treatment with LO/OVRAL® Therefore, if such tests are abnormal in a patient taking LO/OVRAL® it is recommended that they be repeated after the drug has been withdrawn for two months. 3. Under the influence of estrogen-progestogen preparations, pre-existing uterine fibromyomata may increase in size. 4. Because these agents may cause some degree of fluid retention, conditions which might be influenced by this factor, such as epilepsy, migraine, asthma, cardiac or renal dysfunction, require careful observation. 5. In breakthrough bleeding, and in all cases of irregular bleeding per vaginam, nonfunctional causes should be borne in mind. In undiagnosed bleeding per vaginam, adequate diagnostic measures are indicated. 6. Patients with a history of psychic depression should be carefully observed and the drug discontinued if the depression recurs to a serious degree. 7. Any possible influence of prolonged LO/OVRAL® therapy on pituitary, ovarian, adrenal, hepatic or uterine function awaits further study. 8. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. The mechanism of this decrease is obscure. For this reason, diabetic patients should be carefully observed while receiving LO/OVRAL® therapy. 9. The age of the patient constitutes no absolute limiting factor, although treatment with LO/OVRAL® may mask the onset of the climacteric. 10. The pathologist should be advised of LO/OVRAL® therapy when relevant specimens are submitted. 11. Susceptible women may experience an increase in blood pressure following administration of contraceptive steroids. 12. Cholestatic jaundice has been reported in users of oral contraceptives. If this occurs, LO/OVRAL® should be discontinued. This condition is more likely to occur in patients who have experienced cholestatic jaundice of pregnancy. Patients with a history of cholestatic jaundice of pregnancy should be carefully observed during LO/OVRAL® therapy.

ADVERSE REACTIONS OBSERVED IN PATIENTS RECEIVING ORAL CONTRACEPTIVES: A statistically significant association has been demonstrated between use of oral contraceptives and the following serious adverse reactions: thrombophlebitis, pulmonary embolism, cerebral thrombosis and hemorrhage, gall bladder disease.

Although available evidence is suggestive of an association, such a relationship has been neither confirmed nor refuted for the following serious adverse reactions: neuro-ocular lesions, e.g., retinal thrombosis, optic neuritis and hepatic lesions with or without intra-abdominal bleeding.

The following adverse reactions are known to occur in patients receiving oral contraceptives: nausea, vomiting, gastrointestinal symptoms (such as abdominal cramps and bloating), breakthrough bleeding, spotting, change in menstrual flow, amenorrhea during and after treatment, edema, chloasma or melasma, which may persist, breast changes: tenderness, enlargement and secretion, change in weight (increase or decrease), changes in cervical erosion and cervical secretions, suppression of lactation when given immediately post-partum, cholestatic jaundice, migraine, rash (allergic), rise in blood pressure in susceptible individuals, mental depression.



Although the following adverse reactions have been reported in users of oral contraceptives, an association has been neither confirmed nor refuted: anovulation post treatment, which tends to occur more frequently in women with a history of menstrual disorders, premenstrual-like syndrome, changes in libido, changes in appetite, cystitis-like syndrome, headache, intolerance to contact lenses, nervousness, dizziness, fatigue, backache, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, itching and vaginitis.

The following laboratory results may be altered by the use of oral contraceptives: hepatic function; increased sulfobromophthalein retention and other tests; coagulation tests; increase in prothrombin, Factors VII, VIII, IX and X; decrease in antithrombin III; increase in platelet aggregability; thyroid function: increase in PBI, and butanol extractable protein-bound iodine and decrease in T^3 uptake values; metyrapone test; and pregnanediol determination.

NOTE: For more specific details on LO/OVRAL, refer to package insert.

OBSTETRICS

Improvement of faculty teaching performance in a department of obstetrics and gynecology by student evaluation

SANFORD SALL, M.D.
DONALD S. GROMISCH, M.D.
SAMUEL H. RUBIN, M.D.
MARTIN L. STONE, M.D.
New York, New York

The primary purpose of a faculty evaluation program is to upgrade the over-all quality of teaching and to identify the strengths and weaknesses of the individual teacher. Effective medical educators can thereby be suitably identified by objective and subjective criteria. Improvement of faculty teaching performance enhances student learning and can improve recruitment into our discipline.

WITHIN RECENT YEARS, there has been an increased awareness by faculty and students of the need for improvement in the delivery of medical education. Student pressures with faculty acquiescence, although sometimes reluctant, have fostered revision of traditional curricula, introduced selective and elective time for pursuit of special interests, restructured laboratory exercises, encouraged the development and use of self-instructional material, and promoted more exposure to small group teaching. Although these efforts would appear to be of educational benefit, results of the evaluation systems built into these new programs are presently awaited.

Likewise, the medical educator is now under scrutiny by the school administration, departmental chairman, colleagues, and the students he teaches. Traditionally, a teacher of medical students should have a strong academic orientation in the clinical or preclinical sciences, with specialized training perhaps in one area of his discipline. He should communicate his ideas with facility and assist the students in the acquisition of medical knowledge, provide suitable motivation, and develop the autonomy of self achievement. Medical education has developed over the years in accordance

Table I. The evaluation form in current use broken down into its seven categories

Planning for class and organization
1. The instructor clearly stated the objectives of the course or the seminar at the outset.
3. The instructor's presentation was disorganized and hence hard to follow.
8. The instructor organized the material in a logical sequence.
22. The instructor stressed basic problems and restated issues to prevent the group from losing sight of the objectives.
23. The instructor allowed ample time for questions.
30. The instructor summarized the most important points periodically.

Communication
4. The instructor spoke too fast and was hard to follow.
5. The instructor used inappropriate technical jargon.
6. The instructor made an effort to clarify terms to avoid misunderstanding.
11. The instructor responded to questions in a concise and clear manner.
14. The presentation was suited to the student's level of sophistication.

Teaching personality (cognitive)
12. The instructor's presentation indicated a thorough knowledge of his subject.
18. The instructor's biases interfered with his presentation.
20. The instructor seemed quite impressed with his own knowledge.
26. The instructor monopolized the course (or seminar) by exhibiting his brilliance.
28. The instructor at times gave the impression that he was trying to bluff his way through a point he didn't fully understand.
32. The instructor would not admit not knowing the answer to a question.

Teaching personality (affective)
7. The instructor displayed sincere interest in his subject.
16. The instructor is available for consultation outside of the course (or seminar).
27. The instructor was free of disturbing mannerisms.
29. The instructor showed sincere interest in students.
33. The instructor was courteous.
35. The instructor's attitude toward patients seemed compatible with your concept of how a physician should behave.

Motivation
2. The instructor began teaching by arousing interest in the subject.
15. The instructor posed problems for students to solve.
21. The instructor made a real effort to stimulate students to think.
25. The instructor invited student comments instead of providing all the answers.
36. The instructor was so stimulating that you began to consider a career in his specialty.

Instructional techniques or methods
9. Instructional methods were in keeping with the announced objectives.
17. The instructor used audiovisual aids in a manner that detracted from his presentation.
24. The use of additional teaching aids would have provided a better learning experience.
38. The instructor relied excessively on audiovisual teaching aids.
39. Patients were used in a manner to enhance the learning experience.

Subject or content
10. The content was compatible with what has been learned from other courses and from readings.
13. The instructor's presentation was merely a repetition of the textbook.
19. The instructor presented divergent viewpoints for contrast and comparison.
31. The content was relevant to general medical education.
34. The material presented by the instructor will be a building block for future learning experiences.
37. The material presented by the instructor has relevance to your future career.

with individualistic philosophies and with a variation of experiences. Some highly creative educators show a preference for complexity and novelty with an interest in learning situations that require complicated resolutions, and others place a higher value on practical matters and utility. Some in medical education are oriented to achievement of their students and others to their own academic advancement.

At the New York Medical College a project was undertaken to improve teaching performance by faculty evaluation and subsequent teacher training. The enhancement of effective student learning was the primary goal of this research effort in medical education.

Background

A pilot project was started in 1969 to achieve more effective faculty performance in education by facilitating the acquisition of special teaching skills, knowledge, and attitudes which could then be translated by actions into effective student learning. A Medical Education Committee consisting of five full-time members of the faculty (Obstetrics-Gynecology, Pediatrics, Urology, and Internal Medicine) was chosen by the Dean because of their stated common interests in medical education, their motivation to devote time to the project, and their willingness to use their learning to improve instruction in their respective departments. The initial project was designed to evaluate the

teaching skills of individual faculty members and to use these data to help these instructors improve their teaching ability by highlighting not only their weaknesses but their strengths.[1–3]

Over a period of many months the Committee discussed the criteria which contribute to effective teaching and recorded a total of several hundred positive and negative factors. Ultimately, the most critical factors were put into question form and a total of 39 such questions evolved (Table I). Seven key aspects of teaching: planning and organization, communication, cognitive teaching personality, affective teaching personality, motivation, instructional techniques or methods, and subject or content, were appropriately distributed in the questionnaire. Since it is the learner himself who judges how best he learns, it was thought appropriate to have the principal evaluation of teaching skills evaluated by the recipient of that knowledge—the medical student.

At each phase of the development of the evaluation form, trials were run by having randomly selected members of the Junior class evaluate volunteer faculty participants. The questionnaire included a five-point scale multiple choice response, ranging from "strongly agree" to "strongly disagree" (or vice versa if the statement was negatively worded). During the pretest stages, efforts were made to ascertain the validity, accuracy, and reproducibility of the evaluation form. Use of informal faculty evaluation forms previously developed by our students correlated extremely well with the evaluation forms presently developed.

Each of the question responses was fed into the computer in a manner to yield a print out of the responses according to the seven key aspects of teaching previously mentioned.

Methods

All faculty participation was voluntary and an evaluation coordinator for the program was designated by each departmental chairman. These coordinators were responsible for describing the evaluation program to their departmental colleagues and for the distribution and collection of the forms. All students were briefed as to the objective of the evaluation—improvement of student learning by improvement of teaching. At the completion of each participating teacher's exposure to the students, the evaluation form was filled out anonymously and forwarded to the Medical Education Committee and sent to the computer center for analysis.

The entire Junior class, consisting of 135 students, were respondents. Five members of the Department of Obstetrics and Gynecology were evaluated by at least 40 students. Based on the responses of all students participating, an average score for each topic and an average score for all five topics were derived for each instructor, giving a set of six "student rankings." Each instructor was then ranked, within their respective departments, by topic score and over-all score.

As a corollary to this original study, the chairman was asked to cooperate in a comparative study. The chairman was asked to complete a rating sheet for those instructors in his department previously evaluated by the student. As previously computed for the student evaluations, there was a set of six "chairman rankings." Additionally, the chairman was asked to rank his instructors by usual criteria, without considering the detailed questionnaire ("chairman sequence").

Results

The Chairman of Obstetrics and Gynecology's ranking agreed with the student identification of the two lowest ranked instructors (Table II). Although the three highest rated instructors were identified by both students and chairman, there was no agreement in their place rank.

A comparison of the ratings by students and chairman of the over-all teaching performance of the instructors evaluated (Table III) indicates that the chairman consistently rated his faculty better.

Table IV indicates that for all of the categories

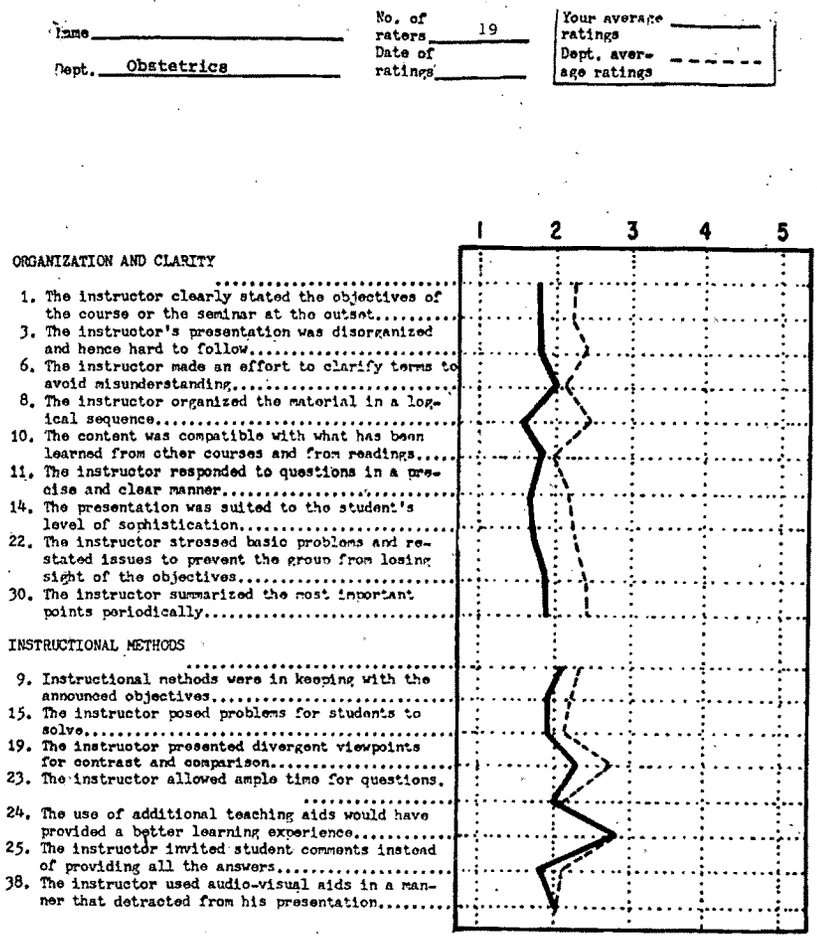

Fig. 1. Evaluation scores and instructor profiles.

evaluated and for the over-all score none of the correlations between rankings of instructors as derived from students and those by the chairman was significant at the 0.05 level.

Comment

Any teacher evaluation program can be considered threatening to many members of a faculty, and the major objective of improvement of teaching skills must be stressed.[4] Likewise, evaluation scores and instructor profiles (Fig. 1) should be kept confidential and made available only to the individual instructor. From our experience it would appear that the majority of our departmental faculty was eager to cooperate in this evaluation.

Within recent years the qualities of a medical educator have assumed equal importance in judging a faculty member's contribution to his department, whereas previously only research potential, clinical ability, number of grants, and publications were considered. Unfortunately, there are only two ways to judge teaching through the medium of the students[5]: The objective criterion is based on what students have learned from the teacher, and the subjective criterion is based on student evaluations of teacher effectiveness. In 1960, 40 per cent of institutions of higher learning engaged in student evaluations of instructors and in the 1970's this should increase.[6] With few exceptions, medical schools have lagged behind in the adoption of systematic student evaluation of faculty. Student evaluation is but one means of assessing an individual's teaching skills and can form an integral part of an instructor's teaching profile. This profile can be utilized in the pinpointing of strengths and weaknesses in an individual's teaching capabilities.

Our initial studies show some disagreement between the departmental chairman and student evaluation of "teacher effectiveness." There were differences as well between the "chairman rankings" and "chairman sequence." A chairman's over-all appraisal of a faculty member includes more factors than his evaluation of that person as a teacher. A hard-working, productive, nondemanding faculty member may be rated very highly by the chairman, yet he may not be an

§Correlation of chairman's sequences assigned to instructors by chairman with chairman's rating.

outstanding teacher. The differences between student and chairman rankings may be due to several factors. The chairman may not adequately audit the teaching sessions of his faculty and be aware of the strengths and weaknesses of his instructors. The fact that the chairman is usually a teacher himself creates a natural bias and he cannot view his faculty through the eyes of students who base their evaluations on teaching skills and not on objective test results.

Phase 2 of this project is the discussion of the "profile" with each instructor evaluated by the Medical Education Committee. The participating teacher is invited to meet with the Committee to review his profile and methods for self-improvement will be discussed. Some faculty members may feel uncomfortable discussing their educational strengths and weaknesses with colleagues and every effort is made to overcome this problem through mutual trust, freedom from coercive or disciplinary potential, and confidence.

Table V. Effect of profile on teaching performance

Rating	Instructor				
	I	*II*	*III*	*IV*	*V*
Before profile					
02	2.26	2.14	2.07	2.44	2.43
04	1.86	2.08	1.95	2.15	2.10
05	1.73	2.20	2.09	2.15	2.06
After profile					
02	1.95	1.87	1.82	1.91	2.06
04	1.77	2.05	1.75	1.94	2.20
05	1.73	1.98	1.78	1.99	2.13

Of interest, however, is that the evaluated individual's review of his teaching profile appears to provide motivation for self-improvement, without formal remedial techniques. This is evident in the improvement in the profile of instructors (02, 04, 05) after receipt of their profile and student re-evaluation (Table V).

The primary goal of our department is educaton, undergraduate and graduate, and teaching in our department is done by senior faculty members (including the chairman), selected for their skills and ability to impart the knowledge that they have. If a faculty member is ineffective as a teacher, he is not given teaching assignments no matter what his rank or research achievements. This constant re-evaluation of faculty teaching in our department has improved student learning and is a major factor in our success in student recruitment into our specialty.[7]

The primary purpose of a faculty evaluation program is to upgrade the over-all quality of teaching in the medical school and to identify the strengths and weaknesses of the individual teacher. Ancillary benefits of teacher evaluation is the ability by objective and subjective criteria to identify effective medical educators and reward them in similar fashion to prolific writers, grant recipients, and productive researchers. The provider and consumer in medical education must find some common ground for the definition and measurement of good teaching. Until this occurs, there is little chance for improvement in learning experience and effectiveness.

Changes in evolution of free epinephrine, norepinephrine, and vanillylmandelic acid in the urine of rabbits during late pregnancy and parturition

S. PARVEZ
H. PARVEZ
Orsay, France

The present study describes evolutionary changes in urinary excretion of epinephrine, norepinephrine, and vanillylmandelic acid during pregnancy and parturition. Both the catecholamines and their metabolite were determined in 24 hour urine samples of rabbits from day 13 of pregnancy. During 13 and 28 days of gestation, urinary excretion of epinephrine was at its lowest value. As compared to normal rabbits, an increase of 135 per cent in epinephrine excretion during day 30 of pregnancy was observed. Norepinephrine excretion reached its maximum level during day 13 but constant declines occurred afterward. Contrary to epinephrine, urinary excretion of norepinephrine was at the highest value days 23 and 30 of pregnancy. After day 19 vanillylmandelic acid declined continuously up to day 30. During parturition vanillylmandelic acid and norepinephrine excretion returned to the control values but epinephrine remained slighly higher. These alterations in catecholamine urinary excretion have been suggested as a consequence of modified endocrine and sympathetic activity.

THE PRESENCE and physiologic role of biogenic amines and their metabolites has been known for several years.[1] The importance of catecholamines during pregnancy has been considered mainly to be of interest in the diagnosis of pheochromocytoma.[2] Cyclic changes in concentration of uterine epinephrine were observed earlier.[3–5] Adrenergic receptor activity of catecholamines in gestational myometrium also varies to a great extent.[6–8] Very few studies have been performed to determine the influence of pregnancy and parturition on urinary excretion of epinephrine and norepinephrine.[9–11] Most of the past observations are highly speculative and limited to human beings. Among all the investigators, Zuspan[11] was the only one who determined the excretion of epinephrine and norepinephrine in urine samples collected for 24 hours. He noticed increased excretion of both epinephrine and norepinephrine during the first 24 hours following delivery but only the increase in norepinephrine excretion was statistically significant. Our recent paper shows important changes in urinary catecholamine levels throughout pregnancy in rats. We also observed statistically significant increases in plasma epinephrine on days 30 and 31 of gestation in rabbits.[13] The present study was designed to determine pregnancy-induced alterations in urinary excretion of catecholamines. Parallel determinations of urinary vanillylmandelic acid were also made. Such a study has not been performed previously in rabbits.

Methods

Albino rabbits of New Zealand strain were utilized throughout the experiments. The females were made pregnant by keeping one male with one female for 1 hour under constant observation. After copulation, the females were separated immediately and kept in individual stainless steel cages. They were verified for pregnancy by palpation 14 days after copulation. Under normal conditions parturition occurred between days 31 and 32 of pregnancy.

Collection of urine. Twenty-four hour urine was collected by placing one pregnant rabbit in an indi-

vidual metabolic cage. The surrounding walls of the metabolic cages were made of high-quality stainless steel. The bottoms of the cages which were open were equipped with Armodur funnels (special synthetic material which does not interfere with trihydroxindole procedure). Special separating discs made of Armodur were placed on the top of the funnels. Both the funnels and the discs were well rinsed with twice-distilled water and finally with 2N HCl. This procedure prevented the urine from being in contact with the metallic part of the metabolic cages and also provided for the separation of feces from urine. The urine was collected in 500 ml. Pyrex flasks containing 5 ml. of 5N HCl. Throughout urine collection, the temperature was maintained at 20° C.

Separation of urinary catecholamines. Epinephrine and norepinephrine were separated by their adsorption on acid-activated aluminum oxide.[14] The batch

process was preferred to column chromatography.[16] The acid-activated aluminum oxide was well rinsed with 2 × 25 ml. twice-distilled water. The urine was mixed and filtered and 25 ml. of it was adjusted to pH 8.4 by addition of different concentrations of NaOH solution (0.2 to 2N). The urine at pH 8.4 was transferred to a beaker containing 1 Gm. of washed aluminium oxide and stirred constantly. The pH was maintained at 8.4 by a direct-reading glass electrode pH meter. After 5 minutes of stirring, the urine was centrifuged for 1 minute at 5,000 × g and the supernatant was discarded. The alumina was washed with 15 ml. of twice-distilled water and centrifuged and the supernatant was discarded. Epinephrine and norepinephrine were eluted with addition of 4 ml. of 0.25N acetic acid.[16] After thorough mixing the acid supernatant was separated from the alumina for fluorometric estimation of catecholamines. The total

Fluorometric assay of catecholamines. The method of Euler and Lishajko[16] utilizing the trihydroxindole reaction was applied. Fluorescence was measured with an Eppendorf apparatus. The results are expressed in micrograms per kilogram of body weight per 24 hours. This method of expressing results for urinary excretion of catecholamines has been widely employed by von Euler and many others.[17–20] The later authors adopted this method of expressing results to compare catecholamine excretion in many different species. Recently some correlation between body weight and

*E, Epinephrine; N, norepinephrine; VMA, vanillylmandelic acid. The total excretion of free E and N as well as E + N + VMA have been provided to evaluate total changes. The percent increases in E and N calculated from their respective control values show the influence of one catecholamine on another one. E(E + N) is a rough estimation of rate of norepinephrine conversion to epinephrine.

catecholamine excretion has been observed. Therefore, catecholamine excretion in micrograms per kilogram per 24 hours takes into account all the changes possibly induced by variations in body weight from one animal to another, especially during late pregnancy.

Assay of vanillylmandelic acid. Vanillylmandelic acid was assayed spectrophotometrically by its conversion to vanillin with several modifications of the previous techniques.[21, 22] A 5 ml. sample of urine was used for each determination. Final extraction was made in 4 ml. of potassium carbonate to avoid the use of micro cells. The optical density was measured on a Beckman DBT spectrophotometer at 360 mμ. The extraction of vanillylmandelic acid was linear within concentrations of 10 to 150 μg. The details of the method are published elsewhere.[23]

Statistical analysis was performed according to the method of Fisher, utilizing Student's t test. The means are expressed with standard errors.

Results

Fig. 1 illustrates the evolutionary changes in urinary epinephrine in micrograms per kilogram per 24 hours from day 13 of pregnancy to parturition. Constant increases in epinephrine excretion were observed up to days 23/24 of pregnancy. At days 23/24 urinary epinephrine was markedly higher than on days 13/14. Afterward, constant declines occurred up to days 28/29. During days 28/29 epinephrine was at its lowest value. This decline was followed by increased epinephrine output on days 29/30 and 30/31. Urinary excretion of epinephrine reached its maximum value during days 30/31 of pregnancy. Parturition at day 31 or 32 showed constant declines in excretion of this hormone.

The alterations in urinary excretion of norepinephrine during last part of pregnancy and parturition are shown in Fig. 2. Urinary norepinephrine demonstrated continuous declines in its excretion during days 13/14 to 23/24 of pregnancy. At days 23/24 urinary epinephrine was tenfold lower than on days 13/14. The excretion started to rise afterward up to days 28/29. These increases were followed by constant declines again to days 30/31. At parturition on day 31 or 32 the output of norepinephrine again started to increase. At parturition norepinephrine excretion was nearly the same as in the nonpregnant rabbits.

Fig. 3 shows the evolutionary pattern of vanillylmandelic acid in the 24 hour urine of pregnant rabbits during days 13/14 of pregnancy to parturition. During days 13/14 and 19/20 of pregnancy excretion of this catecholamine acid metabolite increased. At days 19/20 this value was more highly increased than on days 13/14. Except for a small increase on days 26/27 continuous declines in urinary excretion of vanillylmandelic acid were observed. At days 30/31 of pregnancy the excretion was 3½ times lower than on days 13/14. Similarly to epinephrine and norepinephrine, vanillylmandelic acid showed increases in its excretion during parturition at day 31 or 32.

Table I provides a comparison during different days of pregnancy in the total excretion of epinephrine + norepinephrine + vanillylmandelic acid. The ratio epinephrine/(epinephrine + norepinephrine), which is a rough evaluation of the rate of norepinephrine conversion to epinephrine, is also provided. The per cent increases or decreases in epinephrine and

norepinephrine as compared with their respective nonpregnant values are also given. These ratios or per cent changes in all the catecholamines provide a rapid comparison between different days of pregnancy. The maximum increase in epinephrine + norepinephrine excretion occurred during days 13/14 of urine collection. The total excretion of epinephrine + norepinephrine + vanillylmandelic acid increased to the maximum value on days 19/20 of pregnancy. Except for days 13/14, 17/18, and 32/P, the per cent increases in epinephrine excretion as compared with control values were followed by declines in norepinephrine excretion. These increases provide direct relationship of urinary epinephrine with urinary norepinephrine.

Comment

The results of the present investigation are in agreement with our previous findings about the accelerated release of catecholamines in plasma of rabbits on days 30/31 of pregnancy. Urinary epinephrine and norepinephrine are mainly the product of catecholamines in plasma as 4 per cent of the total blood catecholamines are excreted in urine.[24] In our previous paper we suggested that the enhancement of plasma epinephrine results from adrenomedullary secretion due to its direct influence on catecholamine storage in the adrenal gland.[13] The increase in adrenomedullary secretion can be considered as an important factor for the rise in urinary excretion of epinephrine as any change in plasma catecholamines would directly affect urinary content of both epinephrine and norepinephrine. The present findings also show the highest increase on days 30/31 of pregnancy in urinary output of epinephrine, which is the principal hormone of the adrenal medulla; at the same time a strong decline in urinary norepinephrine occurred. This observation suggests that the increased epinephrine excretion is not only induced by an increased rate of adrenomedullary secretion but also by accelerated synthesis of epinephrine from norepinephrine in the adrenals: when there is increased epinephrine synthesis, less norepinephrine is available for secretion from the adrenals.

The findings of Zuspan[11] about the urinary excretion of epinephrine and norepinephrine in pregnant and parturient women show important increases in the output of both the amines. He noticed nearly twofold and threefold increases in epinephrine and norepinephrine, respectively, 24 hours after delivery, but only norepinephrine urinary excretion showed statistically significant differences from the antepartum or postpartum values.[11] These clinical observations appear difficult to compare with urinary excretion of epinephrine and norepinephrine in rabbits. In the rabbit we observed the maximum increase in urinary excretion of epinephrine on days 30/31 of pregnancy, which is at least 24 to 48 hours in advance of parturition. This maximum increase in epinephrine before labor cannot be considered due to the stress observed during labor and delivery, just as severe muscular exercise, operation, and trauma also produce an increase in the output of these hormones.[25–27] The findings of a similar study in human beings, goats, rats, sheep, and cats are difficult to compare with our present observations as in that study the urine was hydrolyzed prior to catecholamine estimation and the results express the total amount of free and conjugated epinephrine and norepinephrine.[28] Moreover, the latter investigators expressed their results in micrograms per 24 hours without taking in account the differences in body weight from one subject to another.

Our extensive studies on catecholamines in plasma, urine, and tissues in the rat throughout the duration of pregnancy, parturition, and postpaturition provide evidence that hormonal factors play an important role in the altered pattern of catecholamine regulation in gestation.[12, 29, 30] The activities of enzyme monoamine degradation (monoamine oxidase and catechol-O-methyl transferase) are also very low during the last part of pregnancy.[31] These declines in activities of enzyme monoamine oxidase and catechol-O-methyl transferase could be related to concentration changes of corticosteroids, progesterone, and estrogens during pregnancy. All these hormones have been shown to exert an important action on the enzymes of norepinephrine synthesis and degradation.[32–34] The respective increases and and declines in urinary epinephrine and norepinephrine on days 23/24 of pregnancy also suggest that catecholamine biosynthesis was affected on these dates. This is further evidence in favor of our hypothesis of direct participation of endocrine function with the regulation of biogenic amines in pregnancy. Recently it has been shown that plasma and serum cortisol in rabbits increases to its maximum value on day 30 of gestation and this increase is followed by a sharp decrease at parturition.[35] Peripheral plasma levels of progesterone in the rabbit during pregnancy also fluctuate to a great extent and these fluctuations are specially marked during the last days of pregnancy.[36] The action of all these hormones on catecholamine biosynthesis, release, and metabolism is well established and supports our hypothesis of endocrine involvement.

The variations in norepinephrine excretion could be related to epinephrine as most of the increases in epinephrine were followed by decreases in norepinephrine (Table I). Since a major portion of norinephrine in blood is released from sympathetic nerves, these declines in norepinephrine excretion could also be attributed to a decline in activity of the sympathetic nervous system. The decreased excretion of vanillylmandelic acid throughout the gestation results from decreased activities of enzymes of catecholamine metabolism.[31] When the catecholamines are degraded at a lower rate, the metabolite formation is also low.

The observed alterations in epinephrine, norepinephrine, and vanillylmandelic acid suggest that the processes of catecholamine excretion and metabolism are under hormonal influence during last part of pregnancy in rabbits. Our results on glycogen storage during pregnancy and under hormone administrations suggest markedly important declines in hepatic glycogen throughout the last part of pregnancy and these differences could be correlated with catecholamine variations.[37] An important link between catecholamines and different steroid hormones is proposed. A comprehensive review of all possible interactions between catecholamines, progesterone, estrogens, and many other hormones has been elaborately analyzed by Zuspan and his collaborators.[38]

The authors express their sincere thanks to S. Sohlberg of Gothenberg University, Department of Physiology, Sweden, for his generous participation and discussions in this project. We are indebted to M. B. H. Youdim of Oxford University, Department of Clinical Pharmacology, Oxford, England, for his encouragement, advice, and supply of useful literature. The technical assistance of Miss Danielle Telliez is gratefully acknowledged. The kind collaboration of Abid-Raza is also acknowledged. We are thankful to A. and E. Snood for kindly reading and correcting the language.

The content of catecholamines in the Fallopian tube and the uterus and the plasma levels of estradiol and progesterone were studied in cycling women. During the follicular phase norepinephrine levels were 33.4 ± 7.1, 50.5 ± 8.0, and 145.7 ± 43.6 ng. per gram of wet tissue in the external, middle, and internal segments of the Fallopian tube, respectively. During the luteal phase norepinephrine content increased significantly in the external and middle portions (219.3 ± 57.0 and 206.2 ± 34.3 ng. per gram) whereas it remained unchanged in the internal one (185.2 ± 53.6 ng. per gram). The NE content of the external and middle segments correlated significantly with plasma progesterone levels (r = 0.76 and 0.82, respectively, whereas oviductal epinephrine levels did not show significant changes as a function of the stage of the menstrual cycle. Uterine epinephrine content decreased by 67 per cent during the luteal phase whereas norepinephrine remained unchanged.

THE SIGNIFICANCE of the sympathetic nervous system in the regulation of the contractile activity of the oviduct has become apparent in recent years, since tubal dysfunction affects fertility.[1, 2] The smooth muscle of the Fallopian tube is innervated by adrenergic nerve fibers along its entire length.[3] Alpha- and beta-adrenergic receptors mediating changes in resting pressure[4] and motility[5] have been well demonstrated in human Fallopian tubes in vivo and in vitro. Norepinephrine, the sympathetic postganglionic neurotransmitter, is present in the circular muscular layer of the Fallopian tube, particularly in the isthmus, in which a high density of adrenergic terminals running parallel to the muscle fibers occurs. In addition, vascular sympathetic innervation has been demonstrated throughout the tube.[3]

Since the short adrenergic neurons innervating the genital tract exhibit functional properties that differentiate them from long adrenergic neurons,[6] a hypothesis can be postulated according to which these differences may be due in part to sex steroid action at the level of

the target organ. In the rabbit oviduct, for instance, norepinephrine levels are modified by the administration of estradiol or progesterone.[7] This article deals with the modifications in norepinephrine and epinephrine levels of different portions of the human Fallopian tube and the uterus as a function of the plasma levels of estradiol and progesterone. It will be shown that a regional distribution of catecholamines exists in the human tube and that norepinephrine content exhibits changes during the menstrual cycle which correlate with plasma progesterone levels.

Materials and methods

Tissues. Fallopian tubes were obtained from patients having a salpingectomy at the same time as hysterectomy. The tubes were divided into three zones as follows: (1) *internal,* the short portion (23 to 25 per cent) with a narrow lumen of about 0.2 to 0.5 mm. lying distal to the fundus; (2) *middle,* the longest portion (61 to 62 per cent) with its ever-widening lumen, from 1 to 2 mm. at the isthmus to 2 cm. near the distal end; (3) *external or infundibulum,* the distal portion terminating in the fimbriated end (13 to 14 per cent). In addition, myometrial and plasma samples were also taken.

Assays. Catecholamine concentration was measured spectrofluorometrically, as described by Laverty and Taylor,[8] after isolation by adsorption onto alumina at pH 8.6.[9] Internal and external standards were used in order to correct procedure losses. Recovery from alumina columns averaged 74 per cent.

Plasma progesterone and estradiol levels were determined by a double-antibody radioimmunoassay method. To measure progesterone, an antiserum produced in rabbits in response to 11-α-hydroxyprogesterone hemisuccinate-bovine serum albumin (BSA) was used.[10] Plasma diethylether extracts were processed in triplicate. Goat antirabbit gamma-globulin was utilized for separation of bound and free fractions. A standard curve was constructed for each assay with unlabeled progesterone at nine dose levels to give a range from 5 to 1,500 pg. Results were expressed in picograms per milliliter of plasma. Specificity of the antiserum was assessed by incubation with unlabeled 17-α-hydroxyprogesterone, 20-β-hydroxyprogesterone, pregnenolone, and corticoids. All the studied steroids failed to cross-react up to a maximal concentration of 10 ng. Sensitivity = 10 pg. could be distinguished from 0. The assay recovery was 88.0 ± 5.4 per cent.

To measure estradiol, antiserum of Wein Laboratories (Succasunna, New Jersey) was utilized. Extracts of plasma were purified by thin-layer chromatography and 25 pg. could be clearly distinguished from 0. The assay recovery was 63.0 ± 6.7 per cent.

Results

The levels of epinephrine and norepinephrine in different portions of normal human Fallopian tubes as a function of plasma levels of estradiol and progesterone are shown in Table I.

Despite the great variance in norepinephrine content among individual samples, a definite pattern of distribution could be established. During the proliferative phase of the menstrual cycle, norepinephrine levels of the internal portion of the Fallopian tube were two to threefold those of the external and middle portions. No differences were observed between the external and the middle segments. High levels of plasma progesterone and a four to sixfold increase in norepinephrine content of the Fallopian tube in the external and middle segments were observed in the luteal phase. In contrast, no significant changes were detected in the internal oviductal segment (Table I). Norepinephrine content of the external and middle portions of the human Fallopian tube correlated significantly with plasma progesterone (Figs. 1 and 2) but not with plasma estradiol. In addition, no correlation was observed between tubal norepinephrine content and plasma estradiol, nor between epinephrine

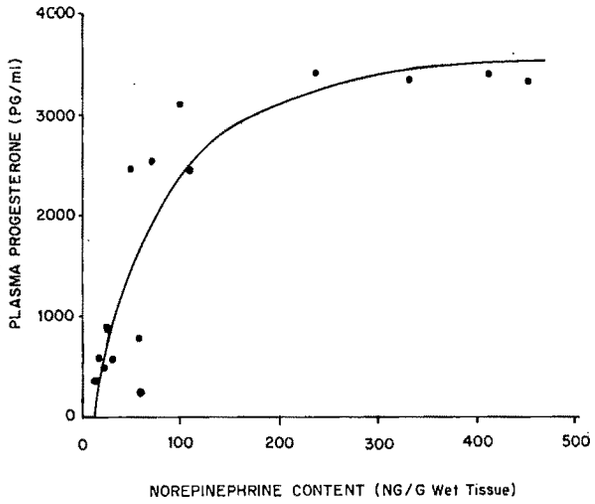

Fig. 1. Correlation between norepinephrine content of the external segment of the human Fallopian tube and plasma levels of progesterone. Curves were fitted with a computer, following Seidel's[18] method of successive approximations (r = 0.77; n = 15).

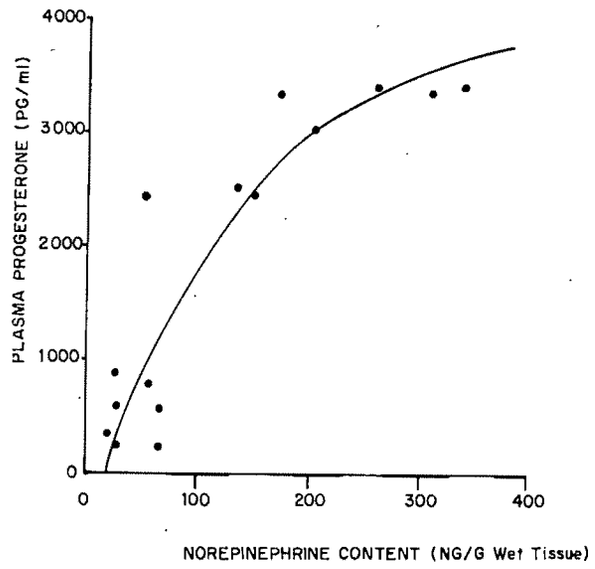

Fig. 2. Correlation between norepinephrine content of the middle segment of the human Fallopian tube and plasma levels of progesterone. Curves were fitted with computer, following Seidel's[18] method of successive approximations (r = 0.87; n = 15).

ratios and plasma estradiol and progesterone levels. Likewise, epinephrine content did not show significant changes as a function of the stage of the menstrual cycle in any of the segments of the Fallopian tubes.

Table II shows the levels of epinephrine and norepinephrine of the human myometrium during the menstrual cycle. Epinephrine content decreased sig-

nificantly during the luteal phase whereas norepinephrine remained unchanged. Correlation between epinephrine and plasma progesterone levels approached significance ($r = 0.68$; $n = 10$).

Comment

The foregoing results indicate that the human Fallopian tube exhibits regional differences in norepinephrine content concomitant with the fluctuation in progesterone levels. During the follicular phase norepinephrine concentration of the internal segment of the tube was two to three times greater than that of the external and middle portions. After ovulation and concomitantly with a functional corpus luteum, a rise in neurotransmitter content occurred in the external and middle segment of the tube, whereas norepinephrine content of the uterine portion of the tube did not change appreciably.

Owman and associates[11] reported regional differences in the concentration of norepinephrine in human Fallopian tubes resembling those observed in the present work during the follicular phase, i.e., norepinephrine levels of the internal portion of the human oviduct were significantly larger than those of the remaining tube. They failed, however, to detect cyclic changes in the total content of the catecholamine of the tube; no information was provided on cyclic changes in the regional distribution of norepinephrine nor on plasma estradiol or progesterone levels.

The functional significance of the changes in oviductal neurotransmitter content is still obscure. In rabbits, insemination and HCG treatment resulted in a significant fall in norepinephrine levels of the isthmus, whereas administration of estrogen or progesterone in doses adequate to disrupt egg transport induced increases in isthmic neurotransmitter content.[7] These observations were interpreted to suggest that a normal passage of eggs requires low levels of norepinephrine in the isthmus.

Both estrogens and progesterone are relevant entities in the control of ovum transport in the oviduct. It is widely accepted that estrogens stimulate and progesterone represses spontaneous oviductal contractile activity.[1, 2] The predominant response to catecholamines of isolated isthmic muscle obtained from the estrogenic phase in women and rabbits is a contraction mediated through α-receptors. Inhibitory responses through β-receptors can be obtained in specimens collected during the luteal phase. This view was recently challenged by Boling and Blandau,[12] however, who found that isolated rabbit oviductal muscle subjected to the influence of estrogens became increasingly active only when progesterone was administered.

In the present work a significant correlation was observed between norepinephrine content of the middle and external portion of Fallopian tubes and plasma progesterone levels, suggesting that ovum passage through the tube may be concomitant with a significant increase in neurotransmitter concentration. Thus, progesterone dominance brings about changes in norepinephrine concentration that may be involved in the acceleration of egg transport during the luteal phase. It should be stressed, however, that even though steroid effects may be mediated in part by changes in the autonomic innervation of the oviduct, sex steroids probably exert influences on oviductal function which are not mediated through adrenergic innervation.

In the uterus, the concentration of norepinephrine did not change as a function of the stage of the ovarian cycle (Table II). In contrast, uterine epinephrine levels decreased by 67 per cent during the luteal phase. Essentially similar results were reported by Cha and associates.[13] These findings on uterine epinephrine content differ remarkably from the absence of changes in tubal epinephrine levels during the menstrual cycle (Table I) as well as from the significant modifications in uterine epinephrine content observed in rats after estradiol treatment.[14, 16] Since tubal and uterine cells, lacking the enzymephenylethanolamine N-methyltransferase (PNMT), are unable to convert norepinephrine into epinephrine, the presence of epinephrine in these cells should come from the blood stream, probably through an active uptake process as suggested by Wurtman and associates.[17]

Hormonal studies in pregnancy

I. Total unconjugated estrogens in maternal peripheral vein, cord vein, and cord artery serum at delivery

INDER R. SARDA, PH.D.
R. HUGH GORWILL, M.D.
Kingston, Ontario, Canada

The concentration of unconjugated total estrogens (primarily estrone, estradiol-17β, and estriol) were measured by rapid radioimmunoassay method in serum samples from maternal peripheral vein, cord vein, and cord artery in normal pregnancies at delivery. The serum concentration of total free estrogens found in cord vein was four to five times higher than in maternal peripheral vein and cord artery. Levels obtained in maternal peripheral vein, cord vein, and cord artery were 47.8 ± 1.8; 140.1 ± 8.57, 31.8 ± 2.15 ng. per millilitre (± standard error of the mean), respectively. These values are compared with those reported by others.

DURING THE LAST two decades a number of investigators have reported levels of free and conjugated estrogens in maternal and cord blood with the use of different techniques.[1–8] The results of these studies have indicated that the placenta is the principal source of the greatly increased amounts of these steroids during pregnancy. The present studies were undertaken to study the levels of total free estrogens in maternal peripheral vein, cord vein, and cord artery blood in normal and abnormal pregnancies, especially pregnancies characterized by intrauterine growth retardation. In this paper we report a rapid radioimmunoassay method for the measurement of total free estrogens and values from normal pregnancies.

Material and methods

Materials. All blood samples were collected in labor or at delivery in normal patients after spontaneous labor. The maternal peripheral vein samples (MV) were drawn in 10 ml. B-D Vacutainers during early labor. The cord artery (CA) and cord vein (CV) samples were drawn either from the clamped cord before delivery of the placenta or from an isolated segment of the cord immediately after fetal delivery. These samples were drawn into dry syringes through 18 gauge needles. The blood was allowed to clot for at least one hour at room temperature then centrifuged and serum removed and stored at −20 degrees C. until analysis.

Ethyl ether, iso-octane, and ethyl acetate were reagent grade obtained from Baker Chemical Co., Phillipsburg, New Jersey. Each freshly opened can of ether was used once and discarded. Iso-octane and ethyl acetate were double distilled and stored in small aliquots. These were used within two to three weeks. Charcoal (Norit A) and dextran T-70 were prepared as a suspension every week. Deionized double-distilled water was used throughout the assay. The counting fluid used was a mixture of Aquasol (New England Nuclear Corp., Boston, Massachusetts) and toluene scintillation grade (1,000 ml. Aquasol and 700 ml. of toluene). Plastic counting vials obtained from New England Nuclear were used. Celite (No. 545), obtained from Fisher Scientific Company, was washed with 6N HCL, distilled water, methanol, and ethyl ether. It was stored at 600° C.

Table I. Evaluation of the method

Sample	*No. of replicate determinations*	*Mean (ng./ml.)*	*S.E.M.*	*Coefficient of variation (%)*
Cord vein serum	9*	128.5	±0.75	1.56
Cord vein serum	20†	130.0	±1.08	3.70
Pooled cord serum (Control)	13	146.2	±2.5	6.0
Pooled maternal serum in early labor (Control)	12	54.6	±0.82	5.1
Male serum containing 125 ng./ml. estrone + estradiol-17β + estriol (25 ng. + 25 ng. + 75 ng., respectively)	8	120.8	±2.35	4.38
Recovery of added tritiated estriol	100	92.8 ±5.0 (S.D.)	±0.46	4.13

*Determination performed in duplicate at nine different times for intra-assay variation.
†Determination performed in duplicate in one experiment for interassay variation.

All glassware was rinsed with distilled water, methanol, and ethyl ether before use. Kimble disposable tubes (10 × 75 mm.) were used for the assay. Disposable 5 ml. glass pipettes from Kimble or Corning were used for making celite columns. These pipettes were thoroughly washed with detergent, distilled water, methanol, and ethyl ether. Then they were silianized by a one per cent solution of silicad. Eppendorf pipettor was used for addition of charcoal suspension and for the addition of tritiated steroid into assay tubes.

Nonradioactive steroids were obtained from Steraloids Inc., Pawling, New York, and were checked for purity. Standard solutions were prepared in buffer. Radioactive estriol-2,4,6,7-^{3}H (^{3}H-E3) (specific activity 110 c. per millimole), estradiol-17β-2,4,6,7-^{3}H (specific activity 114 c. per millimole), and estrone-2,4,6,7-^{3}H (^{3}H-E_1) (specific activity 110 c. per millimole) were obtained from New England Nuclear Corp., Boston, Massachusetts, and were stored in solvents suggested by the supplier at four degrees C. The purity was checked every three months by paper and thin-layer chromatography. These labeled steroids were purified every three months by water/ether partition followed by celite column chromatography. The purified triatiated steroids were stored at four degrees C. in ethanol solution. Periodically, an aliquot was dried and dissolved in phosphate buffer to obtain a final concentration of 12,000 c.p.m. in 0.1 ml. for the assay and 1,000 c.p.m. in 0.1 ml. for the recovery.

Assay buffer consisted of 0.1M phosphate buffer containing 1 Gm. per liter of sodium azide, 9 Gm. per liter of sodium chloride, and 1 Gm. per liter of gelatin. The pH was 7.0 before adding gelatin. This buffer was used in the assay to dilute samples, to make standard solutions, and to dilute radioactive steroids.

The antiserum to estriol-3, 16α, 17β-trihemisuccinate-HSA (S-310 No. 5) was purchased from Dr. G. E. Abraham.* The cross-reaction of this antiserum with other steroids has been reported by Tulchinsky and Abraham[9] and was checked by us in our laboratory. This antiserum cross-reacts with all three classical estrogens (estriol 100 per cent, estradiol-17β 140 per cent, estrone 140 per cent). It also shows slight cross-reaction (ten to 20 per cent) with some other estrogen metabolites. The antiserum was diluted according to the instructions provided by Dr. Abraham and stored in 0.1 ml. aliquots at −50 degrees C. Final dilution was stored at four degrees C. and used for three to four weeks. The final dilution was such that 0.1 ml. of diluted antiserum bound 50 to 55 per cent of 10,000 c.p.m. (20 pg.) of ^{3}H-estriol.

Rapid method. The serum sample of 20 to 100 μl with 1,000 c.p.m. of ^{3}H-estriol, made up to 1 ml. by deionized glass double-distilled water, was extracted twice with 5 ml. of ethyl ether. The combined ether extracts were evaporated under nitrogen to dryness. The dried extract was dissolved in 1 ml. of assay buffer. An aliquot of 0.5 ml. was used to calculate recovery. Duplicate aliquots of 20, 50, 100, or 200 μl, depending on the concentration of estrogens expected, was used for radioimmunoassay.

The radioimmunoassay method followed is essentially the same as that reported by Tulchinsky and Abraham[9] for estriol. The standard curve was constructed in triplicate with 25 to 400 pg. of estriol. There was no significant variation in the curve from one experiment to another. All samples were counted in a Packard Liquid Scintillation Counter (Model 3320), with an efficiency for ^{3}H of 30 per cent. Samples were normally counted for 20 minutes or 20,000 c.p.m. This gives a counting error of less than one per cent.

B. Summary

Subjects	*Source of sample*	E_2	E_2	E_3	*Total*	*Total estrogen as measured by the rapid method*
7	MV	9.8 ± 1.8	24.8 ± 3.6	12.9 ± 1.5	47.5	51.6
8	CV	24.2 ± 3.4	8.7 ± 1.1	136.7 ± 19.0	169.6	169.9
7	CA	4.1 ± 1.0	1.9 ± 0.26	26.1 ± 3.3	32.1	29.8

All values are nanograms per milliliter ± S.E.M.

E_1 = Estrone; E_2 = estradiol-17β; E_3 = estriol; MV = maternal vein; CV = cord vein; CA = cord artery.

Table III. Unconjugated total estrogens in maternal vein, cord vein, and cord artery serum at delivery

Source of serum sample	*Number of samples*	*Range (ng./ml.)*	*Mean ± S.E.M. (ng./ml.)*
Maternal vein	49	26-70	47.8 ± 1.8
Cord vein	35	80-250	140.1 ± 8.57
Cord artery	30	17-58	31.8 ± 2.15

With each set of assays four control samples were used. These were: (1) deionized glass double-distilled water stored at four degrees C. in small aliquots, the same used for diluting the serum samples; (2) pooled maternal, pooled cord vein serum, and male serum containing 125 ng. per milliliter of estrogens (estrone, 25 ng.; estradiol-17β, 25 ng.; and estriol, 75 ng.). Water sample served as a check on the method blank. Lately, instead of male serum we use ether-extracted pooled pregnancy serum containing 125 ng. per milliliter estrogens. This also serves as plasma blank.

Chromatographic method. In order to demonstrate the validity of this rapid method we have analyzed in parallel eight serum samples after fractionation of estrone, estradiol-17β, and estriol with the use of celite column chromatography for the separation of these steroids. Estriol antiserum was used.

The serum sample of 50 to 100 μl with 1,000 c.p.m. of estrone and 1,000 c.p.m. of estradiol-17β added made up to 1 ml. by deionized glass double-distilled water was extracted twice with 5 ml. of ethyl ether. The combined ether extracts were evaporated under nitrogen to dryness. Packing of celite column and chromatography was performed as reported by Abraham and associates.[10] The combined ether extract was transferred in three aliquots of 0.3 ml. each with iso-octane on to the celite columns. Elution was first with 3.5 ml. of iso-octane, then with 5 ml. of 15 per cent

Table IV. Findings of other investigators compared with those of the present study

Investigators	*Sample*	*No. of samples*	*Mean (ng./ml.)*			*Total**

*Sum of estrone, estradiol-17β, and estriol; not assayed as total estrogens except for the present study.

ethyl acetate in iso-octane (this fraction contains estrone), then with 5 ml. of 30 per cent ethyl acetate in iso-octane to recover estradiol-17β. The tubes were dried under nitrogen, and 1 ml. of assay buffer was added, and then kept at 40 degrees C. for 15 to 20 minutes to dissolve the steroids. An aliquot of 0.5 ml. was used to calculate recovery. Duplicate aliquots of 50, 100, or 200 μl were used for radioimmunoassay.

The radioimmunoassay procedure was the same as that in the rapid method with the exception that standard curves were constructed with the use of a standard solution of estrone and estradiol-17β and tritiated estrone and estradiol-17β solutions were used respectively for the assay instead of estriol. (We found that use of tritiated estriol did not change the values appreciably.)

For the estimation of estriol, the method followed was essentially the same as that reported by Tulchinsky and Abraham.[9]

Results and comment

Recovery. In the rapid method the mean recoveries of labeled estrone, estradiol-17β, and estriol were not significantly different. We have therefore used tritiated estriol as internal standard. The recovery was always found to be over 90 per cent. The mean recovery of 100 samples was found to 92.8 per cent ± 5 per cent (S.D.). In the method involving celite column chromatography the recovery varied from 65 to 90, with a mean recovery for estrone of 77.5 ± 3.8 (S.D.), estradiol-17β, 78.0 ± 5.8 (S.D.), and estriol, 77.8 ± 4.5 (S.D.). All serum values were corrected for procedural losses.

Sensitivity. The sensitivity of the standard curve was 10 pg. for estradiol-17β and 20 pg. for estrone and estriol. Water blanks and celite column blanks were always zero (undetectable). The sensitivity of the method was 0.5 ng. per milliliter.

Precision and accuracy. The method was evaluated for its precision and accuracy and was found to be satisfactory (Table I). The within- and between-assay variance was also determined. The coefficiency of variation was less than five per cent. The interassay variation was 3.7 per cent, while the intra-assay variation was only 1.56 per cent. Three control samples, that is, pooled maternal serum, pooled cord vein, and male serum containing 125 ng. per milliliter estrogens (25 ng. estrone, 25 ng. estradiol-17β, 75 ng. estriol) were used with each experiment. The value of these samples was previously established by repeated analysis in duplicates. This is shown in Table I. In any experiment in which the value of any of these controls was significantly different than the mean, the results were discarded.

Specificity. The specificity of the antiserum was checked by cross-reaction studies with various steroids and was found to be of the same order as that reported by Tulchinsky and Abraham.[9] The cross-reactions of progesterone, dehydroepiandrosterone, testosterone, pregnenolone, and 16α OH-dehydroepiandrosterone

were particularly checked in the rapid method. Addition of up to 5 ng. of these steroids did not change the zero value in the assay. In serum from cord vein values up to 1,500 ng. per milliliter for progesterone have been reported. With the use of the sensitivity and dilution factor it represents only 3 to 4 ng. per tube in our assay. It is therefore not likely to interfere in the rapid method. Other steroids are present in much smaller amounts.

This was further proved by the values obtained by the fractionation of serum for estrone, estradiol-17β, and estriol with the use of celite chromatography. The sum total of the values of estrone, estradiol-17β, and estriol was comparable to the total value obtained by the rapid method, suggesting that other steroids present did not interfere in this rapid method (Table II).

With the use of this rapid method unconjugated total estrogens were measured in maternal peripheral vein serum during labor and in cord vein and cord artery serum from pregnancies classified as clinically normal. The results are reported in Table III. The values for maternal vein, cord artery, and cord vein compare favorably with other reported values (Table IV). The cord artery levels of unconjugated estrone, estradiol-17β, and estriol are very low compared to the levels reported by Simmer and co-workers,[8] while they are similar to those reported by others.[5, 13] Cord vein levels are in agreement with their values. The levels in cord vein were four to five times higher than maternal peripheral vein and cord artery, as expected. Patients with very high levels of estriol in cord artery serum have been found (Table II, Subject 8). Such large amounts of unconjugated estrogens in cord artery possibly reflect the failure of conjugation by the fetus. In another patient total unconjugated estrogen values over 300 ng. per milliliter have been seen in cord vein (Subject 7).

It is not possible to directly compare the total estrogen results with those of others because to our knowledge there is no previous report of the concentration of total free estrogens in maternal peripheral vein, cord vein, and cord artery serums. Most investigators have either reported values for estriol only or for estrone, estradiol-17β, and estriol separately (Table IV).

Further studies are in progress to assess these and other parameters (estrogen precursors) in abnormal pregnancies and attempt to elucidate significant patterns of variations. The total estrogen values obtained by this method compare favorably to those obtained following chromatographic purification of the extract. The method is accurate and faster. It is possible to complete 24 to 36 samples in two working days or 12 samples in one working day by use of this method. We have recently begun to study the feasibility of using this method during the second and third trimester of pregnancy.

The authors wish to thank Professor J. A. Low for his interest and advice, Miss Ann Lyng and Miss Margaret Webster for their excellent technical assistance, and all the staff members of our department for providing blood samples.

Comparative effects of hyperosmolar urea administered by intra-amniotic, intravenous, and intraperitoneal routes in rhesus monkeys

DAVID A. BLAKE, PH.D.
LONNIE S. BURNETT, M.D.
BARBARA C. MIYASAKI, B.S.
HENRY S. LIM, M.D.
THEODORE M. KING, M.D., PH.D.
Baltimore, Maryland

Hypertonic urea solutions (58 per cent weight/volume) were injected rapidly into ten anesthetized rhesus monkeys at a dose of approximately 2 Gm. per kilogram by the intravenous, intraperitoneal, or intra-amniotic routes. An additional monkey received an intra-amniotic dose of 12.5 Gm. per kilogram. A tracer dose of ^{14}C-urea was included for measuring absorption and elimination. The following parameters were monitored before and for four hours after urea injection: arterial and cerebrospinal fluid pressures, heart and respiration rates, urine flow, and urea clearance. Serum electolytes, hematocrit and white count, and cumulative urea excretion were measured for one week. Monkeys were observed for three to six months after injection. At doses up to approximately twice the human dose (on a body weight basis) there were no urea-related deaths and no serious side effects noted in any of the experiments. These results support the suggestion that urea is a relatively safe hyperosmolar agent for inducing midtrimester abortions, especially with regard to inadvertent systemic injection.

INTRA-AMNIOTIC HYPEROSMOLAR urea has been reported to be an effective and relatively safe agent for the induction of midtrimester abortion.[1–6] Its chief advantage over the more commonly used hyperosmolar saline is the elimination of the risk of hypernatremia. The modest and transient rise in serum urea that occurs after intra-amniotic urea does not appear to be associated with adverse effects.[6] However, the inadvertent intravenous or intraperitoneal injection of large doses of urea might be expected to exert considerable toxicity. In order to evaluate the seriousness of this risk, we have studied the effects of hyperosmolar urea by the intravenous, intraperitoneal, and intra-amniotic routes in female rhesus monkeys.

Material and methods

Adult female rhesus (*Macaca mulatta*) monkeys were obtained from the Johns Hopkins Primate Colony. In some experiments pregnant animals were used. Duration of gestation was usually known to within two days. Atropine (0.04 mg. per kilogram and phencyclidine (0.5 mg. per kilogram; Sernylan, Parke, Davis and Co.) were administered preanesthetically, and anesthesia was induced and maintained with 0.5 to 0.8 per cent halothane (Fluothane, Ayerst Labs.) and 50 per cent nitrous oxide via an endotracheal tube. A Foley catheter was inserted into the bladder for continuous collection of urine. Intravenous infusion of five per cent dextrose in 0.45 per cent saline was maintained at a rate of 0.3 to 0.5 ml. per minute with an infusion pump. With the maintenance of sterile conditions, femoral artery pressure was measured directly with saline-filled polyethylene tubing which

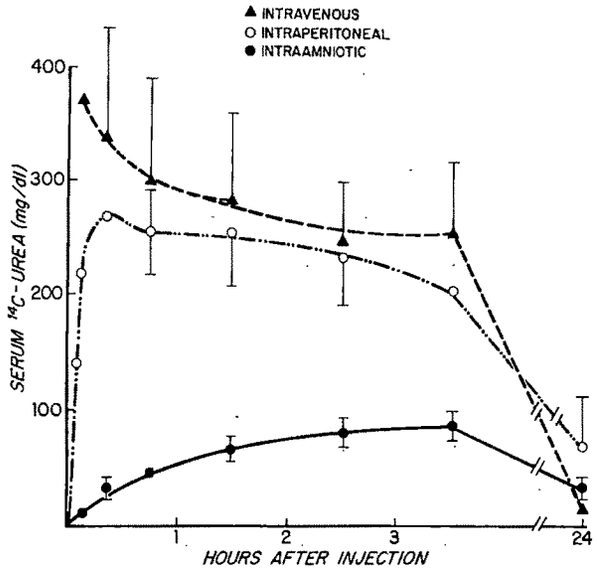

Fig. 1. Serum concentration profile of ^{14}C-urea in rhesus monkeys after rapid injection of approximately 2 Gm. per kilogram as a hyperosmolar (58 per cent weight/volume) solution by three routes. *Points* are means of two or three values and *bars* indicate ±S.E.M.

was connected to a Statham P-23 De pressure transducer. Polyethylene tubing was also inserted into the subarachnoid space by lumbar puncture and connected to a similar pressure transducer for measurement of cerebrospinal fluid (CSF) pressure. A strain gauge was firmly attached to the chest at a position found to give maximal response during respirations. All transducers were connected to a Brush-Gould six-channel polygraph for continuous recording.

Urea was prepared for injection by adding 40 ml. of five per cent dextrose in water to 40 Gm. of sterile lyophilyzed urea (Urevert, Travenol Labs.). This produces a nearly saturated solution of urea having an approximate concentration of 58 per cent weight/volume). ^{14}C-urea (4.5 mc. per millimole; New England Nuclear Corp.) was added to the nonradioactive urea solution so that the injected dose contained approximately 25 μc of radioactivity. The entire dose of urea was injected over three and one-half minutes. Intravenous injections were made into a superficial leg vein. Intraperitoneal injections were administered through a polyethylene catheter which was placed into the peritoneal cavity through a small abdominal incision. Intra-amniotic injections were made through a polyethylene catheter which was threaded through a 16 gauge Tuohy needle inserted transabdominally. Prior to intra-amniotic injection amniotic fluid was withdrawn maximally. In all experiments, immediately after the urea injection was completed, oxytocin (Pitocin, Parke, Davis and Co.) was added to the dextrose/saline infusion at a concentration calculated to deliver 24 mU. per minute which is equivalent on a body weight basis to that used in human abortions.[6]

Arterial blood and amniotic fluid were sampled at the times indicated in Fig. 1. Urine collection intervals bracketed the blood sampling times. Serum, urine, and amniotic fluid were radioassayed by liquid scintillation counting and results calculated as milligrams of urea per milliliter.

Renal clearance of ^{14}C-urea was calculated from the urine flow rate (U), urinary ^{14}C-urea concentration (C), and serum ^{14}C-urea concentration at the midpoint of the urine collection period (S) by the equation: clearance = U × C/S.

Four hours after urea injection, physiologic monitoring was terminated, all catheters removed, incisions sutured, and the monkey permitted to recover from anesthesia. The animal remained in a cage designed for collection of total voided urine for seven postoperative days. Urine was collected and radioassayed on Days 1, 4, and 7.

Venous blood was obtained prior to urea injection and one, four, and seven days afterward for determination of hematocrit, total white cells, sodium, potassium, chloride, bicarbonate, glucose, and urea nitrogen. All hematologic and serum electrolyte determinations were performed by the Division of Clinical Laboratories of the Johns Hopkins Hospital.

Results

Survival. The details of dose and route of urea administration, duration of pregnancy, and outcome of the eleven monkeys studied are given in Table I. Only one urea-related death occurred in a monkey (No. 8) which had been given an intra-amniotic dose equivalent to approximately ten times the usual human dose on a body weight basis. Death occurred 20 hours after the injection and the serum urea nitrogen shortly after death was approximately 1,400 mg. per deciliter. The data from this monkey were not included with the other results. Monkey No. 4 died approximately 24 hours after intraperitoneal injection of urea. The presence of a large amount of blood in the cage and autopsy findings suggested that death was caused by hemorrhage secondary to incomplete abortion. Monkey No. 1 had to be euthanized because sterile procedure was not employed. All surviving animals appeared normal and healthy at three to six months' follow-up evaluation.

Urea serum levels. Fig. 1 shows the mean ± standard error concentrations of ^{14}C-urea in maternal serum during the first 24 hours. The rapid absorption

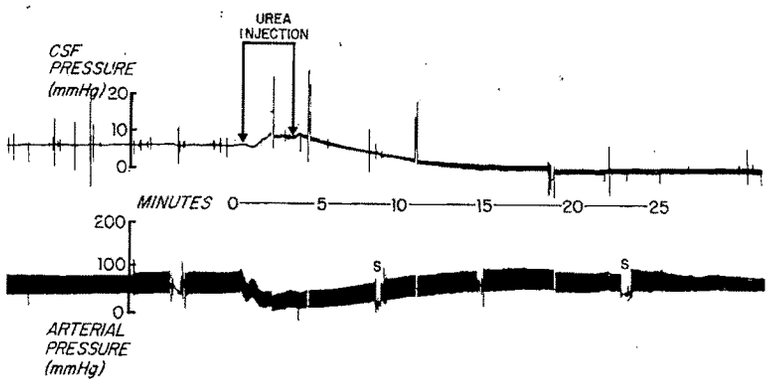

Fig. 2. Arterial and cerebrospinal fluid pressure responses in an anesthetized rhesus monkey (No. 3) to intravenous injection of hyperosmolar urea. *S* = Sampling time.

of intraperitoneal urea is apparent in that the serum concentration peaked within 30 minutes and nearly reached that measured after intravenous injection. For this reason, the results of other measurement in the intravenous and intraperitoneal groups were combined for comparison to those obtained in the intra-amniotic group.

The average serum concentration of intravenous urea was 375 mg. per deciliter four minutes after the end of the three and one-half minute injection. It then decreased exponentially with a half-time of five to six hours (determined graphically on a semilog plot). A similar rate of elimination was estimated for urea after intraperitoneal and intra-amniotic administration. The apparent volume of distribution of urea after intravenous injection was estimated by extrapolation of a semilog plot to the theoretic concentration at zero time. The injected dose divided by the zero time concentration of urea gave an apparent volume of distribution of 70 to 85 per cent of body weight slightly higher than expected if the distribution was equal to total body water (approximately 60 to 65 per cent of body weight).

Arterial and cerebrospinal fluid pressures. Intravenous injection of hyperosmolar urea caused a rapid but evanescent fall in arterial pressures followed by a slow rise to above the preinjection level and a return to it within 30 minutes (Fig. 2). These pressure changes were not accompanied by any marked or consistent change in heart rate. Intraperitoneal urea injection caused a modest increase in both systolic and diastolic pressures reaching a peak in about five minutes (one and one-half minutes after completion of the urea injection) and then returning to preinjection levels in another 10 minutes (Fig 3). CSF pressure rose transiently during the intravenous injection and then fell slowly to 5 to 15 mm. Hg below the preinjection level at two hours with a slower rise toward base line thereafter. A similar fall in CSF pressure occurred after intraperitoneal injection of urea. No significant or consistent changes occurred in arterial pressure after intra-amniotic injection. However, CSF pressure decreased slowly by an average of 5 mm. Hg at 60 minutes, returning to preinjection levels by four hours.

Respiration. The rate of spontaneous breathing did

not show discernable changes in any of the experiments.

Urine flow rate and urea clearance. Intravenous and intraperitoneal injection of urea caused an initial diuresis to a maximum at approximately 20 minutes after the start of the injection and then tapering off to a flow rate approximating the rate of the dextrose/saline infusion (0.3 to 0.5 ml. per minute) (Fig. 4). As expected, urea clearance by the kidney showed a parallel increase during the period of diuresis.

After intra-amniotic injection, urine flow and urea clearance steadily increased to a plateau level at about two and one-half hours (Fig. 5). Urea clearance was significantly higher three to four hours after intra-amniotic injection (6.1 ± 0.3 ml. per minute) than after intravenous/intraperitoneal injection (4.4 ± 0.6 ml. per minute). However, it should be noted that all of the intra-amniotic monkeys in this group were pregnant, whereas only three of seven of the intravenous/intraperitoneal group were pregnant.

Serum electrolytes. Fig. 6 shows the standard serum electrolytes before and one, four, and seven days after urea injection. The data for intravenous and intraperitoneal monkeys have been combined for comparison with those of the intra-amniotic animals. The only notably persistent change was a decrease in serum

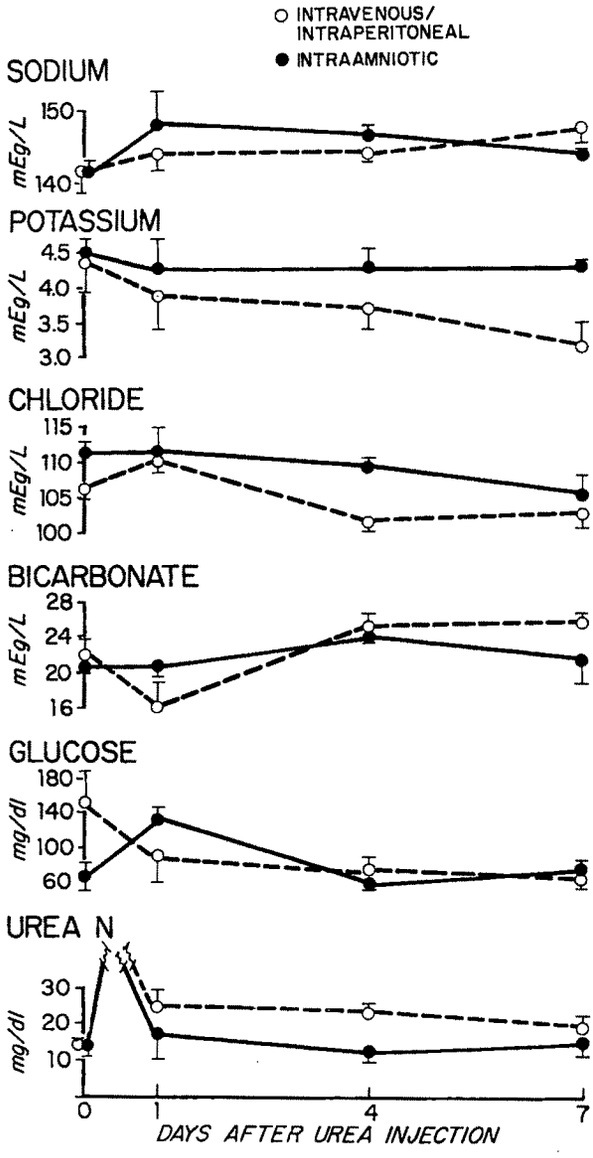

Fig. 6. Serum electrolytes in rhesus monkeys before and after injection of hyperosmolar urea. Values for intravenously and intraperitoneally injected animals have been combined. Points are means ± S.E.M. of three to six animals.

potassium in the monkeys which received systemic injections of urea. Serum chloride and bicarbonate also tended to be lower in this group, suggesting renal loss of these electrolytes during an osmotic diuresis.

Serum urea nitrogen (SUN) levels decreased rapidly during the first day and were within or near normal limits in all animals. Measurement of ^{14}C-urea in urine showed a cumulative 24 hour excretion of 60 to 85 per cent of the dose for the intravenous group, 70 to 110 per cent in the intraperitoneal group, and 35 to 60 per cent in the intra-amniotic group. Urea excretion after the first day was small except in the intra-amniotic

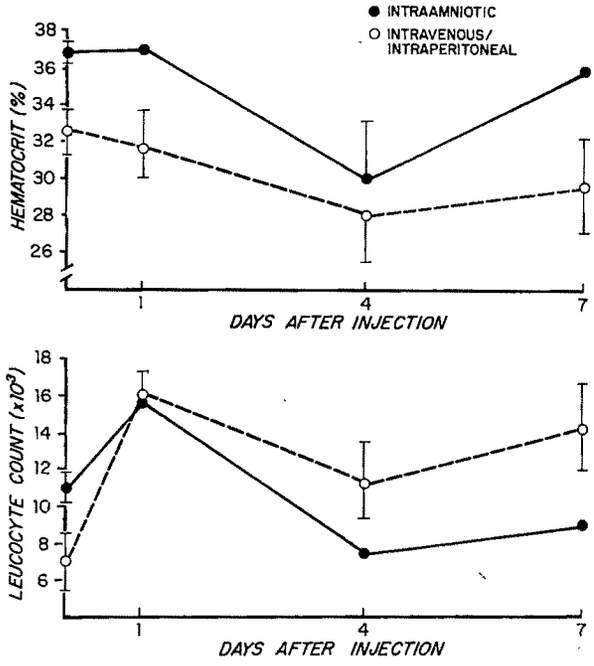

Fig. 7. Hematologic measurements in rhesus monkeys before and after injection of hyperosmolar urea. Values for intravenously and intraperitoneally injected animals have been combined. *Points* are means of two to five animals. *Bars* indicate ± S.E.M.

group in which an additional 15 to 20 per cent was recovered between Days 1 and 4.

Hematology. Because of surgical blood loss and blood withdrawal for various measurements (35 to 50 ml.), the hematocrit decreased moderately in all animals between Days 1 and 4 but was increasing toward the preinjection level within one week (Fig. 7). Marked hemolysis and hematuria was observed for one to two hours after intravenous injection, however, the hematocrits in this group were not different from those of the intraperitoneal injected animals. The total white cell count increased by 50 to 200 per cent within 24 hours in all monkeys, regardless of the route of injection of urea.

This leukocytosis was transient in the intra-amniotic group but persisted for at least seven days after intravenous/intraperitoneal injection of urea.

Comment

Hypernatremia inadvertently produced by hypertonic saline when being used as a midtrimester abortifacient has been reported to be the cause of serious and possibly fatal complications including hemolysis, hypotension, cardiac arrest, apnea, bradycardia, and arrhythmias.[7, 8]

Because of these potential hazards associated with

saline, other hyperosmolar agents such as urea have been investigated for efficacy and safety as midtrimester abortifacients.[9] Although the use of urea has been increasing over the past few years, we are not aware of any serious complications or deaths associated with elevated urea concentration. Indeed, up to 2 Gm. of urea per kilogram of body weight has been administered over a two-hour period to sickle cell patients without serious side effects.[10] However, the rapid elevation of the osmolar concentration of extracellular fluid with urea causes encephalopathy and death in rabbits[11] and marked pulmonary hypertension[12] and systemic hypotension[13] in dogs. Therefore, the safety evaluation of hypertonic urea for use as a midtrimester abortifacient requires an assessment of its toxicity when administered in a manner designed to simulate possible inadvertent intravenous or intraperitoneal injection. Because urea freely diffuses across cell membranes, it would not be expected to produce as much of an osmotic gradient as an equiosmolar dose of a substance such as sodium whose passage across cell membranes is retarded. Moreover, urea is an electrochemically neutral molecule and thus does not directly alter excitable membranes in cardiac and nervous tissue. Thus it is not too surprising that rapid intravenous or intraperitoneal injection of a very large dose (approximately 2 Gm. per kilogram of body weight) of a nearly saturated solution of urea (approximately 10M) did not cause death or persistent physiologic or biochemical changes in monkeys. The transient changes in blood pressure observed during and shortly after urea injection were similar to those reported by other investigators[12, 14] under similar dosage conditions. The observed decrease in cerebrospinal fluid pressure is a well-known effect of intravenously injected urea and has been used clinically in the treatment of excessive intracranial pressure.[15]

The urea effects on renal function are difficult to evaluate because of the antidiuretic effect of coadministered oxytocin. It was felt necessary to administer oxytocin in these studies as it is usually employed as an augmenting agent clinically. It was evident, however, that systemically administered urea caused a diuresis and enhanced urea clearance when compared to intra-amniotic injection.

Marked hemolysis was noted for approximately two hours after intravenous urea injection. Thus it was somewhat surprising to find hypokalemia from one to seven days after injection. Burnett and associates[6] observed in patients a slight rise (0.5 mEq. per liter) in serum potassium 12 hours after intra-amniotic injection of urea, with a return to normal limits within 24 hours. A possible explanation for these observations is that the potassium released from lysed red cells was excreted during the first day during osmotic diuresis. This total body potassium depletion along with the decrease in dietary potassium intake during postoperative anorexia probably resulted in the observed hypokalemia. Changes in renal function may also be related to the marked hemolysis that occurred with intravenous injection.

Mild to moderate leukocytosis has been observed in most patients after intra-amniotic urea injection.[6] The mechanism of this effect is unknown, but it may be associated with the formation of endogenous prostaglandins which are thought to be responsible for many of the effects of hypertonic agents.[16]

Pharmacokinetics of intra-amniotically administered hyperosmolar urea in rhesus monkeys

DAVID A. BLAKE, PH.D.
LONNIE S. BURNETT, M.D.
BARBARA C. MIYASAKI, B.S.
JAMES A. LONGSTRETH, B.S.
THEODORE M. KING, M.D., PH.D.
Baltimore, Maryland

Three rhesus monkeys in midgestation were injected intra-amniotically with hyperosmolar ^{14}C-urea (58 per cent weight/volume, 2.3 Gm. per kilogram, 25 μc) and the concentration of ^{14}C-urea measured serially for 24 hours in amniotic fluid, maternal serum, and maternal urine. The volume of the amniotic space was measured by isotope dilution of ^{99m}Tc-albumin. The experimental values were fitted to a three-compartment mathematical model with the aid of a digital computer program for nonlinear data. The computer-derived concentration versus time curves were in close agreement with the measured values when the flux of urea was primarily from amniotic fluid to fetal water to maternal water with insignificant direct transport between the amniotic fluid and maternal serum. The half-times for distribution of urea into fetus and mother were approximately 30 minutes and 7 hours, respectively. Thus, although the uptake of urea by the fetus from surrounding amniotic fluid is rapid, the further movement of urea from fetus to mother is relatively slow.

UREA HAS BEEN advocated as a substitute for sodium chloride in midtrimester abortion by the intra-amniotic (IA) hyperosmolar technique.[1] The primary advantage of urea over saline is the relative lack of toxicity associated with inadvertent intravenous or intraperitoneal injection.[2, 3] Although there are numerous reports on the clinical abortifacient efficacy of hyperosmolar urea in relatively large series of patients,[4–7] there have been no detailed studies published on its rate of absorbtion and elimination after intra-amniotic injection in human beings or animals. Burnett and associates[7] measured serum urea nitrogen (SUN) in a series of twelve elective midtrimester abortions with 80 Gm. of hyperosmolar urea. The average peak SUN occurred at four hours after injection and returned to preinjection values at 24 hours.

There is evidence that the site of action of hyperosmolar abortifacients is in the decidual cell layer underlying the chorioamnion.[8] Therefore a major determinant of abortifacient activity may be the product of concentration of solute × hours in amniotic fluid which would be proportional to the solute concentration in the decidual environment. Furthermore, the passage of hyperosmolar solute from amniotic fluid into the fetus presumably results in a loss of cardiac function after a critical fetal osmolarity is exceeded.

This investigation was conducted in order to gain insight into these fundamental pharmacologic aspects of the abortifacient action of hyperosmolar urea. Pregnant rhesus monkeys were utilized as a model for human beings and experiments conducted in a manner designed to simulate the clinical technique most commonly employed. At various times after IA injection of ^{14}C-urea as a hyperosmolar solution, its concentration was measured in amniotic fluid, maternal serum, and urine. These values were fitted to a

three-compartment mathematical model with the use of a digital computer program and the relevant pharmacokinetic parameters obtained. This model was used to predict the urea concentration versus time curve for the fetus.

Material and methods

Three midgestation rhesus monkeys obtained from the Johns Hopkins University Primate Colony had been cohabitated with males for two to 12 days during the middle of a menstrual cycle, and pregnancy confirmed by bimanual palpation of the uterus four weeks after mating. The presumed date of conception was the midpoint of the cohabitation time which was designated Day 1 of gestation. All three animals had at least two previous normal pregnancies. The gestational ages and maternal body weights are given in Table I.

Food was withdrawn the night before the experiment. Atropine sulfate (0.04 mg. per kilogram) and phencyclidine hydrochloride (Sernylan, Parke, Davis and Co.; 0.5 mg. per kilogram) were administered prior to maintenance of anesthesia with halothane (Fluothane, Ayerst Labs.; 0.5 to 0.7 per cent) and nitrous oxide (50 per cent) in oxygen. Venous, arterial, and cerebrospinal fluid catheterizations were performed for physiologic monitoring which is reported elsewhere.[3] A venous infusion of five per cent dextrose in 0.45 per cent saline was maintained at a rate of 0.4 to 0.5 ml. per minute throughout the five hours of anesthesia. A No. 10 Foley catheter was placed in the bladder for continuous urine collection.

Hyperosmolar urea was prepared by dissolving 40 Gm. of sterile lyophylized urea (Urevert, Travenol Labs.) in 40 ml. of five per cent dextrose in water producing a solution of approximately 58 per cent (weight/volume) with respect to urea. Approximately 25 μc of ^{14}C-urea (New England Nuclear Corp., 4.5 mc. per millimole) was added to 30 ml. of this solution and 25 ml. of the resultant mixture (containing 13.8 Gm. of urea) used for IA injections. Doses calculated as grams per kilogram are given in Table I.

Prior to aspiration amniocentesis, the volume of amniotic fluid was estimated by the isotope dilution technique with ^{99m}technetium-labeled albumin obtained from the Johns Hopkins Radiation Health Laboratory. ^{99m}Tc-albumin (2 to 5 μc) was dissolved in 1 ml. of 0.9 per cent saline and injected into the amniotic cavity through a polyethylene catheter (PE-90) which had been threaded through a previously inserted 16 gauge Touhy needle. Thorough mixing was assured by repeated withdrawal and infusion from the syringe and allowing 15 to 30 minutes prior to sampling. Amniotic fluid samples (0.5 ml.) were withdrawn at various times and counted in a Baird Atomic II isomatic gamma counter. The volume of amniotic fluid was estimated as the apparent volume of distribution of the injected ^{99m}Tc-albumin calculated with reference to a known dilution.[9] These results are given in Table I (Line 4a).

Maximal amniotic fluid was withdrawn and the volume noted. Urea injection was made through the polyethylene catheter at a steady rate over 3.5 minutes.

Experimental time was designated zero at the start of the injection. Upon completion of the injection, fluid was repeatedly withdrawn and infused to ensure thorough mixing. Immediately after completion of the urea injection, oxytocin (Pitocin, Parke, Davis and Co.) was added to the intravenous infusion at a concentration calculated to deliver 20 to 40 mU. per minute which is approximately equal on a body weight basis to the human dose utilized for augmentation of urea-induced abortions.[7]

Amniotic fluid (0.5 ml.) and blood (2 ml.) were obtained before and at 7.5, 12.5, 15, 22.5, 45, 90, 150, 210, 480, 720, 960, and 1,440 minutes after injection of urea. Total urine was collected at 0, 15, 30, 60, 120, 180, and 240 minutes by catheter. Catheters were removed and the animals allowed to recover from anesthesia after transfer to cages. Urine collection continued until 24 hours by pan collection. In one experiment (No. 3) the monkey was placed in a restraining chair from four to 24 hours and catheter urine collection continued. Aliquots of amniotic fluid, maternal serum, and urine were radioassayed by liquid scintillation counting (Nuclear Chicago Model 725). Counting efficiency was determined by the channels ratio method and disintegrations per minute converted to milligrams of urea equivalent per milliliter. Cumulative urinary excretion of urea was calculated from summation of concentration times volume per interval.

The apparent volume of distribution of urea based on amniotic fluid concentration was calculated by dividing the dose by the concentration in amniotic fluid extrapolated to zero time (C_0). The extrapolation was performed on a semilog plot of ^{14}C-urea concentration in amniotic fluid versus time by extending the slower linear phase (linear on semilog coordinates) back to time equals zero hours, as shown in Fig. 1. Assuming that IA urea freely and rapidly diffuses into the fetus and distributes with total fetal body water at a faster rate than it distributes into maternal body water, this volume [V_d(urea)] was assumed to be approximately equivalent to the volume of amniotic fluid remaining prior to the urea injection ($A_{resid.}$) plus the volume of urea solution injected ($V_{inj.}$) plus total fetal body water (F); (V_d[urea] = $A_{resid.}$ + $V_{inj.}$ + F). The residual amniotic fluid volume after aspiration ($A_{resid.}$) was obtained by subtracting the volume obtained by aspiration ($V_{asp.}$) from the initial volume measured by ^{99m}Tc-albumin dilution (A). The results of these calculations are given in Table I.

An estimate of the first-order rate constant for transfer of urea from amniotic fluid into fetal water was obtained by the "curve-stripping" or "feathering" technique,[10] as shown in Fig. 1. The dashed line represents the early rapid (alpha) phase of the apparent biphasic decline of urea concentration in amniotic fluid thus obtained. The later slower (beta) phase was assumed to represent transfer of urea from the amniotic-fetal compartment to maternal water, and the half time ($t_{\frac{1}{2}}$) of this decay was used to estimate the first-order rate constant for this process (K = 0.693/$t_{\frac{1}{2}}$). The rate constant for elimination of urea from maternal water was estimated from semilog plots of its concentration in serum versus time after intravenous injection of a similar dose into nonpregnant animals.

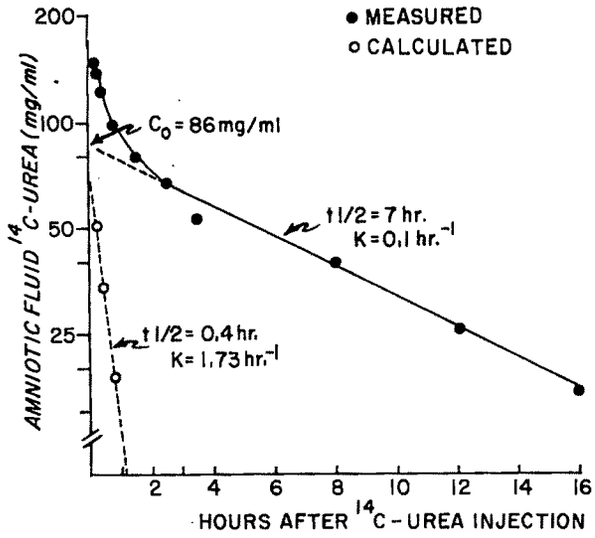

Fig. 1. Semilog plot of ^{14}C-urea elimination from amniotic fluid after intra-amniotic injection of a hyperosmolar solution (58 per cent) in a midgestational rhesus monkey (Experiment No. 3). *Dotted line* (early phase) was obtained by curve-stripping technique.[10] C_0 = apparent initial concentration obtained by back extrapolation of the postdistributive linear phase. Graphically estimated half-times ($t_{\frac{1}{2}}$) used to obtain estimates of the apparent first-order rate constants *(K)* by K = 0.693/$t_{\frac{1}{2}}$.

*Parameters do not represent a least-squares fit because of incomplete urine collection.

These data are reported elsewhere.[3] That this rate constant represents urinary excretion was evident from its similarity to the rate constant obtained from measurements of urea clearance by the kidneys assuming the volume of distribution of urea to be 70 per cent of adult body weight. Thus it was concluded for the purposes of these calculations that nonrenal maternal losses of injected ^{14}C-urea were insignificant.

The urea concentrations in amniotic fluid and maternal serum and cummulative urinary excretion values along with the estimated first-order rate constants and estimated compartment volumes were used to fit the three-compartment scheme shown in Fig. 2 to the experimental data. An IBM370 and digital computer program* developed to aid in fitting nonlinear functions to data were used in obtaining the set of parameters that describe the model in Fig. 2. The parameters obtained allow a "best fit" of the data based on least-squares criteria.

*We thank Dr. Carl Metzler of the Upjohn Company for providing the computer program and details of its utilization.

Results and comment

The body weights and urea dosage were similar in all three experiments (Table I). Although at a similar gestational age, it is apparent from Table I that there were significant differences in amniotic fluid volumes and apparent fetal volumes in the three monkeys. Consequently, at a fixed urea dose, the initial concentration of urea in amniotic fluid (Table I, Line 5) decreased with advancing fetal size. An attempt was made to maximally aspirate amniotic fluid prior to urea injection in order to have minimal dilution of injected hyperosmolar urea and to simulate the clinical technique. The estimates of fetal water volumes (Table I, Line 7) correspond to those expected based on published combined rhesus fetal and placental weights[11] (103 Gm. at 75 days gestation and 249 Gm. at 100 days) and aggregate tissue water contents of approximately 85 per cent (volume/weight).[12] For example, in Monkey No. 2, gestational age 75 days, 85 per cent of the expected combined fetal (43 Gm.) and placental (60 Gm.) weights is 88 ml., a value close to the 85 ml. calculated. Unfortunately, although strong and regular uterine contractions occurred, no fetal weights were available for confirmation because the treatment resulted in missed abortions followed by fetal resorption.

Urea is a small water-soluble molecule (molecular weight = 60) which crosses biologic membranes with relative ease and distributes into a space presumed to be approximately equal to total body water.[13] In addition, it is reasonable to assume that urea distributes across body membranes by simple diffusion through aqueous channels and that the rate of its equilibration between two compartments (for example, fetal and maternal) is primarily limited by water flow between those compartments.[14]

Furthermore, since the total body pool of endogenous urea (85 mg. per kilogram) and the rate of its production (13 mg. per kilogram per hour)[15] are small relative to the dose and elimination rate of ^{14}C-urea injected in these experiments, for the purpose of analysis of the data, the specific activity of the ^{14}C-urea was assumed to remain constant.

From the declining concentration of ^{99m}Tc-albumin radioactivity in amniotic fluid during the first three and one-half hours after urea injection it would appear that its volume was increasing slowly, presumably because its hypertonicity caused an influx of water along the

osmotic gradient (Table I, Line 4d). It was surprising that although the concentrations of urea and thus tonicity differed considerably in the three experiments, the rate of apparent volume expansion was nearly identical in each at approximately 5 ml. per hour. In one experiment (No. 3) the apparent amniotic fluid volume was determined at 24 hours to be 65 ml., only 7 ml. more than that determined 20 hours earlier. Some of the apparent volume expansion (dilution of ^{99m}Tc radioactivity) may have been the result of incomplete binding of the label to albumin or dissociation caused by hyperosmolar urea. Ultrafiltration of amniotic fluid containing ^{99m}Tc-albumin showed that six to ten per cent of the radioactivity was unbound and could have moved out of the amniotic space. Additionally, a small but measurable fraction of albumin is known to be lost from amniotic fluid within ten minutes after injection.[9] Consequently, it was believed unnecessary to account for the small changes of urea concentration in amniotic fluid which possibly resulted from volume expansion.

The biphasic exponential decay in amniotic fluid urea concentration determined in experiment No. 3 is shown in Fig. 1. The initial phase had a $t_{\frac{1}{2}}$ of 24 minutes and the later phase had a $t_{\frac{1}{2}}$ of seven hours. It is assumed that the initial rapid phase represents passage into the fetal and placental tissues and the slower phase represents transfer to maternal water. The amniotic fluid to fetal transport probably represents direct percutaneous passage as fetal skin has been shown to be freely penetrated by isotopic water in midgestation prior to keratinization.[16] There is also evidence that water exchange between amniotic fluid and maternal serum occurs through the cord.[17] Fetal swallowing of amniotic fluid during midgestation is estimated to be only five to ten per cent of fetal body weight per hour, a process too slow to account for the observed rate.

Fig. 3 shows the maternal serum ^{14}C-urea concentrations for the three monkeys. The time of peak serum level (four to six hours) and the shape of the curve approximates that reported clinically.[7] The values are approximately twice those reported in human beings corresponding to the approximate double dose on a weight basis administered to monkeys.

The concordance between measured and computer-predicted urea concentrations in amniotic fluid and maternal serum determined for experiment No. 3 is shown in Fig. 3. This figure also shows the excellent fit obtained with the cumulative amount of urea excreted in urine. The computer-predicted curve for the fetal urea concentrations is also shown, although no direct measurements were available for comparison. Two important observations can be made from Fig. 3. First,

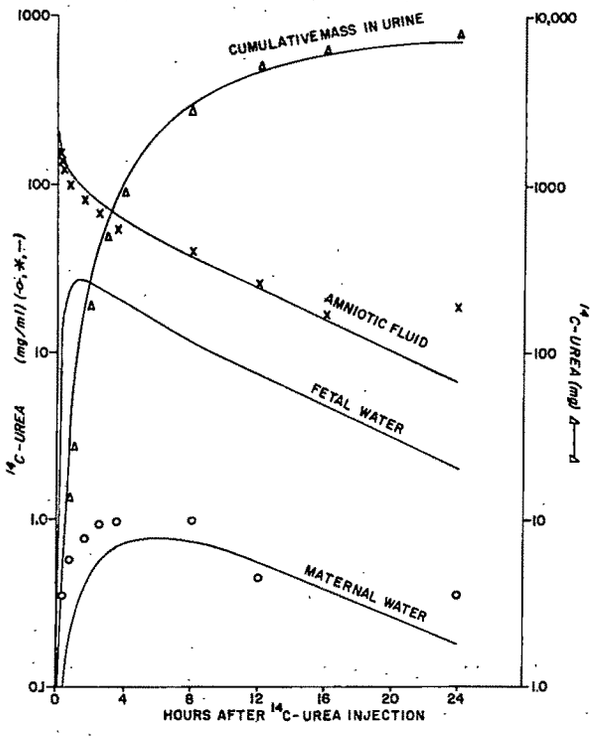

Fig. 4. Computer-derived fits of urea measurements from Experiment No. 3 to the three-compartment model shown in Fig. 2. Ordinates are log scale: *left* for concentrations in amniotic fluid and fetal and maternal water; *right* for cumulative amount in maternal urine. First-order rate constants for best least-squares fit are given in Table II.

the urea concentration in the fetal compartment rises rapidly and peaks at approximately one and one-half hours, corresponding to the rapid initial decline in amniotic fluid urea shown in Fig. 1. Second, although an equilibrium is achieved between amniotic fluid and fetal urea concentration after two hours, the concentration in the fetal compartment remains substantially below that in amniotic fluid even though the apparent rate constant into the fetus is considerably larger than that from the fetal to maternal compartments (Fig. 1 and Table II). The most likely explanation for this observation is that while urea equilibration between amniotic fluid and fetal skin may be rapid, equilibrium of urea within the fetus and placenta is blood flow limited. Blood flow–limited exchange would also explain the even greater differential (approximately 70-fold) existing between urea concentrations in the fetal and maternal compartments.

The computer-derived first-order rate constants for best fitting the measured data to the three-compartment interconnected model (Fig. 2) are given in Table II. Attempts to obtain other best fits by altering initial estimates or weighting the measured values by a factor equal to their reciprocals did not

result in a substantially better fit based on the least-squares determination. An interesting finding is the relative insignificance of direct transfer of urea from amniotic fluid to the maternal compartment (K_{am}). The probability that a molecule of urea in the maternal compartment arrived from the amniotic fluid via the fetal compartment is more than 30 times greater than the probability of its arrival directly. This means that only about three per cent of the urea enters the maternal compartment directly from amniotic fluid. The finding of low urea flux between amniotic fluid and maternal serum is in agreement with the reports of studies of tracer doses of ^{14}C-urea in pregnant rhesus monkeys[15] and in vitro with human chorion laeve.[18] Since most of the urea that appears in maternal serum has previously been transported to the fetus and then across the placenta, a relatively slow rise and delayed peak is seen in the time course of concentration in the maternal serum (Fig. 3). As expected, the rate constant for transfer of urea from amniotic fluid to the fetal compartment (K_{af}) was independent of the concentration in amniotic fluid (*see* Table I).

With the use of a mathematical model involving the amniotic fluid, fetal water, maternal water, and maternal urine, experimentally measured concentrations of ^{14}C-urea after intra-amniotic injection of a hyperosmolar urea solution were fitted with the aid of a digital computer program (Fig. 4). The first-order rate constants derived from this model demonstrate that the transport of urea from amniotic fluid to the maternal circulation is retarded because the solute must first pass through the fetus and placenta. This finding explains the surprisingly modest elevation in maternal serum urea observed after intra-amniotic injection of large doses of hyperosmolar urea for midtrimester abortion.

Patients at high risk for low-birth-weight delivery

D. FRANK KALTREIDER, M.D.
JOHN W. C. JOHNSON, M.D.
Baltimore, Maryland

A retrospective analysis of 8,839 singleton deliveries was undertaken to determine the relationships of maternal age, maternal hemoglobin concentration, and past obstetric performance to the incidence of low-birth-weight (LBC) delivery. Patients under 19 years of age and patients with hemoglobin values less than 9.0 Gm. per 100 ml. were found to have significantly higher incidences of LBW deliveries. In addition, the incidence of LBW delivery was found to vary in proportion to the number of previous LBW deliveries and inversely with the number of previous term deliveries.

IT IS GENERALLY accepted that premature delivery is the most common obstetric complication associated with perinatal death, accounting for the majority of all such fatalities occurring at this time.[1, 2] In addition, surviving infants of low birth weight due to prematurity or fetal growth retardation have high incidences of neurologic, intellectual, and emotional deficits.[3, 4] The incidence of prematurity in the United States is generally quoted as being between 7 and 14 per cent. If one assumes an annual birth rate of three million and an incidence of 8.5 per cent prematurity, then approximately 250,000 premature infants are born annually in the United States alone.[5] Although this serious complication of pregnancy occurs with alarming frequency, an acceptable cause is identifiable in only 40 per cent of the cases. The maternal complications that most frequently predispose to premature labor are hypertensive cardiovascular disease, abruptio placentae, and placenta previa. In these and other circumstances of maternal and fetal jeopardy, premature delivery may be iatrogenic in that termination of pregnancy is required to protect the lives of the mother and her baby. If one adds multiple pregnancies and congenital anomalies of the fetus to this list, approximately 40 per cent of premature deliveries are accountable. The remaining 60 per cent of premature labors are without apparent explanation.[1]

In those deliveries characterized by a birth weight below 2,500 grams, premature labor is usually accepted as the most common cause, although fetal growth retardation is said to account for one third.[6] The differentiation of these etiologic factors is not always possible, but clearly LBW delivery is a major factor associated with obstetric wastage. For purposes of improved management and clinical investigation, it is desirable to identify those maternity patients who are at high risk. The objectives of this study were to determine the relationship of the following three factors to the incidence of LBW delivery: (1) maternal age, (2) maternal hemoglobin concentration, and (3) past obstetric performance, particularly previous premature delivery.

Methods

The obstetric population utilized for this retrospective study was the 8,839 black patients delivered at the University of Maryland between 1955 and 1960. Those patients with multiple pregnancies and those who had had therapeutic terminations of their pregnancies were excluded from the analyses.

Maternal age was determined on the basis of information obtained upon the first prenatal visit. For purposes of this study, the hemoglobin concentration assigned to each patient was the lowest value determined antenatally. The past obstetric performance was derived primarily from the history. In an effort to test the cumulative effects of past obstetric events, the

Sickle cell	20	20	
Megaloblastic	3	67	

patients were subdivided into groups according to the number of previous LBW deliveries and the number of previous mature deliveries.

Because gestational ages could not be accurately ascertained in all patients, it was decided to define LBW delivery as one yielding an infant with a birth weight of 400 to 2,499 grams. Although the majority of such infants are premature, a significant proportion are mature, growth-retarded infants. On the basis of the data available, it was not possible to differentiate these two groups of LBW infants. Those with birth weights of 2,500 grams or more were designated mature, or term. Although a small proportion of these infants were probably premature, this differentiation also was not possible from the available data.

Results

Of the total 8,839 singleton pregnancies analyzed in this study, 1,475 resulted in the delivery of infants weighing between 400 and 2,499 grams. This represents an over-all incidence of LBW delivery of 16.7 per cent in this black population.

Table I demonstrates the incidence of LBW delivery according to maternal age. When the mother was 19 years or younger, the over-all incidence was 20.3 per cent. This was significantly higher than the 15.8 per cent incidence of LBW delivery noted when the mother's age was 20 years or greater ($p < .001$).

Table III. The incidence of LBW delivery according to past obstetric performance

Previous term deliveries	*Previous LBW deliveries*			
	0	*1*	*2*	*3 + >*
0	19.3% (435/2,253)*	35.3% (77/218)	54.1% (40/74)	59.7% (37/62)
1	15.1% (217/1,439)	28.4% (62/218)	36.4% (24/66)	45.2% (28/62)

0	19.3% (435/2,253)	31.8% (35/110)	45.0% (9/20)

*Number of LBW deliveries/total deliveries.

Table II indicates the incidence of LBW delivery in relation to the lowest recorded antenatal hemoglobin value. The incidence of LBW delivery was found to be significantly greater in those patients with a hemoglobin value less than 9.0 grams (27.9 per cent) when compared to those with a hemoglobin concentration of 9 grams or greater (16.8 per cent) ($p < .001$). The 20 per cent incidence observed in patients with sickle-cell disease is in good agreement with that reported in other series.[7] The 67 per cent incidence observed in patients with megaloblastic anemia should be accepted with caution, since only three such cases were identified.

Table III demonstrates the frequency of LBW delivery in relation to the number of past term and past LBW deliveries. The groups are subdivided according to the number of previous term deliveries (0, 1, 2, 3, and 4 or greater); previous LBW deliveries (0, 1, 2, and 3 or more); and previous spontaneous abortions (0, 1, and 2 or more). A striking rise in the rate of LBW delivery is observed with increased numbers of past LBW deliveries. This relationship is consistently present in that increasing numbers of previous LBW deliveries were always associated with increasing incidences of subsequent LBW delivery. Within those groups of patients subdivided according to the number of previous term pregnancies, a three- to fivefold increase in the incidence of LBW delivery was noted between patients that had not had previous LBW

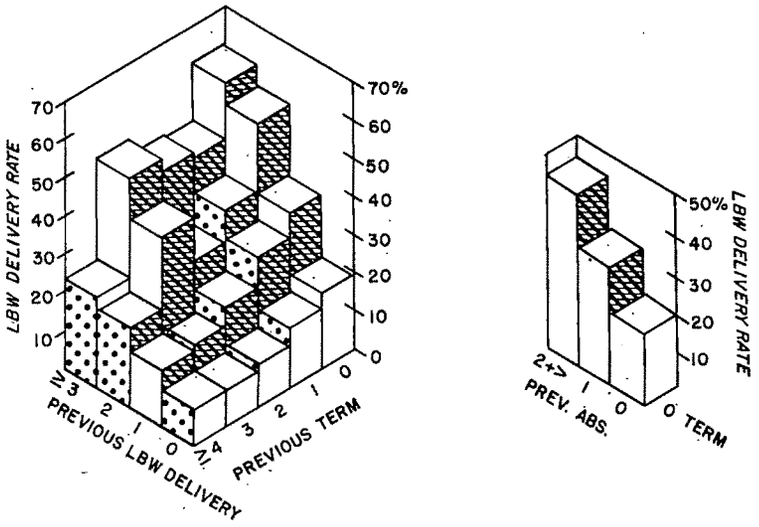

Fig. 1. In the left-hand graph, LBW delivery rates are represented on the vertical axis, according to the number of previous LBW deliveries and previous term deliveries. In the right hand graph, the LBW delivery rates are depicted according to the number of previous spontaneous abortions in nulliparous patients.

deliveries and those that had had three or more. For example, in the group of patients who had had three previous term pregnancies, the observed incidence of LBW delivery was 9.2 per cent among those who had not experienced previous LBW delivery, as opposed to 50 per cent among those who had had three or more previous LBW deliveries ($p < .001$).

The converse relationship between previous term pregnancies and subsequent LBW delivery is also remarkable in that increasing numbers of previous term pregnancies were usually associated with decreasing incidences of subsequent LBW delivery. Within groups subdivided according to the number of previous LBW deliveries, a 50 to 62 per cent reduction in the incidence of LBW delivery was noted between those patients who had not had previous term pregnancies and those who had had four or more.

The association between previous spontaneous abortions and subsequent LBW delivery among nulliparous patients is also shown in Table III. A striking increase in LBW delivery was noted with increasing numbers of previous miscarriages (19 to 45 per cent; $p < .001$).

The relationships shown in Table III are depicted in graphic form in Fig. 1. Those columns with cross-hatching represent LBW delivery rates significantly greater than observed in the corresponding patient group without previous LBW delivery. Those columns with dots represent LBW delivery rates significantly less than the corresponding group without previous term pregnancies. In the portion of the graph demonstrating the relationship between past miscarriages and LBW delivery rates, the columns with cross-hatching represent LBW delivery rates significantly in excess of those observed in patients without previous miscarriage.

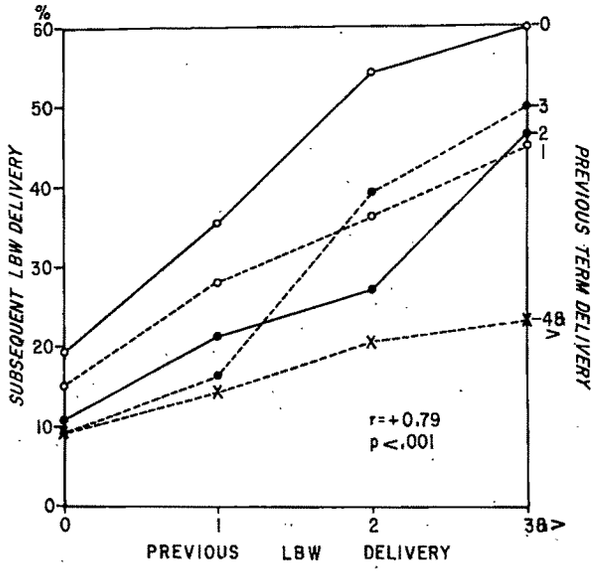

Fig. 2. This graph demonstrates the relationship between varying numbers of previous LBW deliveries and subsequent LBW delivery rates. The rates for patient groups with the same number of previous term pregnancies are joined by lines.

In Fig. 2, the incidences of LBW delivery in the study pregnancies have been plotted against the incidences of previous LBW deliveries. A positive correlation

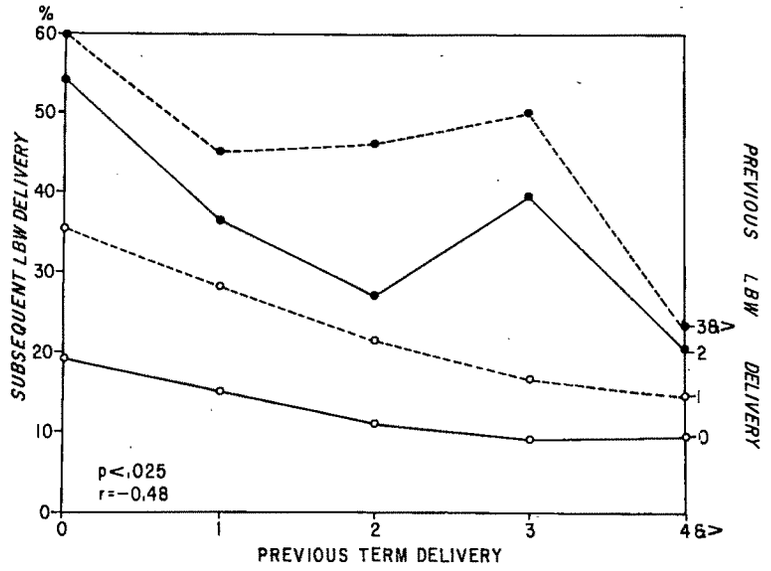

Fig. 3. This graph illustrates the relationship between varying numbers of previous term deliveries and subsequent LBW delivery rates. LBW delivery rates for groups with the same number of previous LBW deliveries are joined by lines.

coefficient was found to be present when the values for all term pregnancies were considered ($r = +0.79$; $p < 0.001$). The values for those patient groups with the same number of previous term pregnancies have been connected by identity lines for purposes of further analysis as discussed below.

In Fig. 3, the incidences of LBW delivery in the study pregnancies have been plotted against the number of previous term deliveries. In this case, a significant negative correlation coefficient was found to be present when the values for all groups were considered ($r = -0.48$; $p < 0.025$). The points for those patient groups with the same number of previous LBW deliveries have been joined by lines for purposes of further analysis as given below.

Comment

Although it would be more meaningful to distinguish those LBW deliveries associated with prematurity from those associated with intrauterine growth retardation, this was not possible in the present study. The LBW babies studied in these analyses undoubtedly include a number of infants whose birth weights were small for gestational age and who did not represent truly premature infants. The relationships demonstrated probably apply to true prematurity, however, since they have been reported in other studies where prematurity was defined according to gestational age.[8]

The increased incidence of LBW delivery noted in the young patients of this study is a common observation reported by many previous investigators.[9, 10] No satisfactory explanation for this association is provided by the present study, although a low socioeconomic status has been suggested as a common factor.[10] The mechanisms have not been documented by which a low socioeconomic status might predispose to premature delivery.

The association between anemia and prematurity has also been noted previously.[11] In a study of teenage pregnancies, Israel and Woutersz[12] concluded that anemia was more common in teenage mothers and that age rather than anemia per se was more likely to account for the increased incidence of prematurity. In the present study, no correction for age nor for socioeconomic status was made in the analysis of the relationship between hemoglobin values and prematurity. Griswald and Cavanagh,[13] in comparing indigent patients with term deliveries and indigent patients with premature deliveries, found the incidence of anemia was only 6 per cent higher in the latter population.

The impact of previous LBW delivery and term delivery. The repetitive tendency of LBW deliveries has been reported by many observers.[8–10] To the authors' knowledge, however, previous studies have not shown the cumulative risk associated with increasing numbers of prior LBW deliveries. Nor has the cumulative benefit of prior term pregnancies been demonstrated.

The mechanism by which LBW delivery leads to successive LBW deliveries remains to be determined. On the basis of the lines representing the values for different term pregnancy groups (Fig. 2), the relationships appear to be linear with the slopes varying inversely with respect to the number of previous term pregnancies. Increasing numbers of past LBW deliveries appear to have an additive effect upon the incidence of subsequent LBW delivery.

The effect of previous term pregnancies on the incidence of subsequent LBW delivery, as depicted in Fig. 3, is opposite to that of previous LBW delivery. In general, increasing numbers of previous mature deliveries are associated with decreasing incidences of LBW deliveries. Thus, previous LBW delivery and previous maturity appear to have cancelling effects, with respect to the incidence of subsequent LBW delivery. Whereas the effect of previous low birth weight delivery appears to be additive, however, that of previous mature delivery does not appear to be simply subtractive. In Fig. 3, the curves connecting points for those patients with less than two previous LBW deliveries appear to be exponential, approaching an irreducible minimum of 10 to 15 per cent incidence. If the two curves representing patients with two or more previous LBW deliveries are extrapolated through the points representing 0, 1, and 4 or more previous term deliveries, they also appear to be exponential, approaching a minimum value of 10 to 15 per cent. The fact that the remaining three values are well above the extrapolated lines might be due to the influence of previous LBW deliveries overriding the opposing influence of previous term pregnancies. It might also be attributed to the fact that these points represent relatively small patient groups. In any event, the exponential feature of these lines suggests that increasing numbers of previous mature deliveries have a divisional, rather than subtractive, effect on the rate of subsequent LBW deliveries. The apparent minimum frequency of 10 to 15 per cent may represent the random occurrence rate in this population.

Since these data are derived from the late 1950's, some question might be raised as to their relevance with respect to present-day obstetric outcome. On the basis of these data, patients who have had two or more previous LBW deliveries, might be expected to experience a subsequent LBW delivery rate of 30 to 60 per cent. In fact, in a prospective study performed during 1971, 1972, and 1973, patients who had had two or more previous premature deliveries were found to experience an over-all incidence of prematurity of about 40 per cent.[14] Furthermore, factors known to be associated with recurrent prematurity (cervical incompentency, fundal anomalies, placenta previa, and abruptio placentae) were infrequently observed in this patient population. Further investigations of this unique high-risk population may give important information on the etiology of idiopathic prematurity.

The impact of previous miscarriages. Although Ross and Schneider[10] suggested that previous spontaneous abortions predispose to subsequent premature delivery, Griswald and Cavanagh[13] were unable to demonstrate such a relationship. The discrepancy between the latter study and our own might be related to the fact that the other authors did not correct for the number of previous term pregnancies. In the present study, evaluation of the effect of previous abortions was limited to nulliparous patients. The incidence of LBW delivery may relate to previous abortions and previous term pregnancies, as it does to previous LBW deliveries and previous term pregnancies. Under these circumstances, it would be necessary to study the effect of abortion within groups subdivided according to the number of previous mature deliveries.

The 45 per cent incidence of LBW delivery observed in nulliparous patients who have had two or more previous miscarriages is a striking increase of this complication. It is of interest that an increased incidence of premature delivery has recently been reported also as a late sequel to induced abortions.[15] It remains to be determined whether the mechanisms are similar that account for the increased incidences of prematurity following spontaneous and induced abortions.

In summary, this retrospective study demonstrated that, within the patient population analyzed, the very young patients and those patients with anemia were at an increased risk for delivery of LBW infants. In addition, those patients who had had previous LBW deliveries or miscarriages were noted to be at an increased risk of subsequent LBW delivery. The risk of LBW delivery appeared to vary directly with the number of previous LBW deliveries, and inversely with the number of previous term deliveries.

The identification of patients at an increased risk for LBW delivery should aid in their clinical management, since the opportunity is thus presented to focus on interconceptional and early prenatal care. In addition, the identification of a specific high-risk patient population can be of assistance in clinical studies and investigations pertaining to the etiology and management of LBW pregnancies.

We are grateful to Dr. Arthur L. Haskins, Jr., for providing the data utilized in these analyses.

Amniotic fluid osmolality in pregnancies complicated by diabetes

PENRHYN BAILEY
MARY BLAKE
BENJAMIN YOUNGER
CLARK HINKLEY
GEORGE CASSADY
Birmingham, Alabama

Amniotic fluid osmolality (AF Osm) was studied in 247 patients whose pregnancies were complicated by maternal diabetes. Significant increases in mean AF Osm accompanied pre-existing fetal as well as subsequent perinatal death. Abnormal increases in AF Osm were associated with a significant increase in risk of perinatal compromise with cumulative morbidity and mortality rates of 54 per cent. These data suggest that serial evaluation of AF Osm enables detection of a "higher risk" group of diabetic pregnancies in which perinatal death is more than doubled.

THE RELATION BETWEEN amniotic fluid osmolality (AF Osm) and fetal compromise has been a recent topic of clinical concern in perinatal medicine.[1-7] Definitive data concerning this relation, particularly in the pregnancy complicated by diabetes, are sparse.[7] The present report attempts to provide preliminary data in this regard.

Material and methods

During a three-year period, 1970 to 1972, a total of 485 amniotic fluid samples were obtained by transabdominal amniocentesis from 247 patients whose pregnancies were complicated by diabetes. Samples were obtained for the most part during prenatal visits to a high-risk perinatal clinic; samples were not obtained during labor. In 119 patients, single AF samples were available, while in 128 serial samples were obtained. Duration of gestation was estimated from menstrual history and confirmed in many cases with fetal sonar measurements as well as by Dubowitz[8] examination of the newborn infant. Criteria for diagnosis of gestational diabetes were similar to those of O'Sullivan and associates,[9] the diagnosis of Class A diabetes being made if whole blood glucose exceeded 110 mg. per cent (fasting), 170 mg. per cent (one hour), 120 mg. per cent (two hours), or 110 mg. per cent (three hours) following a 100 Gm. oral glucose load (GTT). Class AD diabetes (gestational diabetes with carbohydrate decompensation) was diagnosed if whole blood glucose exceeded 120 mg. per cent (fasting) or 180 mg. per cent (two hours) after GTT or if whole blood glucose exceeded 300 mg. per cent at any time. Severity of insulin-requiring diabetes (Classes B to D) was estimated with the criteria of White and co-workers.[10]

Electronic fetal monitoring was performed in many patients and both one- and five-minute Apgar scores were determined at delivery for all patients. Those with electronic evidence of type II fetal bradycardia,[11] predelivery passage of meconium, and/or one- or five-minute Apgar scores of ≤6 were considered to have perinatal asphyxia. Following delivery, most of these infants were cared for in the University High-Risk Nursery where they were screened for biochemical evidence of *hypoglycemia* (serum "true sugar" ≤30 mg. per cent if <37 weeks' gestation or ≤40 mg. per

Table I. Clinical features of 247 study pregnancies complicated by diabetes

Clinical parameter	*Result*
Race (black/white)	163/84
Age	
Years	15-45
Mean ± S.D.	26.5 ± 7.3
Class of diabetes	
A	167 (67.6%)
AD	33 (13.4%)
B	21 (8.5%)
C	16 (6.5%)
D	10 (4.0%)
Death	
Fetal	15 (60.7/1,000)
Neonatal	6 (25.9/1,000)
Perinatal	21 (85.0/1,000)
Morbidity	77 (31.2%)
Macrosomia	49 (19.8%)
IGR	26 (10.5%)
Vascular disease	95 (38.5%)

cent if ≥37 weeks' gestation.[12] Perinatal morbidity was considered present in any infant with evidence of perinatal asphyxia and/or hypoglycemia.

Intrauterine growth retardation (IGR) was diagnosed when birth weight was ≤10 percentile of that expected for gestation, race, and sex; macrosomia was considered present when birth weight was ≥90 percentile of that expected.[13] Diastolic blood pressure ≥90 mm. Hg on two successive examinations and/or proteinuria led to the diagnosis of renovascular disease. As distinction between acute or subacute maternal pre-eclampsia and persistent or pre-existing vascular compromise (hypertensive cardiovascular or renovascular disease) was often not possible in our population, no attempt was made to distinguish between these forms of maternal vascular disease.

Amniotic fluid osmolality was determined by freezing point depression.* Samples were free from overt meconium and/or blood, centrifuged, refrigerated, and analyzed in duplicate or triplicate within 48 hours of receipt. Data were subjected to chi square or Student's t test.

Death rates were calculated as:

$$\text{Fetal death rate} = \frac{\text{fetal deaths}}{\text{total births}} \times 1{,}000.$$

$$\text{Neonatal death rate} = \frac{\text{neonatal deaths}}{\text{total live births}} \times 1{,}000.$$

$$\text{Perinatal death rate} = \frac{\text{neonatal deaths + fetal deaths}}{\text{total births}} \times 1{,}000.$$

Perinatal morbidity	31% (30)	31% (47)

Number of patients indicated in parenthesis.
*$p = <0.025$.

Results

Clinical features of the study pregnancies. Table I summarizes certain clinical features of the 247 pregnancies studied. The study subjects were predominantly black (66 per cent) and the pregnancies for the most part were complicated by gestational diabetes (81 per cent). One fifth of the women were teenagers (49/247), nearly one third in their 30's or 40's (73/247), and half were in their 20's (120/247). Maternal vascular compromise was common. Fetal, neonatal and total perinatal mortality rates in the study group were nearly three times those of our population as a whole during the same years (perinatal mortality rate 85.0 in study group/30.6 in total population 1970 to 1972). In nearly one third of the perinatal patients, asphyxia and/or hypoglycemia was documented (77/247) and one in five was large for gestational age (49/247). Fetal growth retardation was no more common in these patients (26/247 = 10.5 per cent) than that in the general population (ten per cent by definition[13]).

Table II summarizes the effect that severity of maternal diabetes had on the frequency of certain clinical problems. Excess perinatal death was confined

*Mean ± one standard deviation.

to patients of Class AD or greater severity; the rate of 24.0/1,000 in patients with Class A diabetes was similar to that of our general population, but the rate of 212.5/1,000 for those of AD, B, C, and D severity was significantly higher (4/167 versus 17/80; $p < 0.005$). The incidence of perinatal morbidity (asphyxia and/or hypoglycemia) tended to increase with severity of maternal diabetes, but these differences were not statistically significant. Combined mortality and morbidity rates (52 of 167 in Class A = 31 per cent; 16 of 33 in Class AD = 48 per cent; 30 of 47 in Class B-D = 64 per cent) also increased with severity of diabetes; these risks were significantly lower in Class A than in Class AD, B, C, D patients ($\chi^2 = 15.706$; $p < 0.001$). Fetal macrosomia, frequent in all groups, tended to be more common in Classes AD, B, C, and D (21 of 80 = 26 per cent) than in the Class A patients (28 of 167 = 17 per cent), but this difference was not significant. The incidence of fetal growth retardation in Class B, C, and D patients (seven of 47 = 15 per cent) was higher than that in Class A or AD (19 of 200 = nine per cent), but this trend also was not statistically significant. Vascular disease, common in all groups, was more frequent in Class AD patients (18 of 33 = 55 per cent) than in Class A (62 of 167 = 37 per cent) or Classes B to D patients (15 of 47 = 32 per cent); this difference was significant only for the later comparison ($p < 0.05$). The impact of maternal vascular disease on the perinatal infant is further analyzed in Table III. A nearly twofold significant increase in fetal macrosomia in patients with vascular disease was observed (25 of 95 versus 24 of 152; $p = < 0.05$). The incidence of perinatal morbidity was identical in both groups.

In Table IV AF osmolality is related to certain clinical complications in the study pregnancies. Mean osmolality was significantly higher in amniotic fluids obtained from pregnancies with ultimate perinatal death or morbidity, fetal growth retardation, or more severe maternal diabetes than that from those without complications. Fluids from these compromised groups, however, were generally obtained earlier in gestation. As AF osmolality is inversely related to gestational age,[4] further analysis of these data, balanced for gestational age, is presented in Fig. 1. From the data in Fig. 1, it is clearly apparent that, with correction for gestational immaturity, increased AF osmolality consistently correlates only with perinatal death or more severe (Classes B, C, and D) maternal diabetes. In point of fact, increased AF osmolality correlates only with perinatal death; with exclusion of figures from Class B, C, and D patients with perinatal death, mean AF osmolality in the more severe diabetic patients is virtually identical to that in the Class A group (at < 32 weeks, 264 versus 262 mOsm. per kilogram; at 33 to 36 weeks, 257 versus 256 mOsm. per kilogram; at 37 to 41 weeks, 257 versus 254 mOsm. per kilogram, respectively).

Serial AF osmolality measurements were obtained in

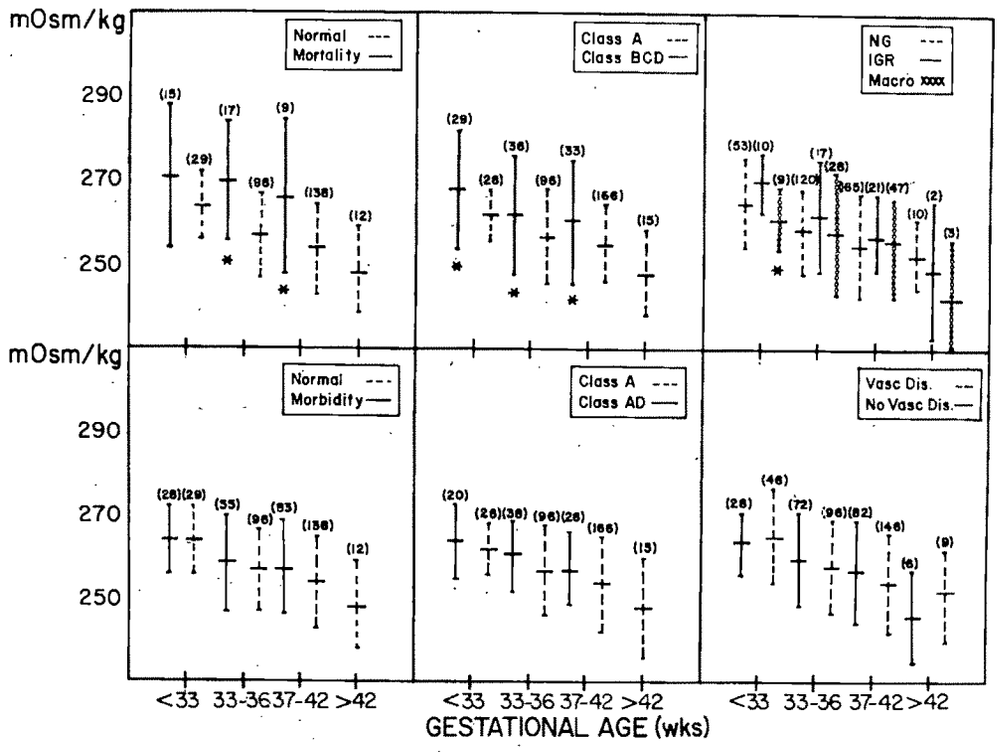

Fig. 1. Amniotic fluid (AF) osmolality (mean ± one standard deviation) at grouped gestational ages in diabetic pregnancies. Number of AF samples in parentheses. Asterisk indicates statistically significant difference between means ($p < 0.05$).

128 patients. Stable or declining values, expected with advancing gestation, were observed in 65 pregnancies; perinatal death occurred in four (six per cent) and morbidity was present in another 19 (a cumulative 35 per cent). The relation of serial AF osmolality to perinatal outcome is summarized in Fig. 2. Perinatal death in the 63 pregnancies with abnormal, serially rising AF osmolality was doubled (9/63, 14 per cent) and morbidity was present in another 25 (a cumulative 54 per cent; $p < 0.05$). Individual AF osmolality values for all 13 perinatal deaths in this series are provided in Fig. 3 in order to demonstrate that consistently altered amniotic fluid osmolality did not invariably precede or predict subsequent perinatal death.

Comment

Amniotic fluid osmolality (AF Osm), primarily dependent on sodium and accompanying anion concentrations in water,[2] declines linearly during late gestation.[7] A temporal relation to improved fetal tubular resorption of sodium[14–16] and increased gut resorption of sodium accompanying increased swallowing movements[17–18] as well as a return of AF Osm toward maternal serum levels following fetal death[1] or life-threatening fetal manipulative surgery[19] suggest an active if not central role for the fetus in determining the ultimate hypoosmolality of the amniotic fluid.[7]

In view of these observations, it is not surprising that several investigators have observed increased AF Osm to accompany a variety of perinatal compromises. Initial work from our laboratory concerned 79 pregnancies complicated by a variety of problems, including Rh sensitization, diabetes, toxemia, and/or hydramnios. Mean AF Osm was significantly increased with prior or subsequent perinatal death as well as in situations of more severe fetal hemolytic disease with survival.[2] Serial AF Osm evaluations were obtained in 48 patients with Rh sensitization; abnormal serial increases in 23 patients were accompanied by a 40 per cent perinatal mortality rate (ten times that of the 25 patients with normal serial declines) and cumulative morbidity and death occurred in 96 per cent (44 per cent in those with decreasing osmolality). While the most striking elevations occurred in situations in which fetal death occurred before amniocentesis, elevated and rising AF Osm was also observed to precede subsequent fetal death or serious perinatal compromise. More recent data from this laboratory in a

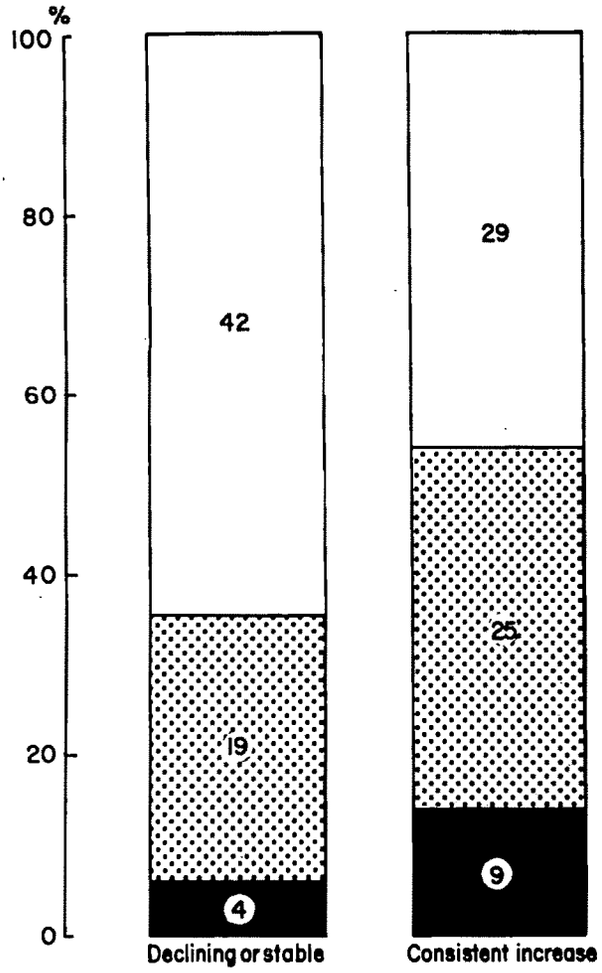

Fig. 2. Relation of serial amniotic fluid osmolality to perinatal outcome. Number of pregnancies studied indicated in each block. Solid block, perinatal death; stippled block, perinatal morbidity (see text for definition); clear block, no morbidity or deaths.

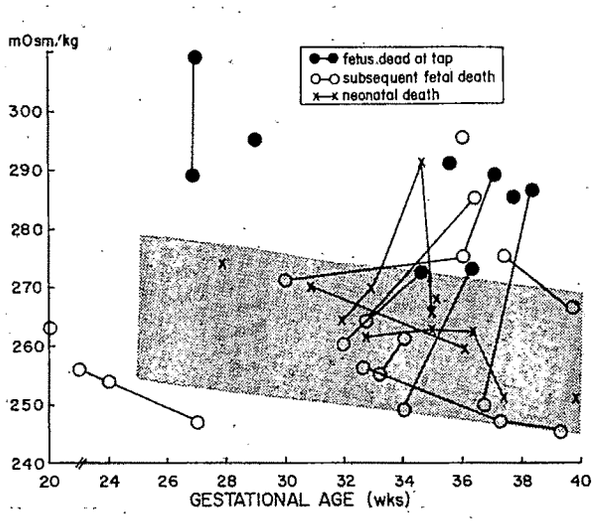
total 156 Rh-sensitized pregnancies have confirmed these earlier serial studies.[7] The work of O'Leary and Feldman[5] is difficult to interpret because of their neglect to analyze their data statistically. AF Osm evaluations from a total 16 diabetic and 81 Rh-sensitized pregnancies (nine with fetal death) were compared to those from 87 normal pregnancies. Although mean AF Osm at 32 to 35 and 36 to 37 weeks' gestation was consistently higher (by as much as 9 mOsm. per kilogram) in the complicated pregnancies, the authors dismissed the clinical value of these findings and their data as reported do not allow a more careful statistical analysis. Kittrich and associates[6] showed a threefold increase in perinatal asphyxia in gestations with AF Osm >275 mOsm. per kilogram.



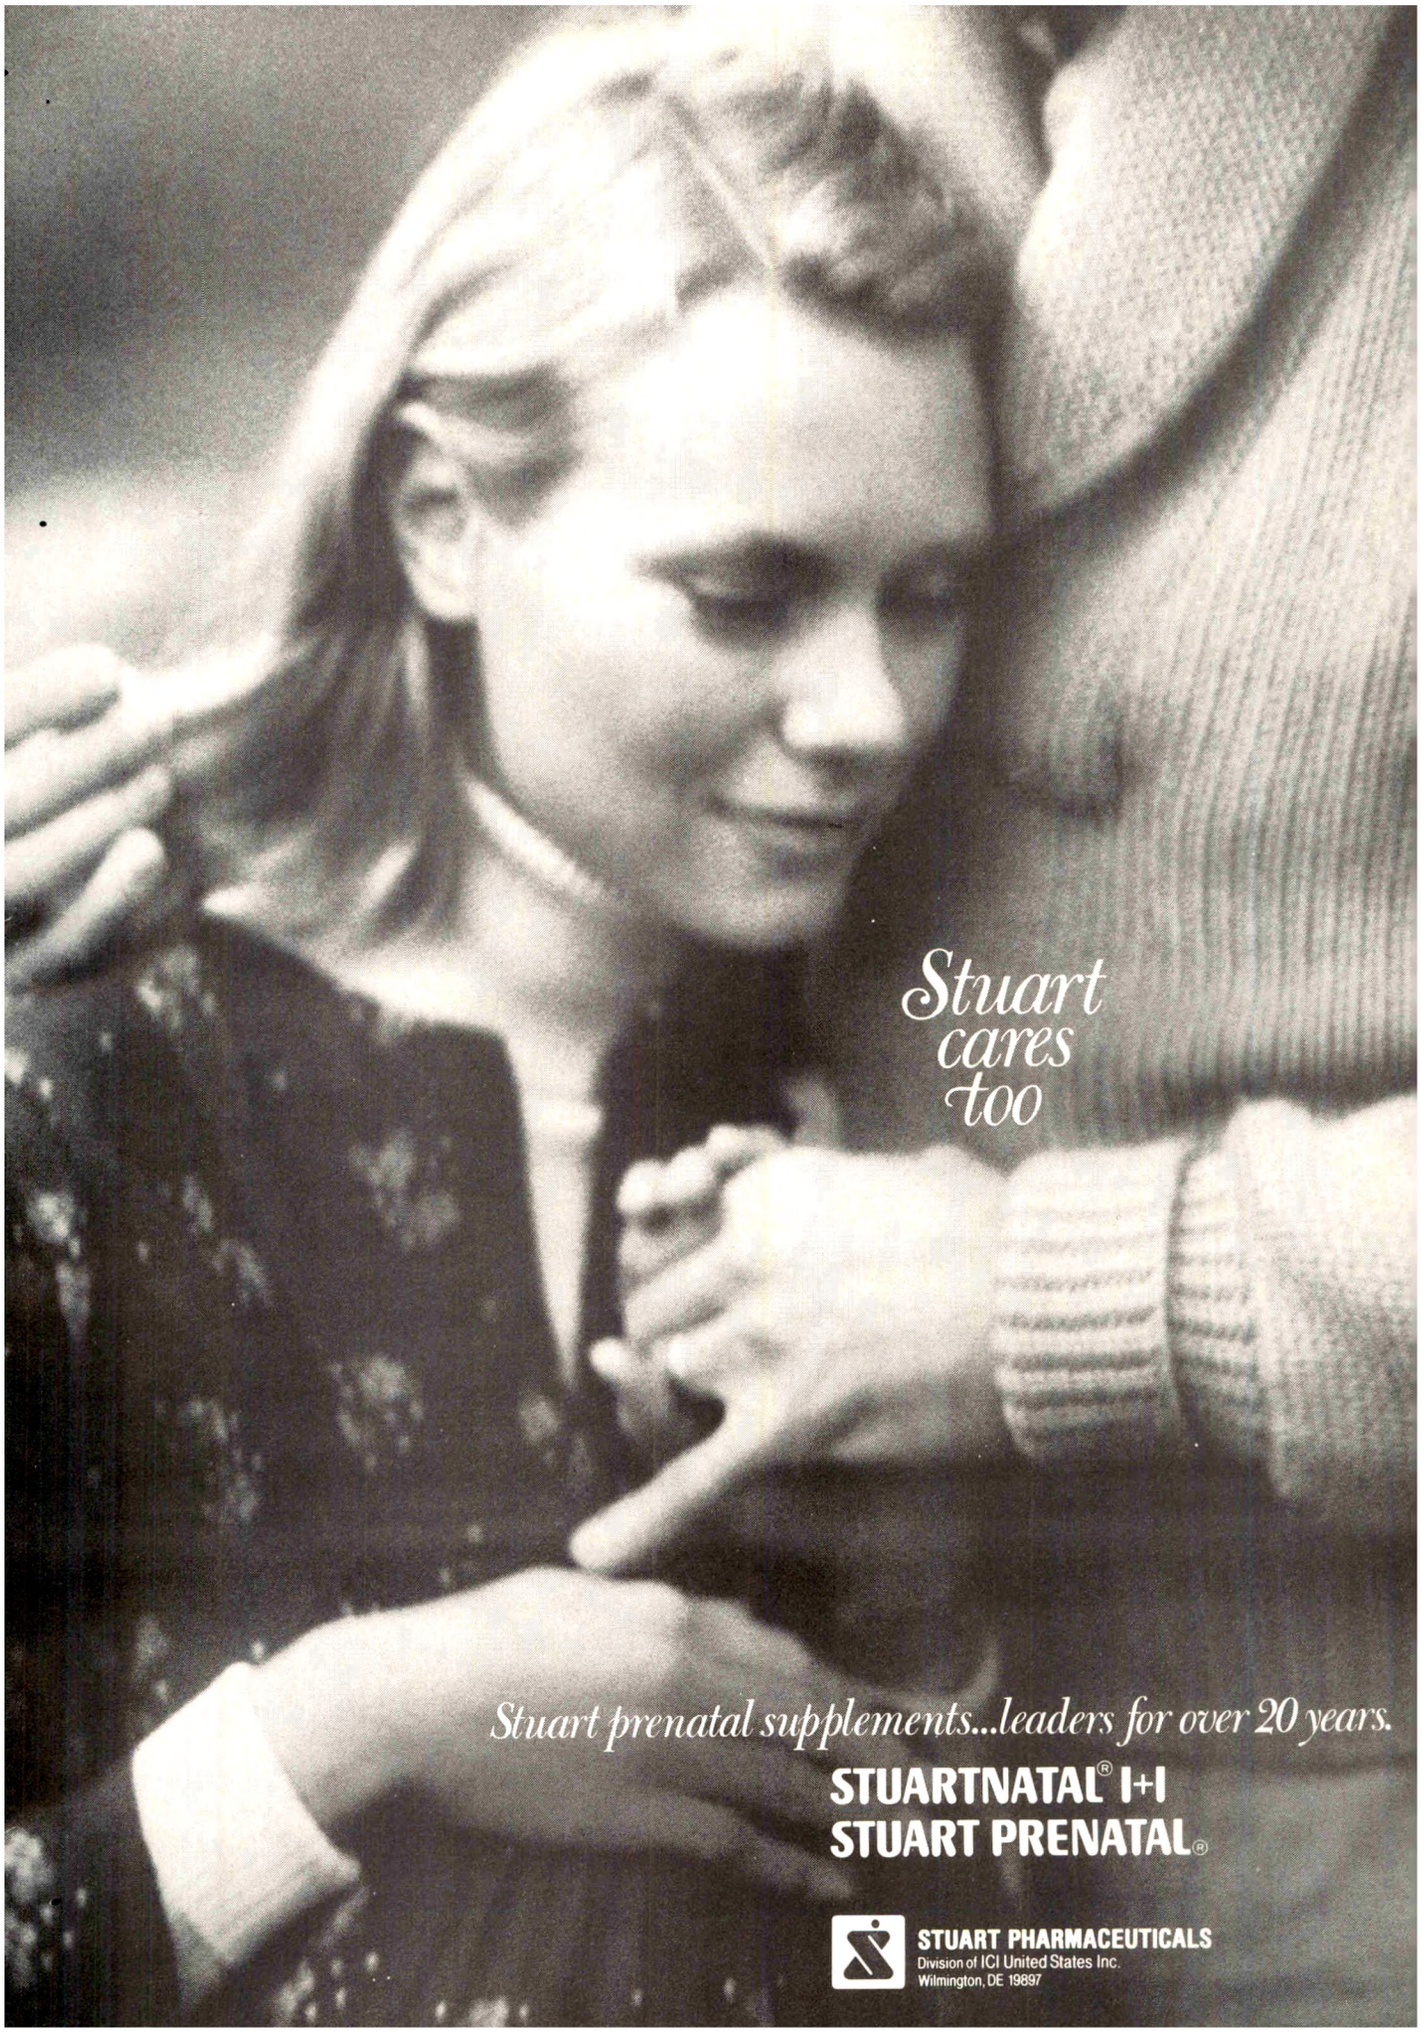


Fig. 3. Relation of amniotic fluid (AF) osmolality to gestational age in 13 pregnancies in diabetic women terminating in perinatal death. Individual AF osmolalities overplotted on normal range (±2 s·y·x) of AF osmolality (stippled area).[2]

Pregnancies complicated by diabetes and postmaturity were significantly more common in their group with "hypertonic" amniotic fluid. Seventeen of 22 pregnancies complicated by diabetes had hypertonic amniotic fluid at delivery.

There seems to be little doubt that increased AF Osm may accompany perinatal compromise. Fluids in these at-risk groups, however, are often obtained early in gestation.[7] AF Osm is inversely related to gestational age, with an expected decline of about 1 mOsm. each week.[2] Balancing the present data for gestational immaturity reveals that significant elevations of mean AF Osm accompany perinatal death. Severity of maternal diabetes, other than increasing the risk of perinatal death, does not directly affect AF osmolality, nor do maternal vascular disease or conditions resulting in altered fetal growth, perinatal asphyxia, or neonatal hypoglycemia. Of particular clinical pertinence are the observations that abnormal serial increases in AF Osm during the course of pregnancy complicated by diabetes accompany a significant increase in risk of perinatal compromise (14 per cent mortality rate and cumulative morbidity and mortality rate of 54 per cent). These data suggest that while serial evaluations of AF osmolality do not invariably predict the unsuccessful outcome of a pregnancy complicated by maternal diabetes (six per cent death and 35 per cent morbidity in patients with "normal" declines in AF Osm), the serial evaluation of amniotic fluid solute content does distinguish a "higher risk" group in which perinatal death is more than doubled.

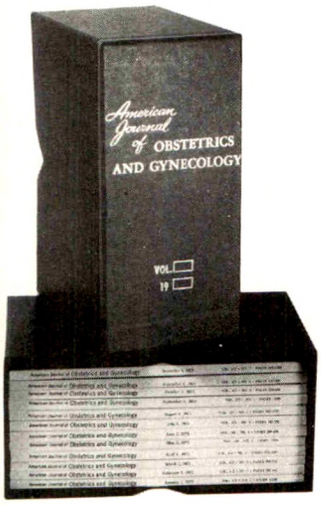
PURCHASING FOR THE HEALTH CARE FACILITY *by* **John H. Holmgren**, *St. Joseph Medical Center, Wichita, Kansas.* Basics of medical technology and health care purchasing are analyzed with a knowledgeable, professional approach. The book will serve as a ready reference, as a purchasing seminar-workshop tool, and as background for students in health care administration. Ways of reducing costs and purchasing are suggested and information is included on inventory, relations with vendors, negotiation, the departmental manual, traffic and transportation, health care purchasing as a profession, and future trends in health care material management. *'76, 288 pp., 18 il., 29 tables, $18.50*

BEHAVIORAL SCIENCE IN CLINICAL MEDICINE *by* **Stewart Wolf**, *Univ. of Texas Medical Branch, Galveston, and* **Helen Goodell**, *Cornell-New York Hospital Medical Center, New York.* Health and well-being depend not only on man's capacity to adapt to the tangible environment, but also to prevailing attitudes and values in his society and to his own goals and aspirations. Therefore, medicine must concern itself with more than just physical science–it must deal with human values also. To this end, the author discusses behavioral science in the context of human ecology, man's needs and expectations, the significance of medical education, the cultivation of the individual and its significance in the practice of medicine, and values and fulfillment. *'76, 256 pp., 22 il., $14.50*

LYMPHOPROLIFERATIVE DISEASES *compiled and edited by* **David W. Molander**, *Memorial Hospital for Cancer and Allied Diseases, New York. (23 Contributors)* A compilation of the known facets of lymphosarcoma and related diseases is presented in this volume along with pathologic anatomy, immune mechanisms, clinical diagnosis and treatment employing irradiation and chemotherapy. The use of isotopes in managing this disease as well as in the diagnosis of occult foci of the disease is also covered. In the chapter dealing with the pathology of malignant lymphomas the new terminology, non-Hodgkin's malignant lymphoma, is used, and new pathologic designations are included. Chapters dealing with complications are included along with a chapter on primary reticulum cell sarcoma of bone. *'75, 592 pp. (6 3/4 x 9 3/4), 256 il. (9 in color), 45 tables, $39.50*

GALACTORRHEA *by* **Barry K. Gould**, *Univ. of Minnesota, Rochester,* **Raymond V. Randall, Roger D. Kempers** *and* **Robert J. Ryan**, *all of the Mayo Clinic, Rochester.* In this up-to-date monograph, forty-one previously unreported case histories are presented for patients with galactorrhea, the excessive or spontaneous flow of milk. The authors stress the often overlooked fact that patients with seemingly idiopathic galactorrhea and amenorrhea or with explanations like birth control pills for their symptoms often have intrasellar or suprasellar tumors. Pertinent literature is reviewed on galactorrhea and its characterization, incidence, classification, pathophysiologic mechanisms and management. *'74, 128 pp., 18 il. (3 in full color), 11 tables, $10.75*

COLPOSCOPY: A Scientific and Practical Approach to the Cervix in Health and Disease (2nd Ptg.) *by* **Malcolm Coppleson**, *King George V Memorial Hospital, Sydney, Australia;* **Ellis Pixley**, *King Edward Memorial Hospital, Perth; and* **Bevan Reid**, *The Univ. of Sydney, Sydney, Australia.* This book provides detailed discussion on the scientific basis of colposcopy, including colposcopic appearances with the corresponding histology. It illustrates the value of colposcopy in defining precise sites of preclinical carcinoma and other epithelial conditions. The text further provides detailed technical aspects of the instrument and its use. This is a timely volume combining both the functions of a manual and atlas. *'75, 360 pp. (6 3/4 x 9 3/4), 225 il. (1 in full color), 5 tables, $21.50*



POISONING: Toxicology–Symptoms–Treatments (3rd Ed.) *by* **Jay M. Arena**, *Duke Univ., Durham, North Carolina.* In this new edition, substantial changes have been made in all sections, and many new items are included for the first time, such as tricyclic drugs, methadone, naloxone hydrochloride, drugs and chemicals in breast milk, methyl mercury in fish and humans, polychlorinated biphenyl, animal poisons, tables of signs and symptoms of poisoning and many other additional tables and materials. The practitioner is often the primary physician who is first involved, and what he does or does not do can be critical and affect the ultimate outcome of a serious poisoning. This book provides the basic information for life-saving measures. *'74, 832 pp. (7 x 10), 26 il. (1 in full color), 123 tables, $39.50*

HUMAN NUTRITION: Its Physiological, Medical and Social Aspects. A Series of Eighty-Two Essays (2nd Ptg.) *by* **Jean Mayer**, *Harvard Univ., Boston, Massachusetts.* Here, in a series of vivid essays, one of the best known nutritionists of this era grapples with the scientific, clinical and administrative aspects of nutrition and its relation to health, poverty, war and technology. As the head and moving spirit of a research laboratory celebrated for its unique contributions to the understanding of the mechanism of regulation of food intake and of the etiology and pathogenesis of various types of obesity in experimental animals and man, he knows as well as anyone what research does and does not tell about that which is relevant for action, and discusses the subject in its entirety. *'74, 740 pp., 5 il., $12.95*

BIRTH DEFECTS AND FETAL DEVELOPMENT: Endocrine and Metabolic Factors *edited by* **Kamran S. Moghissi**, *Wayne State Univ., Detroit, Michigan. (22 Contributors)* This volume clarifies many unanswered questions regarding human reproduction; it reviews and updates the current knowledge and outlines areas which deserve future exploration. The relationship between maternal nutrition and fetal development, the influence of endocrine and environmental factors on fetal growth and well-being, the recognition of factors leading to the respiratory distress syndrome, prenatal detection of congenital and hereditary disorders, and genetic counseling are among the subjects discussed. *'74, 352 pp., 94 il. (1 in full color), 45 tables, $24.50*

DETECT FETAL PULSE

WITH THE

MEDSONICS ULTRASOUND STETHOSCOPE®

Doppler Model FP3A

Detects fetal life early in pregnancy (9-12 weeks) • Confirms fetal life throughout pregnancy • Assesses rate and rhythm of the fetal heart during labor • Pocket size; small, light and durable • Stethoscope style headset for privacy and isolation from background noise • Jack for second headset permits patient or colleague to listen • Operates at an ultrasound frequency of 2.25 MHz • Powered by a single long-life, replaceable battery • Two simple controls; on-off switch and volume.

PRICE $345

Price includes one stethoscope style headset, carrying case, battery, coupling gel and instructions. Extra headset is available for $34.50.

Not too many patients have an "iron will." That's why Abbott hematinics are easy to take.

Comfort minimal chance of gastric upset, thanks to the controlled-release iron (105 mg. Elemental Iron) which can be taken even on an empty stomach.

Convenience 500 mg. of Vitamin C, to enhance iron absorption, is combined with iron and B-Complex* in a single tablet.

Cooperation thanks to the once-a-day dosage.

Iberet-500
Hematinic Supplying Controlled-Release Iron with Vitamin C and *B-Complex (contains no folic acid)

Iberet-Folic-500® ℞
Controlled-Release Iron with Vitamin C and B-Complex including Folic Acid

Please see opposite page for Brief Summary.

ABBOTT

509106

Iberet®-500

One Filmtab® tablet a day supplies:

Controlled-Release Iron

Ferrous Sulfate,
(equivalent to
elemental iron—105 mg.) .. 525 mg.

Plus High Potency Vitamin C

Vitamin C
(as Sodium Ascorbate) .... 500 mg.

Plus the B-Complex
(contains no folic acid)

Niacinamide ..... 30 mg.
Calcium Pantothenate ..... 10 mg.
Vitamin B_1
(Thiamine Mononitrate)..... 6 mg.
Vitamin B_2 (Riboflavin) ..... 6 mg.
Vitamin B_6
(Pyridoxine Hydrochloride) .. 5 mg.
Vitamin B_{12}
(Cyanocobalamin) ..... 25 mcg.

INDICATIONS: For conditions in which iron deficiency occurs concomitantly with deficient intake or increased need for the B-complex vitamins (contains no folic acid).

Iberet-Folic-500® ℞

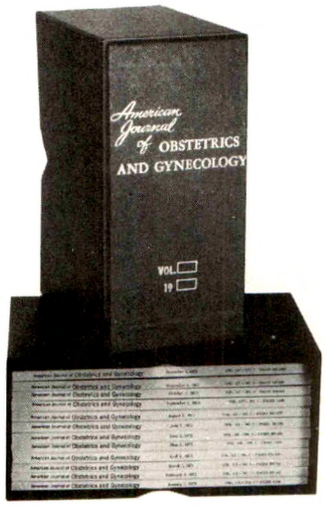
One Filmtab tablet a day supplies the same formula as Iberet-500 plus:

Folic Acid .....800 mcg.

INDICATIONS: In non-pregnant adults, for the treatment of iron deficiency and prevention of concomitant folic acid deficiency where there is an associated deficient intake or increased need for the B-complex vitamins. Also indicated in pregnancy for the prevention and treatment of iron deficiency where there is a concomitant deficient intake or increased need for B-complex vitamins (including folic acid).

CONTRAINDICATION: Pernicious anemia.

WARNINGS: Folic acid alone is improper therapy in the treatment of pernicious anemia and other megaloblastic anemias where vitamin B_{12} is deficient.



PRECAUTION: Where anemia exists, its nature should be established and underlying causes determined. Iberet-Folic-500 contains 800 mcg. of folic acid per tablet. Folic acid especially in doses above 1.0 mg. daily may obscure pernicious anemia, in that hematologic remission may occur while neurological manifestations remain progressive.

ADVERSE REACTIONS: The likelihood of gastric intolerance is remote. If such should occur, the tablet may be taken after a meal. Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

509106

Gradumet—Controlled-release dose form, Abbott.
Filmtab—Film-sealed tablets, Abbott.

PERSONALIZED LIBRARY CASES

Keep your personal copies of AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY in these specially designed library file cases. Two files hold an entire year's issues. Designed to keep your journal copies near at hand in your office, library, or home.

Your case is heavy bookbinder's board in a rich red Kivar cover. Files are scuff-resistant and washable.

Lettering is stamped in gold leaf and the cases make a fit companion for the most costly binding.

Files are reasonably priced—only $4.25 each, postpaid (3 for $12., 6 for $22.). Add $1.00 postage per case for orders outside U. S. Satisfaction unconditionally guaranteed or your money back! Use the coupon for prompt shipment.

The dawn of a new age

Genisis—The Reason for Change

Discovery, isolation, identification, synthesis—the classical pattern for creating drugs which once were available from natural sources only. Antibiotics, vitamins, and sex hormones come to mind as examples of drugs which have been developed and perfected in this manner. Obvious advantages of this evolution include: economy, standardization, reproducibility, and purity.

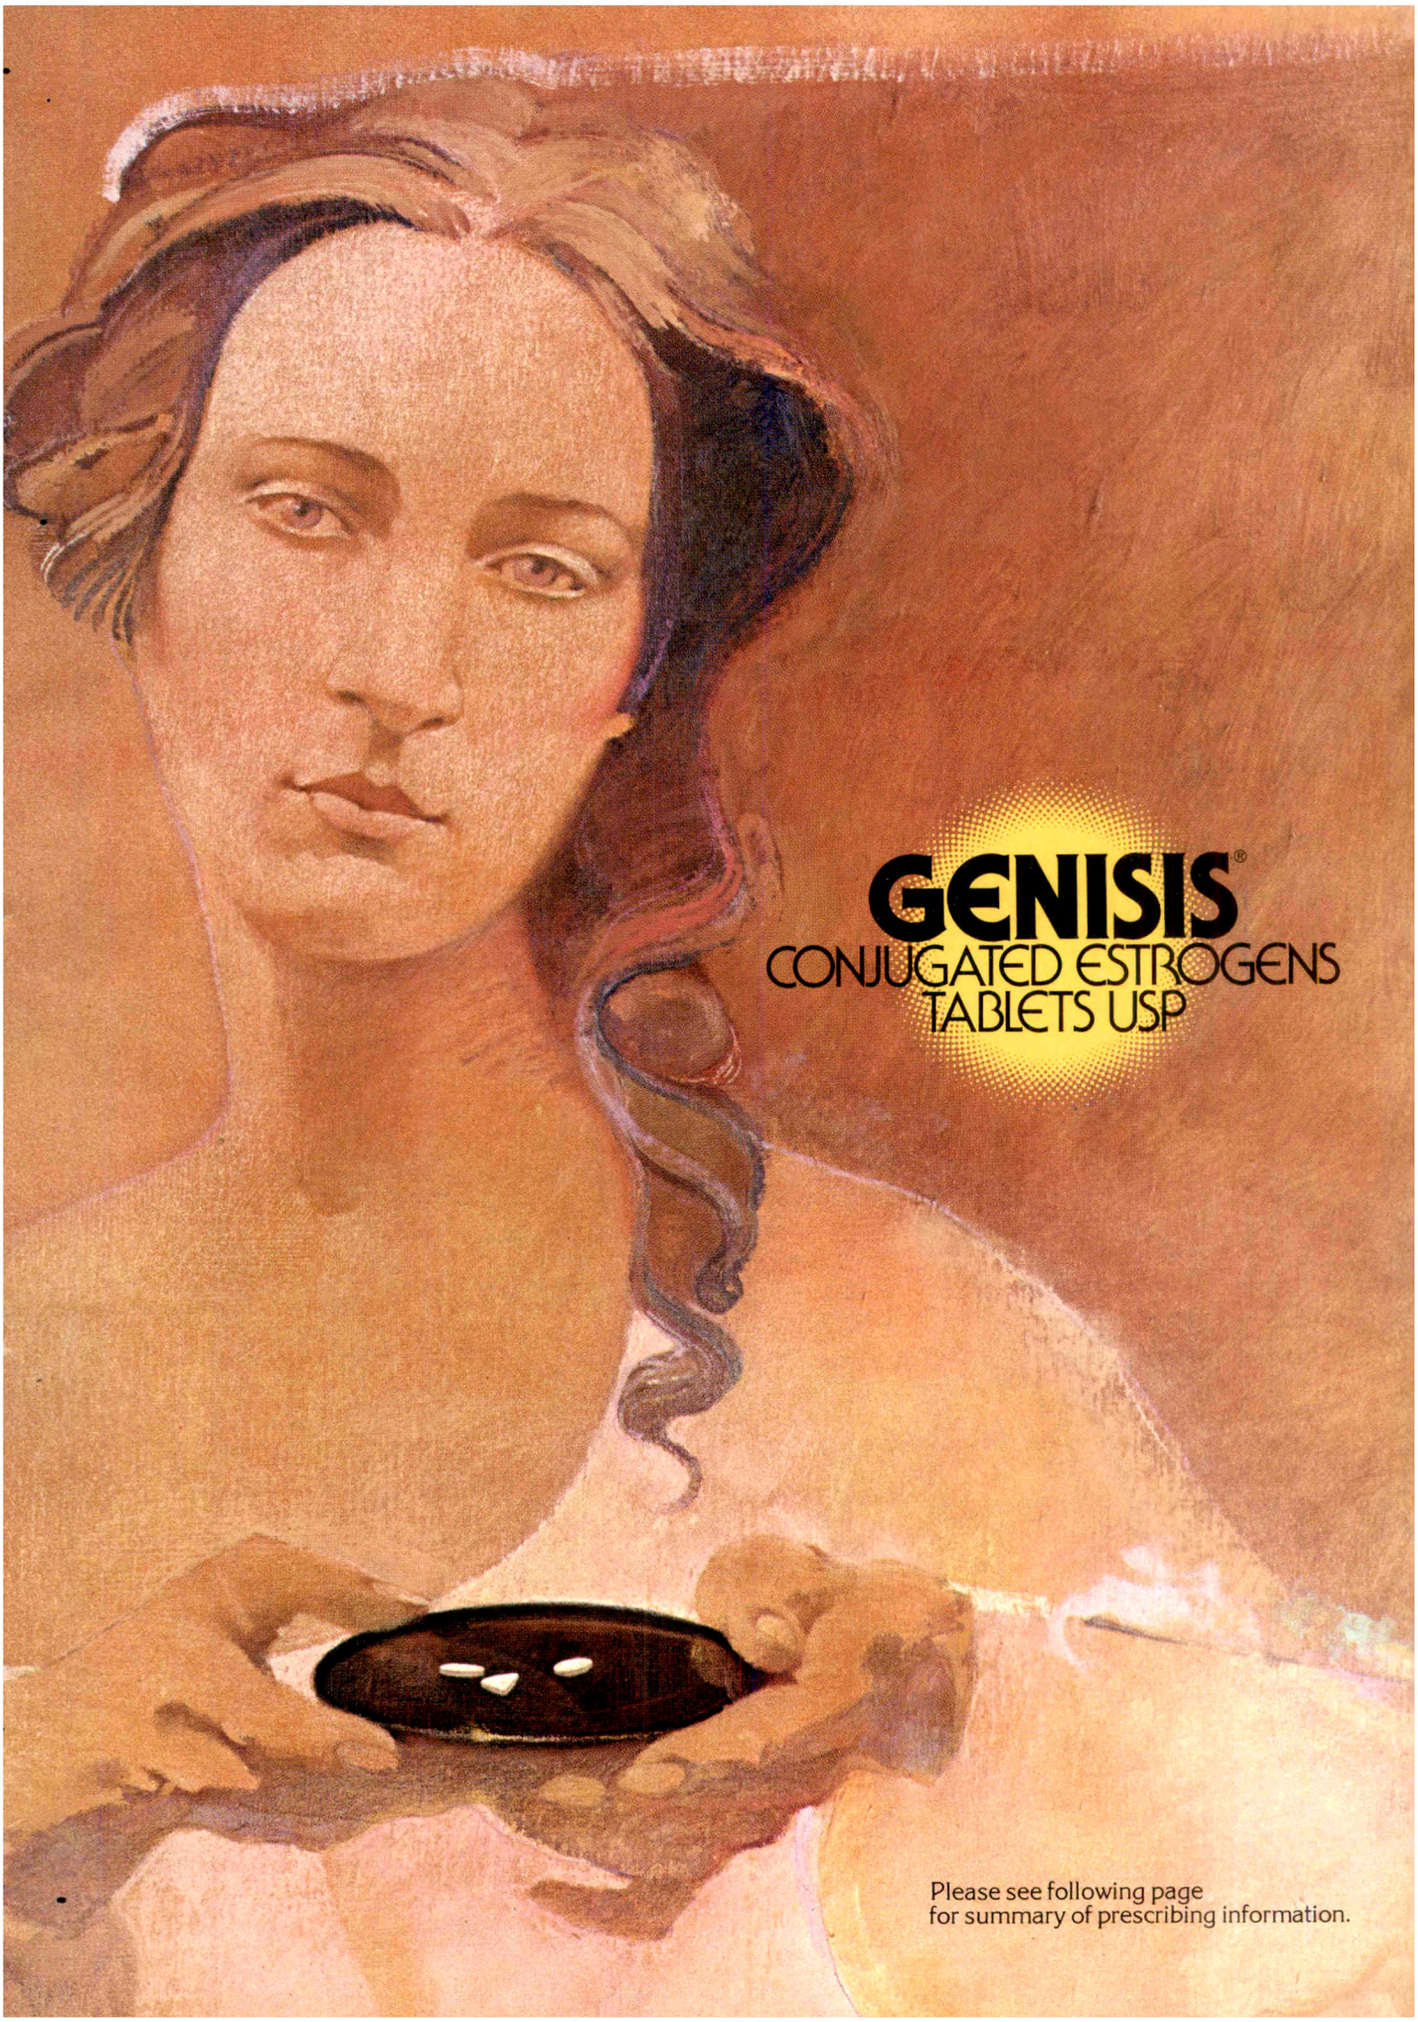
Natural Estrogens—A Mystique

There are those who would have us believe that conjugated estrogens, U.S.P. derived from the urine of pregnant mares is endowed with a certain mystique. What, precisely, is conjugated estrogens "natural"?

A study of the excretion pattern of pregnant-mare estrogens reveals that estrone and equilin are the major components and 17 alpha-dihydroequilin a minor one. Estrone predominates in early pregnancy but as this progresses equilin levels increase and may equal or surpass those of estrone in late pregnancy. This is believed to reflect continuing changes in the placental metabolism of estrogen.[1]

The urine of pregnant mares is pooled to compensate for these variations and provide a raw material of more or less average composition. This practice, however, has the disadvantage of providing a urine pool which contains all of the excreted estrogenic and related hormones whether active or not. For example, an assay study of the estrogenic content of a "large mixture" of mares' urine reveals the following proportions: 51% sodium estrone sulfate, 22% sodium equilin sulfate, 16% sodium 17 alpha-dihydroequilin, and smaller amounts of the sodium sulfates of equilenin, 17 alpha-dihydroequilenin and 17 alpha-estradiol. Related "non-estrogenic" steroids were also present.[2]

Despite these variations, conjugated estrogens, U.S.P. is defined as containing 50 to 65% sodium estrone sulfate and 20 to 35% sodium equilin sulfate.[3]



Genisis—A Beginning

With Genisis, the beginning of a new age of conjugated estrogens, U.S.P. preparations is here. It is free of extraneous natural residues such as "non-estrogenic" steroids. It is prepared synthetically and specifically formulated so that each tablet contains the following approximate proportions of active substances:

Sodium estrone sulfate—60%
Sodium equilin sulfate—30%
17 alpha-dihydroequilin sodium sulfate—10%

Genisis is indicated for those standard indications requiring conjugated estrogens.

Genisis is supplied in snow-white pure uncoated tablets in the usual potencies of: 0.625 mg/1.25 mg/2.50 mg.

GENISIS®
CONJUGATED ESTROGENS
TABLETS USP
Please see following page
for summary of prescribing information.

GENISIS®
CONJUGATED ESTROGENS TABLETS USP

BRIEF SUMMARY
Please consult full package circular before prescribing

Indications
Genisis is indicated for replacement therapy of estrogen deficiency associated with menopausal syndrome, female hypogonadism (hypogenitalism), amenorrhea, female castration or primary ovarian failure.

Important Notes on the Use of Estrogens
In view of the positive relationship between thromboembolic disease and the use of oral contraceptives containing estrogens and progestins, it would seem prudent and in keeping with basic therapeutic principles to utilize, whenever feasible, the smallest effective dose of estrogens in treating patients.

The possible carcinogenicity of estrogens cannot be confirmed or refuted at this time. Close clinical surveillance of all women taking estrogens must be continued.

Contraindications
Patients with, or with history, of:
markedly impaired liver function;
known or suspected carcinoma of breast (except progressing disease not amenable to surgery or irradiation in women at least 5 years postmenopausal, or in men in whom castration is not possible);
known or suspected estrogen-dependent neoplasia, such as carcinoma of the endometrium;
undiagnosed genital bleeding;
thrombophlebitis, thromboembolic disorders, cerebral apoplexy.

Warnings
Discontinue medication at the earliest sign of thrombotic disorders (thrombophlebitis, cerebrovascular disorders, pulmonary embolism, retinal thrombosis), or in the presence of papilledema, retinal vascular lesions or such untoward effects as progression of cancer or hypercalcemia. Discontinue pending examination if there is sudden onset of proptosis, diplopia or migraine.

A statistically significant association has been reported between maternal ingestion of diethylstilbestrol during pregnancy and the occurrence of vaginal carcinoma years later in the offspring. Whether such an association is applicable to all estrogens is not known at this time. In any event, estrogens are not indicated for use during pregnancy.

Estrogens excreted in mother's milk may affect the nursing infant.

Precautions
Certain patients may be unusually responsive and may respond with undesirable manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, edema, etc. Because of possible salt and water retention, estrogens should be used with caution in patients with epilepsy, migraine, asthma, cardiac or renal disease. Estrogens influence the metabolism of calcium and phosphorus. They should be used with caution in patients with certain metabolic bone diseases that are associated with hypercalcemia or in patients with renal insufficiency. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Diabetic patients should be followed closely because of possible decrease in glucose tolerance.

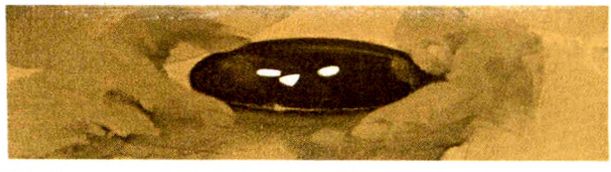
In the event of unexplained or excessive vaginal bleeding during estrogen therapy, nonfunctional causes should be borne in mind. The drug should be discontinued and a thorough investigation made as to the cause, being certain to rule out the possibility of malignancy. Pre-existing uterine fibromyomata may increase in size when estrogens are used. Therefore, patients should be examined at regular intervals throughout therapy. Women with a strong family history of cancer, recurrent chronic mastitis, or abnormal mammograms should be administered estrogens with caution. A pre-treatment physical examination should include special reference to breast and pelvic organs as well as a Papanicolaou smear since estrogens have been known to produce tumors, some of them malignant, in five species of animals.

Continuous use of estrogens will result in prolonged stimulation of the endometrium and breast. In order to avoid this, oral estrogens should be administered cyclically in the menopausal or hypogonadal patient.

The pathologist should be advised of estrogen therapy when relevant specimens are submitted. Certain endocrine and liver function tests may be affected by treatment with estrogens. If such tests are abnormal in a patient taking these drugs it is recommended that they be repeated after the drug has been withdrawn for two months. Any possible influence of prolonged estrogen therapy on pituitary, ovarian, adrenal, hepatic or uterine function awaits further study.

When large doses of estrogens are used, urinary stress incontinence may occur in nonpregnant females.

Adverse Reactions
A statistically significant association has been demonstrated between use of estrogen-progestin oral contraceptives and the following serious reactions: thrombophlebitis, cerebral thrombosis, pulmonary embolism.



Although available evidence is suggestive of an association, such a relationship has been neither confirmed nor refuted for the following serious reactions: coronary thrombosis, neuro-ocular lesions (e.g. retinal thrombosis and optic neuritis).

The following adverse reactions are known to occur in patients receiving estrogens: nausea, vomiting, anorexia, gastrointestinal symptoms (such as abdominal cramps or bloating), edema, breakthrough bleeding, spotting or withdrawal bleeding, breast tenderness and enlargement, change in body weight (increase or decrease), headache, increased cervical mucus, allergic rash, loss of libido and gynecomastia in the male, reactivation of endometriosis, aggravation of migraine headaches, hepatic cutaneous porphyria becoming manifest, cholestatic jaundice, rise in blood pressure in susceptible individuals, mental depression, cystitis-like syndrome, loss of scalp hair, erythema nodosum, hemorrhagic eruption, premenstrual-like syndrome, changes in libido, changes in appetite, nervousness, dizziness, fatigue, backache, erythema multiforme, itching, possible diminution in lactation when given immediately post-partum, irritability, malaise.

Dosage and Administration
Dosage requirements will vary with the severity of menopausal symptoms. Initially, doses ranging from 1.25 mg to 3.75 mg daily may be required to bring symptoms under control. When this has been accomplished dosage should then be gradually decreased until the minimal effective maintenance dose is established. This will usually be 0.625 mg or 1.25 mg daily or possibly less.

Caution
Federal law prohibits dispensing without a prescription.

How Supplied—0.625 mg tablets—bottles of 100 and 500
1.25 mg tablets—bottles of 100 and 500
2.5 mg tablets—bottles of 100

FETUS, PLACENTA, AND NEWBORN

Rapid infusion of sodium bicarbonate and albumin into high-risk premature infants soon after birth: A controlled, prospective trial

RICHARD D. BLAND, M.D.
TERRELL L. CLARKE, M.D.
LEWIS B. HARDEN, M.D.
Honolulu, Hawaii

We conducted a controlled, prospective trial to evaluate the effectiveness of rapidly infusing sodium bicarbonate ($NaHCO_3$) and salt-poor albumin into high-risk, premature infants in the first 2 hours of life. Fifty-three infants, randomized into one of four treatment groups, received 8 ml. per kilogram of a solution containing either (A) glucose in water, (B) salt-poor albumin, (C) $NaHCO_3$, or (D) a combination of albumin and $NaHCO_3$. After the initial infusion, the babies received no colloid or alkali solutions until 4 hours of age. We managed them supportively with warmth, appropriate oxygen administration, isotonic fluid infusion, and close monitoring. Among the infants who received alkali, 14 of 26 acquired the respiratory distress syndrome (RDS), 11 died, and four had intracranial hemorrhage. Among babies who received no alkali, RDS occurred in 11 of 27, 5 died, and none had intracranial hemorrhage. These results do not support the common practice of rapidly infusing $NaHCO_3$ into high-risk, premature infants, and they suggest that the early management of such infants needs renewed critical evaluation.

OBSTETRICIANS, pediatricians, and anesthesiologists have infused hyperosmotic solutions of $NaHCO_3$ into newborn infants with acidemia for more than a decade. Reports by Hutchison and associates[1] and by Roberts and co-workers[2] supported the effectiveness of this practice in reducing the incidence of RDS and death, but neither included a suitable control group. In a controlled, prospective trial, Sinclair, Engel, and Silverman[3] were unable to demonstrate any benefit from rapid infusions of alkali to infants of low birth weight. The impact of that study, however, was limited by the small number of patients in each treatment group. A subsequent trial of early vs. delayed treatment of acidemia in low-birth-weight infants by Hobel and associates[4] demonstrated no difference between groups for incidence of RDS or related death. That study did not include a control group of infants from whom alkali was withheld.

Two retrospective studies carried out over the past decade have associated rapid infusions of $NaHCO_3$ with an increase in the mortality rate, accompanied by a high incidence of intracranial hemorrhage.[5, 6] Several editorial comments have ably outlined the controversy

From the Department of Pediatrics, Tripler Army Medical Center.

This investigation was supported in part by the United States Army Research and Development Command.

Received for publication February 5, 1975.

Accepted June 12, 1975.

which prevails over this therapeutic approach and have stated the need for further controlled, prospective trials.[7-10] This report describes the results of such a trial and is intended to provide some rationale for further evaluating therapy of acidemic premature infants.

Clinical population and methods

From October, 1970, to July, 1971, at Tripler Army Medical Center in Hawaii, we conducted a prospective study to assess the usefulness of infusing various solutions into the umbilical vein of high-risk infants shortly after birth. All infants admitted to the study were hypoproteinemic (cord serum total protein level of 4.6 Gm. per 100 ml. or less) and premature (less than 37 weeks' gestation). Previous experience in our nursery had shown us that RDS occurs in over 50 per cent of such infants, with a mortality rate of 34 per cent.[11]

The infants were weighed immediately on admission to the nursery, and gestational age was assessed on the basis of maternal menstrual history and obstetric milestones, adjusted according to various physical[12] and neurologic[13] criteria for maturity. We gave Apgar scores to each infant at 1 and 5 minutes of age. A small amount of serum was extracted from the cord blood sample after centrifugation for rapid determination of the serum total protein concentration. We used a modified refractometric technique requiring only one drop of undiluted serum transferred by pipette onto a hand refractometer.*[14] We measured the pH of arterial or "arterialized capillary" blood, and in many cases we measured the Pao_2 and $Paco_2$ on a blood gas analyzer† within 10 minutes of sampling.

For each infant admitted to the study, a nurse selected a therapy card, randomly mixed in sets of four (one for each therapy group) and matched according to birth weight (divided into 500 Gm. intervals). The card instructed her to draw up one of the following solutions in a sterile 30 ml. syringe:

A: 8 ml. per kilogram of glucose in water (5 Gm. per 100 ml.)

B: 8 ml. per kilogram of salt-poor albumin‡ (25 Gm. per 100 ml.)

C: 3 ml. per kilogram of $NaHCO_3$ (7.5 Gm. per 100 ml.) and 5 ml. per kilogram of water

D: 1.5 ml. per kilogram of $NaHCO_3$ (7.5 Gm. per 100 ml.), 4 ml. per kilogram of salt-poor albumin (25 Gm. per 100 ml.), and 2.5 ml. per kilogram of water

We explained the nature of the study to one or both parents of each infant, and we obtained permission to include the infant in the trial. We then inserted a polyethylene catheter* into the baby's umbilical vein through the ductus venosus to the inferior vena cava, where we measured the venous pressure and infused the trial solution over a 5 to 10 minute period. In some cases, we were unable to advance the catheter through the ductus venosus, and in those patients we infused the solution through the portal venous system. We removed the catheter promptly and if there was any evidence of sustained distress, we inserted a peripheral venous line or an umbilical arterial catheter. In all cases, we completed the initial infusion before the infant was 2 hours old, usually in the first 30 minutes. We obtained a chest x-ray for each infant, and we measured arterial blood gases and pH at frequent intervals when the infant had sustained distress or required supplemental oxygen.

When admitted to the study, all infants breathed spontaneously. After the initial infusion, the patients received no colloid or alkali solution over the first 4 hours of life. We managed them supportively with warmth, appropriate oxygen administration, isotonic fluid infusion, and close monitoring. The study took place prior to the use of continuous positive airway pressure or ventilation with positive end-expiratory pressure in our nursery.

We diagnosed RDS on the basis of a sustained respiratory rate greater than 60 per minute, repeated observations of xiphoid and rib retractions, an expiratory grunt, and cyanosis without oxygen, with symptoms for at least 72 hours or until death, thereby excluding cases of transient neonatal tachypnea. All infants with RDS had x-ray evidence of diminished aeration with "air bronchograms." Patients who died had postmortem examinations within 24 hours of death.

Results

Table I demonstrates the striking similarity in major characteristics of the four groups of infants. By the unpaired t test, there was no significant difference between groups for gestational age, birth weight, initial pH, venous pressure, Apgar scores, or serum protein concentration of the cord blood. While all infants who received $NaHCO_3$ alone were male, it is noteworthy

Birth weight (Gm.)	2,149 (122)	1,791 (161)	2,075 (124)	1,982 (136)
Initial pH	7.28 (0.03)	7.25 (0.03)	7.23 (0.03)	7.27 (0.03)
Apgar score 1 min.	6.4 (0.6)	6.0 (0.6)	6.3 (0.8)	6.3 (0.7)
Apgar score 5 min.	7.7 (0.4)	7.1 (0.5)	7.6 (0.8)	6.2 (0.7)
Initial venous pressure (cm. H_2O)	4.6 (0.7)	4.8 (0.7)	4.0 (0.9)	4.2 (0.9)
Cord blood serum total protein concentration (gm./100 ml.)	4.0 (0.1)	4.0 (0.1)	3.9 (0.1)	4.0 (0.1)

*Group A received 8 ml. per kilogram of glucose in water; Group B received 8 ml. per kilogram of salt-poor albumin; Group C received 3 ml. per kilogram of $NaHCO_3$ and 5 ml. per kilogram of water; Group D received 1.5 ml. per kilogram of $NaHCO_3$, 4 ml. per kilogram of albumin, and 2.5 ml. per kilogram of water. We list average values, with standard error of the mean (S.E.M.) in parentheses.

that the sex distribution was virtually identical for the infants who received no $NaHCO_3$ (Groups A and B) and for those who did (Groups C and D).

Acidemia and respiratory distress, while present in the majority of infants, were not essential prerequisites for admission to this trial. Yet no infant in the $NaHCO_3$-infusion group had a pH in excess of 7.34, and only two had pH values greater than 7.30 before receiving alkali.

We observed the outcome of our management, looking primarily at the incidence of RDS, survival, and intracranial hemorrhage. The results are shown in Table II. Combining the infants who received $NaHCO_3$ (Groups C and D), 14 of 26 acquired RDS, 11 died, and four had intracranial hemorrhage (two intraventricular and two extensive subarachnoid). Among those babies who did not receive $NaHCO_3$ (Groups A and B), RDS developed in 11 of 27, five died, and there were no cases of intracranial hemorrhage. The likelihood that this distribution of deaths could have occurred by chance alone is <0.12 with chi-square analysis and the 2 × 2 contingency table corrected for continuity.[15]

Among those infants who remained in distress and required repeated measurements of arterial blood gases within the first 12 hours of life, the $Paco_2$ was higher in the patients who received $NaHCO_3$ than in those managed without alkali infusions, as shown in Table III ($p < 0.01$, by unpaired t test). While the average postinfusion pH was lowest in the group that received $NaHCO_3$ alone, the difference was not significant.

Table II. Outcome of infants in the four groups

	Nonalkali groups		*Alkali groups*	
	A	*B*	*C*	*D*
No. with RDS	5	6	8	6
No. died	1	4	6	5
No. with intracranial hemorrhage	0	0	3	1

Table III. pH and $Paco_2$ measurements of infants who remained in distress and required repeated determinations of arterial blood gases within the first 12 hours of life

	Nonalkalki groups		*Alkali groups*	
	A	*B*	*C*	*D*
No. of infants	8	11	9	10
Postinfusion $Paco_2$ (torr) (Mean and S.E.M.)	41 (4)	32 (3)	46 (4)	49 (4)
Postinfusion pH (Mean and S.E.M.)	7.32 (0.03)	7.35 (0.02)	7.29 (0.04)	7.33 (0.02)

Table IV summarizes data for the four infants who had intracranial hemorrhage at postmortem examination. As a group, they were lighter (average 1,549 grams), less mature (average gestation 31.8 weeks), and in more distress soon after birth (average Apgar scores 3.7 at 1 minute and 6.3 at 5 minutes, average initial pH 7.19) than the study patients taken together. The $Paco_2$ of all four infants was >50 torr after the initial infusion, and the pH rose appreciably in but two of the four babies after they received $NaHCO_3$-containing solutions. Another infant in the $NaHCO_3$ group died at 36 hours of age with massive pulmonary hemorrhage but had no evidence of bleeding into the brain.

Comment

Usher[16] began administering $NaHCO_3$ in dilute solutions and by slow intravenous infusion to newborn infants in 1958. Five years later, Dawes and his colleagues found that asphyxiated newborn lambs and rhesus monkeys resuscitated with hyperosmotic intravenous solutions of alkali and glucose recovered more quickly and had less residual brain damage than animals given no intravenous fluids.[17–19] There were no control animals who received isotonic fluids, and the authors were careful to warn against the application of

this approach to the management of human newborn infants without supportive clinical data.

Hutchison and associates[1] reported that rapid infusions of alkali improved the survival rate of infants afflicted with RDS and recommended this mode of therapy for all premature infants with acidemia. That same report described but neglected to discuss a substantial increase in the incidence of intracranial hemorrhage among infants treated with rapid infusions compared with a previous group treated more conservatively. More recent observations by Usher[5] and by Simmons and associates[6] have confirmed this association.

Finberg[20] attributed this relationship to abrupt changes in serum osmolality induced by such infusions, with rapid shifts in fluid from the intracellular to the extracellular compartment. He based his explanation on the finding of hemorrhagic encephalopathy in cats given large volumes of hyperosmotic solutions.[21, 22] If this mechanism is responsible for producing hemorrhage, infusion of salt-poor albumin should have a comparable effect by inducing similar fluid shifts from the intracellular space. Yet we did not find an association between infusions of albumin and intracranial hemorrhage.

Several investigators have shown that administration of hypertonic solutions may produce a fall in pH resulting from dilutional effects on extracellular buffers and release of protons from intracellular buffers.[23–25] Though we diluted the $NaHCO_3$ which we infused to an osmolality of approximately 550 mOsm. per liter, we were unable to show a sustained elevation of arterial blood pH among infants given $NaHCO_3$. This finding was, at least in part, the result of CO_2 retention, and emphasizes the importance of adequate ventilation in correcting the acidemia of RDS. Holmdahl and associates,[26] and more recently Steichen and Kleinman,[27] showed that in the presence of fixed ventilation (as we might see in premature infants with the most severe RDS), infusions of $NaHCO_3$ may produce a rise in $Paco_2$. Since hypercarbia induces cerebral vasodilatation,[28] is it possible that this effect of $NaHCO_3$ infusions, without respiratory adjustment, particularly in the presence of elevated venous pressure, might induce intracranial hemorrhage?

The usual rationale for infusing alkali into newborn infants with acidemia is that pulmonary vascular resistance varies directly with hydrogen ion concentration,[29] and a sudden rise in arterial pH improves pulmonary blood flow and increases Pao_2.[30, 31] Johnson and co-workers[32] found, however, that the effects of hyperosmotic $NaHCO_3$ on the pulmonary vascular resistance of fetal lambs may not be related strictly to pH, but may reflect changes in circulating volume.

Rapid infusions of $NaHCO_3$ produce a small, transitory rise in arterial blood pressure, serum sodium concentration, and osmolality, with a fall in packed red blood cell volume.[33] These changes are consistent with a transient increase in circulating blood volume, similar to the changes which occur in cats after rapid infusion of hypertonic saline.[22] It might be argued then that any physiologic benefit derived from infusion of $NaHCO_3$ is related simply to intravascular volume expansion.

It was this rationale which led us to compare infusions of solutions which merely maintain intravascular volume to those which alter blood pH and osmolality. We initiated the trial as a pilot study, and perhaps it is unfortunate that we turned our attention to evaluating the effectiveness of albumin infusions vs. glucose in water[34] before reaching a more definitive answer to the issue regarding $NaHCO_3$ and intracranial hemorrhage.

The groups in this trial, though randomized, were small, and the data were limited, with no consistent measurements of serum sodium concentration or arterial blood pressure. Some infants who received $NaHCO_3$ were not severely acidemic, and some who received albumin probably were not hypotensive, though all had low serum protein concentrations. These shortcomings aside, the incidence of RDS and

death was higher in the alkali-treated groups than in the nonalkali groups, and there were four cases of intracranial hemorrhage found in those infants who received $NaHCO_3$ vs. no cases among babies who received glucose in water or albumin. These results do not support, in any way, the usefulness of rapid infusions of $NaHCO_3$ to high-risk infants, and they suggest that early management of such infants needs renewed critical evaluation.

Hyperfibrinogenemia and polycythemia with intrauterine growth retardation in fetal lambs

LOREN R. PICKART, PH.D.
ROBERT K. CREASY, M.D.
M. MICHAEL THALER, M.D.
San Francisco, California

Plasma concentrations of albumin and fibrinogen and arterial hematocrits were determined during the last third of gestation in growth-retarded and control fetal lambs. The mean fetal plasma albumin concentration increased slightly as term approached and was not significantly different in the two groups. The mean plasma fibrinogen concentration did not change in the control fetuses, but was significantly elevated in the growth-retarded fetuses, as was the mean arterial hematocrit. The theoretical implications of these findings relative to capillary blood flow are discussed.

ALTHOUGH intrauterine growth retardation is a relatively common clinical problem, very little is known about the influences that growth retardation may have on the biochemical and physiologic functions of the fetus or neonate.

We have produced fetal growth retardation in the fetal lamb by a gradual embolization of the uteroplacental vascular bed.[1] Changes in the plasma concentrations of fibrinogen and albumin and in the arterial hematocrit were measured. Hyperfibrinogenemia and polycythemia characterized the terminal portion of the gestation in these growth-retarded fetuses. The theoretical implications of these findings in relation to peripheral capillary blood flow are discussed.

Methods

Embolization of the maternal placental implantation site in pregnant sheep was performed as previously described.[1] Dated pregnant sheep were used in all experiments. In brief, catheters were inserted in fetal and maternal vessels at approximately 110 days of gestation. The catheters were exteriorized, and the pregnancies allowed to proceed normally. Alfalfa and water were provided *ad libidum* for the remainder of the experiment. Growth retardation in the developing fetus was produced by daily injection of nonradioactive microspheres (15μ diameter) into a catheter placed in the main uterine artery supplying the pregnant horn. Control animals were prepared in a similar manner but did not receive the embolization with microspheres. With this procedure, approximately 30 to 40 per cent of the total number of cotyledons are grossly abnormal, being reduced in thickness. Microscopic examination reveals extensive fibrosis and hyalinization.

Samples of fetal femoral arterial blood were obtained for biochemical and hematocrit determinations at intervals during the subsequent course of the gestation. Blood samples used for the biochemical assays were placed in citrated tubes and centrifuged, and the plasma was immediately pipetted and frozen at −20° C. The fetal plasma fibrinogen concentration was determined by the Saifer-Newhouse[2] method, the fetal plasma albumin was assayed by paper electrophoresis,[3] and the fetal arterial hematocrit was determined with a microcentrifuge.

The studies in both groups of animals were terminated at approximately 140 days of gestation and the fetal weight and organ weights determined for confirmation of intrauterine growth retardation.

Table I. Fetal plasma fibrinogen concentration* in control and growth-retarded fetal lambs

Gestational age (days)	*Control fetuses*	*Growth-retarded fetuses*	*P values*
114-122	131 ± 24 (8)†	160 ± 71 (6)	0.05
123-129	143 ± 17 (5)	247 ± 89 (3)	0.025
130-140	118 ± 30 (11)	236 ± 127 (10)	0.0005

*Values are mean concentration in milligrams per 100 ml ± 1 S.D.

†Numbers in parentheses indicate number of fetuses.

Table II. Arterial hematocrit (means ± 1 S.D.) in control and growth-retarded fetal lambs at the onset and termination of the chronic study

	Controls	*Growth-retarded*
Onset	0.34 ± 0.02	0.35 ± 0.04
Termination	0.35 ± 0.04	0.44 ± 0.03*

*Significant difference at $p < 0.05$.

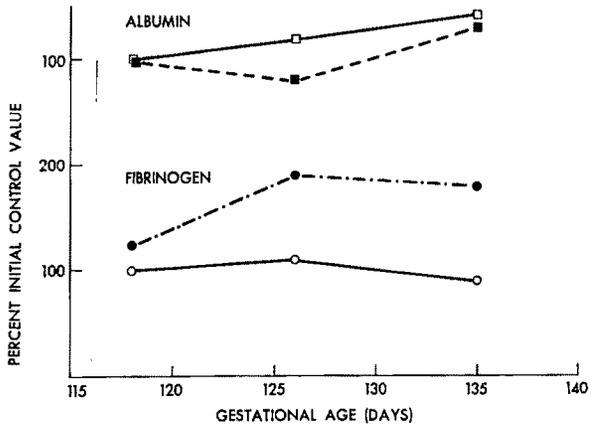

Fig. 1. Changes in plasma albumin (squares) and fibrinogen (circles) concentrations during gestation in fetal sheep. Growth-retarded fetuses are denoted by interrupted lines. Differences between normal and growth-retarded fetuses at the ages tested were not significant for albumin and highly significant for fibrinogen (see Table I.).

The unpaired t test (two-tailed) was used to check for significant differences between the control and embolization groups.

Results

The results of the embolization procedure in regard to detailed anatomic and physiologic data have been previously reported.[1, 4] In brief, this procedure results in fetuses which are significantly smaller in weight and length. Most fetal organs are reduced in size, particularly the liver and thymus. Fetal Po_2 is reduced 15 to 25%.[1, 4] The fetuses in the present embolization group showed similar evidence of fetal growth retardation.

The mean fetal plasma fibrinogen concentration in the control group remained relatively constant between 114 and 140 days of gestation, as shown in Table I. The mean fetal plasma fibrinogen in the growth retarded fetuses was significantly increased over the control group.

Small but statistically significant differences in plasma fibrinogen concentrations were noted in the earlier sampling period (114 to 122 days). The differences in fibrinogen concentration between control and growth-retarded fetuses became more pronounced as gestation progressed, as shown in Fig. 1.

The plasma albumin concentrations in the control group increased in a linear manner as gestation advanced and were not significantly different from those of the growth-retarded fetuses.

At the onset of the study the mean fetal hematocrits were similar, as shown in Table II. At the end of the study the mean fetal hematocrit in the control group was 0.35 ± 0.04, and 0.44 ± 0.03 in the growth-retarded fetuses—a significant difference.

Comment

The results indicate that embolization of the maternal uteroplacental vascular bed is associated with an increase in the concentration of plasma fibrinogen and the arterial hematocrit of the fetal lamb. The increase in fibrinogen is not derived from maternal sources, as it is not transferred across the mammalian placenta,[5] and it is most unlikely that the increase in hematocrit is due to transfer of maternal red cells.

The polycythemia in the growth-retarded fetuses may be explained as a response to arterial hypoxemia found in these fetuses. The hyperfibrinogenemia may be explained as a result of fetal stress, as the concentration of the plasma clotting protein fibrinogen is an excellent indicator of stress in adult mammals. Various types of traumatic or toxic injuries, such as burns, crushing of extremities, and treatment with endotoxin, talcum powder, and turpentine, rapidly stimulate production of fibrinogen in the liver and increase the plasma fibrinogen concentration.[6] Even psychological stresses, such as electroshock[7] or crowding,[8] will produce a rise in circulating fibrinogen within 24 hours.

A number of studies on hyperfibrinogenemic states have indicated that the increased concentration of the protein is due to an accelerated hepatic synthesis rather than a decreased catabolism of fibrinogen.[6, 9] In these experimental growth-retarded fetuses an etiologic factor could have been the embolization process itself,

as intravascular clotting and formation of thrombin are known to increase the rate of hepatic fibrinogen synthesis.[10] Small peptides produced by the clotting mechanism have also been proposed as being able to stimulate synthesis of fibrinogen.[11] Although fibrinogen does not cross the placental barrier, it is conceivable that the small peptides could cross the placenta and affect the fetal liver. It is also interesting that the increase in fetal fibrinogen concentrations occurred despite an approximately one-third reduction in fetal liver weight.

In contrast with fibrinogen, the albumin concentrations in stressed fetuses in our experiments were either unaffected or depressed, but the decreases in albumin were not statistically significant. Similarly, Neuhaus and associates[12] have shown that in traumatized adult animals hepatic production of fibrinogen, seromucoid, and acute-phase globulin are increased, whereas albumin synthesis either is reduced slightly or remains unaltered. Thus the response of fetal sheep to placental embolization appears to be similar to that seen in stressed adult animals.

Sarcione[13] demonstrated that plasma proteins which are elevated during stress (e.g., acute phase protein, fetal alpha protein, fibrinogen) are characteristic of "fetal synthetic patterns." Sarcione suggested that de-repression of "fetal genes" in adult liver may be responsible for this effect. The possibility that the increased fibrinogen concentration seen in the growth-retarded lamb fetuses could conceivably reflect a retarded progression to adult plasma protein patterns deserves further investigation.

The in vivo flow of blood through the microcirculation has been shown to be of an intermittent and pulsative nature.[14, 15] At the velocities of blood flow, or shear rates, found in the capillaries, blood exhibits non-Newtonian flow characteristics, acting as a solid during a no-flow period and as a liquid during flow periods. These properties of capillary flow are due to the intermittent formation and dissolution of red blood cell–fibrinogen aggregates at low blood velocities (0.1 to 0.5 cm. per second) found in the microcirculation.[16] The propensity of human blood to form these aggregates appears to be a synergistic function of the plasma fibrinogen concentration and the hematocrit.

While there is only a weak interaction of fibrinogen and red blood cells in sheep and goats, most mammals studied demonstrate a strong interaction of the two factors, which markedly increases erythrocyte aggregation in the capillaries. In a human fetus, an increase in hematocrit and fibrinogen similar to that in the growth-retarded sheep fetus would theoretically be expected to greatly increase the clumping and sludging of blood in the capillary beds, with the potential of reducing oxygen tension and tissue perfusion.[16–19]

In an attempt to quantify the above interactions, Merrill[16] and co-workers have defined the force required to cause static blood to flow as the *yield shear stress* of blood. Yield shear stress alternately may be considered to represent the force necessary to disrupt the fibrinogen-erythrocyte aggregates formed in nonflowing blood. When the theoretical yield shear stress is calculated by the equations obtained by Merrill with the data from these studies, we find that a tenfold increase in yield shear stress would be expected to exist in blood of human fetuses if a similar situation in hematocrit and fibrinogen existed (see Appendix).

This synergistic interaction between polycythemic and hyperfibrinogenemic states could, in human subjects, exacerbate a number of factors which contribute to fetal distress. Clinically, sludging of blood has been associated with anoxic lesions of tissues, low blood flow rates, reduced cardiac output, increased vascular resistance, and congestive heart failure.[17, 20] These studies on fetal sheep suggest that an elevated blood fibrinogen may play a role in the frequent occurrence of life-threatening situations in growth-retarded human fetuses and newborn infants.

Appendix

Merrill[16] and co-workers measured the yield shear stress (Ty) of blood at the shear strain rates found in the microcirculation. The yield shear stress of human blood when the hematocrit ranges between 30 and 50 per cent is closely approximated by the equation:

$$Ty = A(H - 0.06)^3 \quad (1)$$

where the hematocrit is H, and A is a strong function of the fibrinogen concentration. The effect of plasma fibrinogen concentrations of 100 to 400 mg. per 100 ml. on Ty correlates with the equation:

$$Ty = BCf^2 \quad (2)$$

where Cf is the plasma fibrinogen concentration in mg. per 100 ml., and B is a constant which is a weak function of other plasma proteins.

These equations were used to estimate the increase in yield shear stress in the blood of growth-retarded fetuses over control fetuses in our experiments. If $A = BCf^2$, then substitution in Eq. (1) yields:

$$Ty = BCf^2(H - 0.06)^3. \quad (3)$$

In the last sampling interval (130 to 140 days) the mean hematocrit and fibrinogen levels were 33.7 per cent and 118 mg. per 100 ml. for the control fetuses, and 43.7 per cent and 236 mg. per 100 ml. for the

growth-retarded fetuses, respectively. From Eq. (3), these values give the ratio:

$$\frac{\text{Ty (retarded)}}{\text{Ty (control)}} = \left(\frac{236}{118}\right)^2 \left(\frac{0.437 - 0.06}{0.337 - 0.06}\right)^3 = 10.06.$$

Thus, the increase in yield shear stress of blood in growth-retarded fetuses compared with controls would be approximately tenfold.

Estriol in pregnancy

IV. Normal concentrations, diurnal and/or episodic variations, and day-to-day changes of unconjugated and total estriol in late pregnancy plasma

HIDEHIKO KATAGIRI, M.D.*
WOLFGANG DISTLER, M.D.**
ROGER K. FREEMAN, M.D.
UWE GOEBELSMANN, M.D.
Los Angeles, California

Normal values of unconjugated, total, and immunoreactive (measured without extraction) plasma estriol (E_3) have been determined from radioimmunoassay data obtained in 217 uncomplicated third-trimester pregnancies. Small but significant diurnal variations in unconjugated and total plasma E_3 have been observed in a study comprising 12 women who were hospitalized during late pregnancy for diabetes, toxemia, or placenta previa. The late morning decreases in unconjugated and the afternoon/evening decreases in total plasma E_3 concentrations, averaging some 10 to 15 per cent, were overshadowed by considerable episodic fluctuations and may thus be clinically irrelevant. Day-to-day changes of unconjugated and total plasma E_3 concentrations in late pregnancy were similar and smaller than changes in urinary E_3 measurements. The urinary E_3/creatinine ratio, however, reducing inadequacies of 24 hour urine collections, varied less than unconjugated or total plasma E_3. The data suggest that a decrease in unconjugated or total plasma E_3 must exceed 40 to 45 per cent of the mean of the three preceding determinations if it is to be considered a signal of fetal distress.

ADVANCES in radioimmunoassay technique facilitate routine determinations of unconjugated or total plasma estriol (E_3) during the third trimester of pregnancy in many clinical laboratories.[1] Whether or not plasma E_3 determinations are useful in assessing fetal status in high-risk pregnancies, however, remains to be established. Moreover, even the presence and magnitude of diurnal and/or episodic variations and day-to-day changes in plasma E_3 concentrations are a matter of dispute.[2–6] Knowledge of these parameters, however, appears to be a prerequisite for a meaningful clinical evaluation of plasma E_3 determinations as a diagnostic adjunct in complicated pregnancies. This study therefore was undertaken to establish normal values and confidence limits for plasma concentrations of unconjugated, total, and immunoreactive (measured in unextracted plasma) E_3 in uncomplicated third-trimester pregnancies and to delineate their diurnal and/or episodic variations as well as day-to-day changes in comparison with urinary E_3 excretion in patients with complicated pregnancies.

Materials and methods

In order to determine normal third-trimester plasma E_3 concentrations, a single venous blood sample was drawn from 300 apparently healthy women between

29 and 40 weeks of gestation who were followed in our prenatal clinic. A total of 217 of these gravidas were delivered at the Los Angeles County–University of Southern California Medical Center, Women's Hospital, within 42 weeks of their last menstrual period, completed singleton pregnancies without complications, and had normal healthy babies with birth weights above the tenth percentile and 5 minute Apgar scores of 7 and above. Only the data obtained in these 217 uncomplicated pregnancies were utilized to establish the normal late-pregnancy plasma E_3 values reported in this paper.

Nine diabetic gravidas and three women with toxemia, all hospitalized and in late pregnancy, were included in a study to assess possible diurnal and/or episodic fluctuations of plasma E_3. Venous blood was drawn from these volunteers at 6 A.M., 9 A.M., 12 A.M., 4 P.M., 7P.M., 12 P.M., and again at 6 A.M. and urine was collected during each of the 6 time intervals.

Day-to-day changes in plasma E_3 concentrations were determined and compared with those observed in 24 hour urinary estriol excretion in 14 hospitalized patients whose pregnancy was complicated by diabetes mellitus (n = 11), placenta previa (n = 2), and toxemia (n = 1). Observation periods ranged from 6 to 31 days, averaging 13 days per patient. All patients delivered normal healthy babies without signs of distress during labor and delivery. All patients except the two with placenta previa had negative oxytocin challenge tests.[7] Thus, no decrease in plasma or urinary E_3 in response to significant fetal distress was expected to have occurred during the observation period. Twenty-four hour urine collections were begun and completed at 6 A.M.

Venous blood samples were collected into EDTA tubes. The plasma was separated immediately by centrifugation and stored at −15° C. until assayed. Unconjugated, total, and immunoreactive plasma E_3 were determined by radioimmunoassay (RIA) as previously described.[1, 8] In brief, unconjugated plasma E_3 was measured as follows: 500 c.p.m. of trititated E_3 was added as recovery standard to 0.5 ml. of plasma prior to extraction with 3 ml. of 12 per cent ethyl acetate in n-hexane, followed by a second extraction with 3 ml. of 40 per cent ethyl acetate in n-hexane. The latter extract was evaporated and redissolved in 0.4 ml. of 70 per cent ethanol, of which 0.20 ml. was subjected to liquid scintillation counting for recovery control and 20 μl, in triplicate, was submitted to RIA with the use of an antiserum against estriol-6-(O-carboxymethyl) oxime coupled to bovine serum albumin (E_3-6-CMO-BSA). Dextran-coated charcoal was used to separate bound and unbound tritiated E_3. The sensitivity of the assay

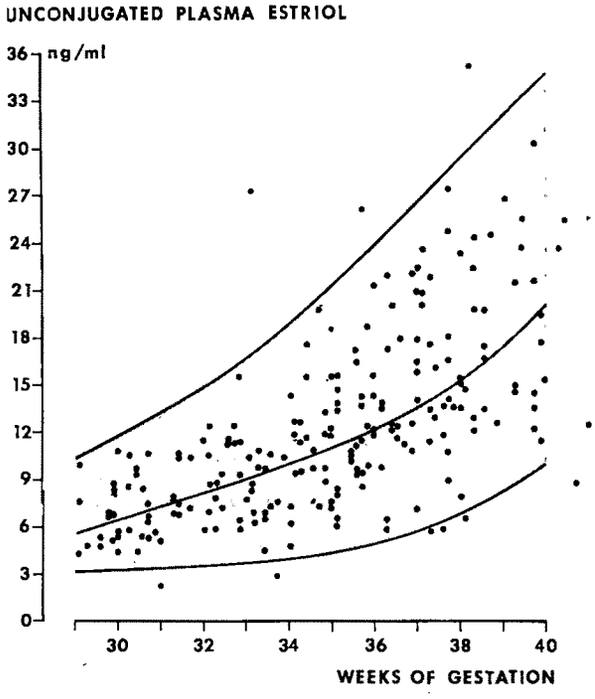

Fig. 1. Third-trimester unconjugated plasma estriol concentrations and 95 per cent confidence limits, calculated by Rankit analysis, in 217 women with uncomplicated pregnancies delivering normal healthy babies with birth weights above the tenth percentile. Note that the spread of values above the mean is greater than that below the mean.

was less than 1 ng. per milliliter, water and solvent blanks were undetectable, and intra- and interassay coefficients of variation (CV) were 10.7 and 9.5 per cent, respectively.

Total plasma E_3 was measured similarly by RIA.[1] In brief, 600 c.p.m. of tritiated estriol-3-sulfate-16-glucosiduronate (E_3-3S,16G)[9, 10] were added to 100 μl plasma aliquots as recovery standard. Following hot acid hydrolysis, the hydrolyzed E_3 was extracted with diethyl ether. Aliquots of the residue of the ether extract were subjected to RIA and to liquid scintillation counting to assess procedural loss. Water and solvent blanks were undetectable. A 5 ng per milliliter quantity was measured with a coefficient of variation of 10 per cent. The interassay CV was 6.8 per cent.

Immunoreactive E_3 was determined by subjecting 10 μl plasma aliquots directly to RIA with an antiserum against estriol-4-azobenzoic acid coupled to bovine serum albumin (E_3-4-ABA-BSA).[8, 11] This RIA was shown to determine unconjugated E_3 as well as estriol-3-sulfate (E_3-3S) and estriol-3-glucosiduronate (E_3-3G), but neither estriol-16-glucosiduronate (E_3-16G) nor E_3-3S, 16G.[1, 8] As little as 3 ng. per milliliter could be determined with a CV of 10 per cent. The interassay CV was 7.7 per cent.

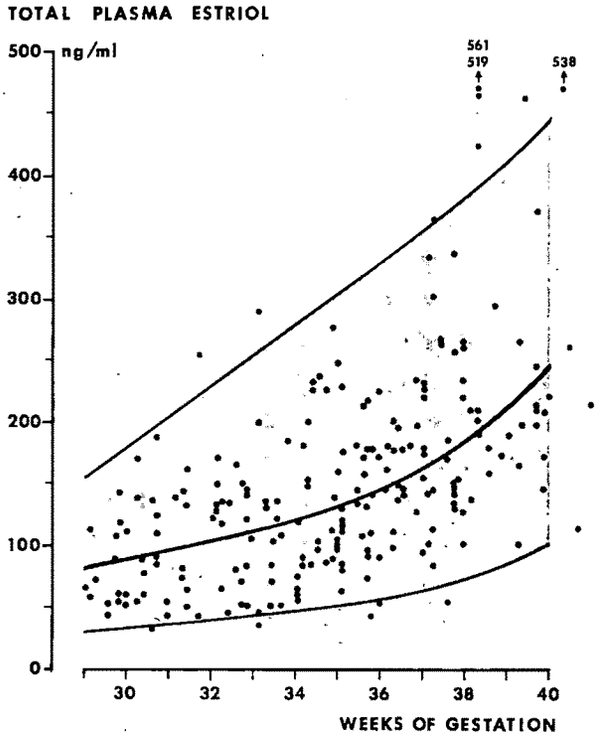

Fig. 2. Third-trimester total plasma estriol concentrations and 95 per cent confidence limits, calculated by Rankit analysis, in 217 women with uncomplicated pregnancies delivering normal healthy babies with birth weights above the tenth percentile. Note that the spread of values above the mean is greater than that below the mean.

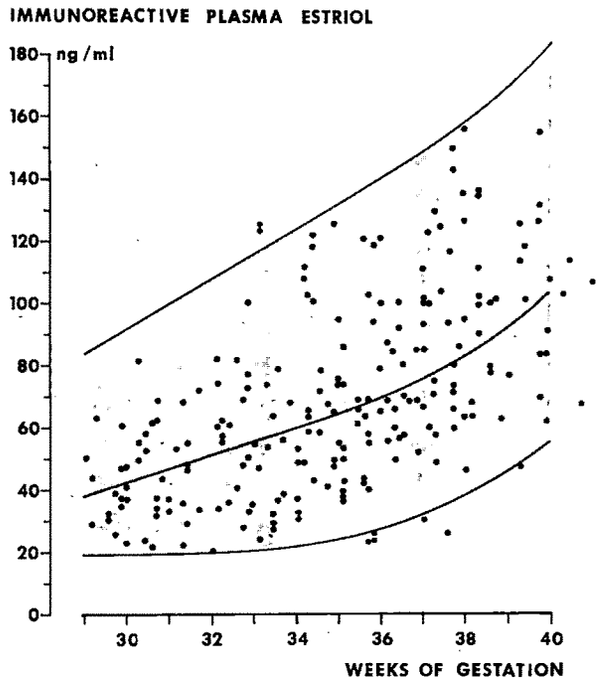

Fig. 3. Third-trimester immunoreactive plasma estriol concentrations and 95 per cent confidence limits, calculated by Rankit analysis, in 217 women with uncomplicated pregnancies delivering normal healthy babies with birth weights above the tenth percentile. Note that the spread of values above the mean is greater than that below the mean.

Urinary E_3 and creatinine were determined colorimetrically as previously described.[12]

Day-to-day changes in plasma total and unconjugated E_3 as well as in 24-hour urinary estriol excretion, as such and corrected for creatinine excretion, were analyzed by computer as previously described for urinary E_3.[12] Changes were expressed as increase or decrease in per cent of the mean of the three preceding determinations.

Results

Plasma unconjugated, total and immunoreactive E_3 concentrations in normal pregnancies. The concentrations of unconjugated, total, and immunoreactive plasma E_3 determined in 217 normal pregnancies are depicted in Figs. 1 to 3. Individual values were averaged for 2 week periods from 29 and 30 weeks up to 39 and 40 weeks. Statistical analysis revealed a larger spread of values above than below the means calculated for each 2 week period. The 95 per cent confidence limits shown in Figs. 1 to 3 therefore were determined by Rankit analysis.[13, 14]

Approximately as many blood samples were drawn between 9 A.M. and 12 A.M. (n = 98) as between 1 P.M. and 3 P.M. (n = 119). When the biweekly means of plasma unconjugated, total, or immunoreactive E_3 concentrations determined in the morning were compared with the corresponding afternoon means, no significant difference could be detected by t-test analysis.

A comparison between the biweekly averages of unconjugated, total, or immunoreactive plasma E_3 in women delivering infants with birth weights between the tenth and fiftieth percentiles with the corresponding means in women delivering infants with birth weights above the fiftieth percentile is depicted in Table I. Although five of the six biweekly means of unconjugated plasma E_3 concentrations in gravidas with infants between the tenth and fiftieth birth weight percentiles were smaller than those above the fiftieth percentile, none of these differences was statistically significant (t-test). Similarly, total plasma E_3 concentrations, on the average, were higher in five out of six biweekly groups of gravidas with infant birth weights above the fiftieth percentile, but this was significant ($p < 0.05$) in only one of the biweekly groups. No

distinct pattern was observed for immunoreactive E_3.

Assessment of possible diurnal and/or episodic variations. Unconjugated, total, and immunoreactive plasma E_3 concentrations as well as urinary E_3 and creatinine excretion were determined in 12 hospitalized women in late pregnancy over a 24 hour period. All plasma E_3 assays were carried out in duplicate on two different days. The results are

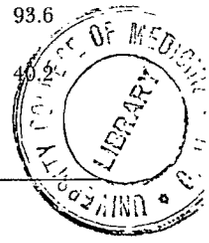
‡Toxemic patients.

presented in Tables II to IV and their averages are depicted in Fig. 4. The data obtained in individual patients were normalized to per cent values by calculating the ratio of the observed value to the patient's 24 hour average times 100.

For unconjugated plasma E_3, relative levels below 100 per cent were observed more frequently at 9 A.M. and 12 A.M. than at other times. The averages of the relative unconjugated plasma E_3 concentrations calculated for 9 A.M. and 12 A.M. were significantly lower ($p < 0.01$, t test) than those determined for 6 A.M., 4 P.M., 7 P.M., 12 P.M., and 6 A.M. next morning (Table II).

Relative total plasma E_3 concentrations below 100 per cent were found more frequently at 4 P.M., 7 P.M., and 12 P.M. than at 6 A.M., 9 A.M., and 6 A.M. next morning (Table III). The averages of the relative total plasma E_3 levels calculated for 12 A.M., 4 P.M., 7 P.M., and 12 P.M. were significantly lower than the 9 A.M. average with a nadir at 4 P.M. (Fig. 4). Immunoreactive plasma E_3 concentrations, as depicted in Table IV, failed to reveal any significant difference between the averages of the relative levels calculated for the various hours listed, but also exhibited a nadir at 4 P.M. (Fig. 4).



Urinary E_3 and creatinine excretion was determined in the same 12 women for six subsequent time periods during this 24 hour study. As shown in Fig. 4, E_3 excretion in milligrams per hour varied considerably. Despite large patient-to-patient variations, the average 7 P.M. to 12 P.M. E_3 excretion rate was significantly lower than that observed from 6 A.M. until 9 A.M. The E_3/creatinine ratios varied to a lesser extent than the E_3 excretion rates. A nadir was observed between 4 P.M. and 7 P.M. The 4 P.M. to 7 P.M. E_3/creatinine ratio was significantly lower than the one from 6 A.M. to 9 A.M. and from 12 P.M. to 6 A.M.

Day-to-day changes in plasma and 24-hour urinary E_3. These were determined in 14 hospitalized patients in the third trimester during observation periods ranging from 6 to 31 days. Increases in plasma and urinary E_3 above the mean of the three preceding values outnumbered and were larger than decreases as shown in Table V. The averages of the decreases observed with

‡Toxemic patients.

total and unconjugated plasma E_3 were virtually equal. Both were significantly smaller than the average of decreases in 24-hour urinary E_3. When the 24-hr urinary E_3 excretion was corrected for changes in creatinine excretion, however, average day-to-day changes were lower than those observed for plasma total and unconjugated E_3. Further analysis of the decreases, as presented in Table VI, indicates that about 2 per cent of decreases in plasma total and unconjugated E_3 exceeded 40 per cent, whereas the largest decrease observed for the urinary E_3/creatinine was below 40 per cent.

Comment

The plasma concentrations of unconjugated E_3 measured in 217 women with uncomplicated pregnancies delivering normal healthy babies agree with those reported by Den and associates,[15] Goebel and Kuss,[16] and de Hertogh and associates,[17] employing E_3-6-CMO-BSA antisera for RIA without preceding chromatography, but are larger than those published by Tulchinsky and Abraham[18] and by Cohen and Cohen,[19] who utilized celite partition chromatography prior to RIA. The biweekly averages of total plasma E_3 observed in these 217 women were lower than the weekly means reported by Nachtigall and associates[20] and Mathur and associates,[21] who used fluorimetry, but agreed better with those published by Macourt and associates,[22] who employed competitive protein-binding analysis with uterine cytosol. Unconjugated plasma E_3 averaged approximately 8 per cent of the total plasma E_3. The unconjugated-to-total E_3 ratio appeared constant during the third trimester of pregnancy. Plasma concentrations of immunoreactive E_3 comprising predominantly unconjugated E_3, E_3-3S, and E_3-3G averaged 48 per cent of total plasma E_3 throughout the third trimester. According to a previous study from this laboratory,[10] E_3, E_3-3S, and E_3-3G amount to approximately 50 per cent of total plasma E_3. Our immunoreactive plasma E_3 levels are not comparable to those measured by Podoba and associates[23] because the latter authors used the anti-E_3-16, 17-dihemisuccinate-BSA serum of Gurpide and associates[24] and reported to have measured E_3 and E_3-

16G in ethanolic plasma extracts. Rankit analysis[13, 14] established a log-normal distribution of plasma unconjugated, total, and immunoreactive E_3 and was essential in delineating meaningful lower 95 per cent confidence limits for normal pregnancies. Differences of average unconjugated, total, and immunoreactive plasma E_3 concentrations between women with comparable gestational age who delivered infants with birth weights between the tenth and fiftieth and above the fiftieth percentiles, respectively, were not significant.

Tulchinsky and associates[5] reported to have ruled out substantial diurnal variations of unconjugated plasma E_3, but in a detailed study, Goebel and Kuss[6] demonstrated a circadian rhythm with the highest values at 8 P.M. and the lowest levels at 8 A.M., measuring unconjugated plasma E_3 in 2 hour intervals over a 24-hour period in normal late pregnancy. Our study was carried out in pregnant women hospitalized for diabetes and toxemia because it appeared clinically more important to assess the possibility and extent of diurnal and/or episodic plasma E_3 changes in high-risk pregnancies than in normal gestation. Our results document diurnal variations of unconjugated plasma E_3 with average 9 A.M. and 12 A.M. levels being approximately 10 per cent lower than average concentrations at all other hours measured, but overshadowed by sizable episodic changes.

Selinger and Levitz[2] originally reported lower total plasma E_3 concentrations at 4:30 P.M. than at 8 A.M. and 9 P.M. in normal third-trimester pregnancies. Also, Townsley and associates[3] published diurnal variations of total plasma E_3. More recently, Levitz and associates[4] presented evidence contradicting significant periodicity of total plasma E_3 levels but indicating rather large episodic fluctuations in uncomplicated pregnancies. Our results gathered from pregnant women with diabetes and toxemia are consistent with considerable episodic fluctuations in total plasma E_3 levels, but also indicate minor diurnal variations: mean 4 P.M., 7 P.M., and 12 P.M. concentrations were approximately 10 per cent lower than 6 A.M. and 9 A.M. averages.

No discernible diurnal pattern of serum immunoreactive E_3 concentrations was observed in contrast to minor diurnal variations of unconjugated and total plasma E_3. In view of substantial episodic fluctuations, the diurnal variations seem clinically irrelevant. This impression is further substantiated by the fact that no significant difference was found between averages of plasma unconjugated, total, and immunoreactive E_3 measured from 9 A.M. to 12 A.M. and 1 P.M. to 3 P.M. in groups of normal pregnant women of comparable gestational age.

A possible explanation for the decrease in unconjugated plasma E_3 during the late morning hours is the

assumption that, in response to rising maternal serum cortisol levels, fetal plasma cortisol concentrations increase due to placental transfer and reduce fetal ACTH output and production of fetal adrenal E_3 precursors.[25] The afternoon/evening decrease in total plasma E_3 might than be explained by the fact that the bulk of total plasma E_3 consists of conjugates of hepatic and enteric origin,[26] some of which reach the circulation hours after their steroid moiety was transferred across the placenta.[27] In addition, E_3-3S and E_3-3S,16G which comprise more than half of the total plasma E_3,[10] are not rapidly excreted. While unconjugated plasma E_3 levels appear to constitute an up-to-date reflection of fetoplacental E_3 production, total plasma E_3 concentrations are subject to metabolic delay, particularly by the entero-hepatic circulation.[28] The late afternoon decrease in urinary E_3 output thus may result from lower total plasma E_3 levels rather than from changes in renal clearance.

The changes in urinary E_3 excretion and the variations of urinary E_3/creatinine ratios observed over the 24-hour study period indicate that the E_3/creatinine ratio does not correct for fluctuations in E_3 excretion measured over a limited time period only. This finding is consistent with some reports,[29, 30] but in disagreement with others.[31–33] Our 5 year clinical experience with thousands of urinary E_3 and creatinine determinations permits us to conclude that the E_3/creatinine ratio is not a reliable substitute for a 24-hour urinary E_3 determination if the creatinine measured in the urine aliquot submitted for analysis comprises less than half the patient's 24-hour creatinine excretion.[34]

It is of interest to note that day-to-day changes in unconjugated plasma E_3 concentrations equaled those of total plasma E_3 and that both were considerably smaller than variations in 24-hour urinary E_3 excretion despite in-hospital urine collections. However, the smallest day-to-day changes were observed with urinary E_3/creatinine ratios on 24-hour urine collections. These data are in agreement with our conclusions from a previous larger study[12] suggesting that a fall in urinary E_3 of more than 35 per cent may be regarded as "significant" if it is accompanied by a comparable decrease in E_3/creatinine ratio. Based on limited data from 14 patients totaling 127 observations of day-to-day changes in this study, a fall in plasma unconjugated and/or total E_3 may have to exceed some 40 to 45 per cent of the mean of the three preceding determinations in order to have less than a 1 per cent likelihood of representing a change which is unrelated to reduced fetoplacental E_3 production secondary to fetal distress. Further long-term experiments in high-risk pregnancies are necessary to establish whether fetal distress drops plasma unconjugated and/ total E_3 in excess of 40 to 45 per cent and whether or not recognition of such a decrease within 24 hours would leave sufficient time for successful obstetric intervention.

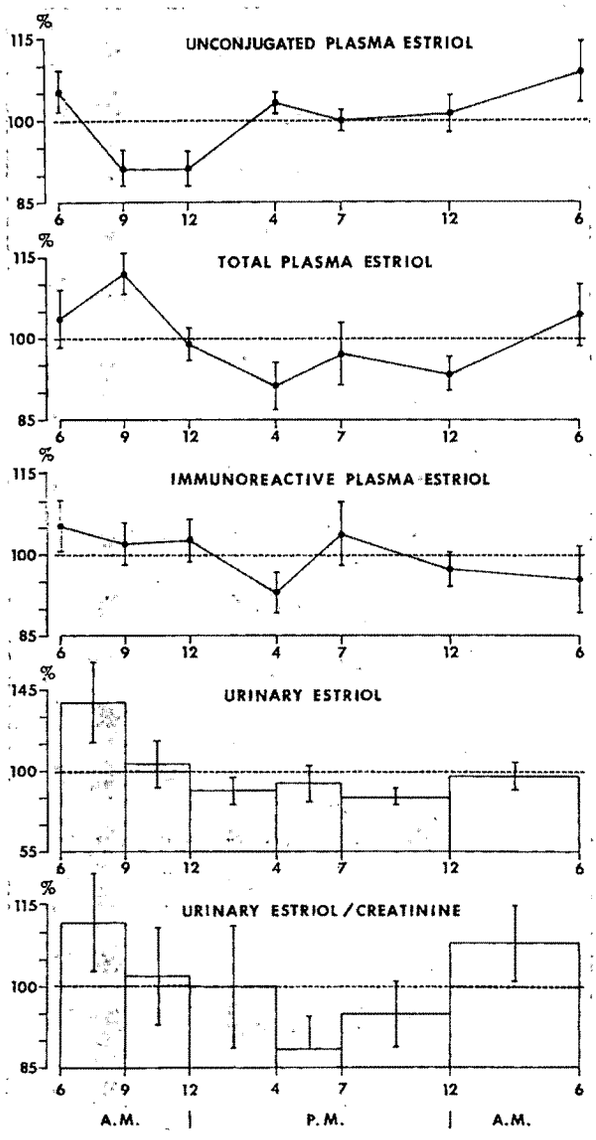

Fig. 4. Averages and standard errors of relative unconjugated, total, and immunoreactive plasma E_3 concentrations and of urinary estriol and estriol/creatinine excretion rates at various times in a 24 hour period. The data obtained in 12 individual patients were normalized to per cent values by calculating the ratio of the observed value to the patient's 24 hour average × 100.

The authors are indebted to Mrs. A. G. Freeman, R. N., B. S., for collecting blood specimens from normal pregnancies, to the Nursing Staff from the high-risk antepartum ward of the LAC-USC Women's Hospital for their kind cooperation, and to Miss Y. Livett for expert technical assistance.

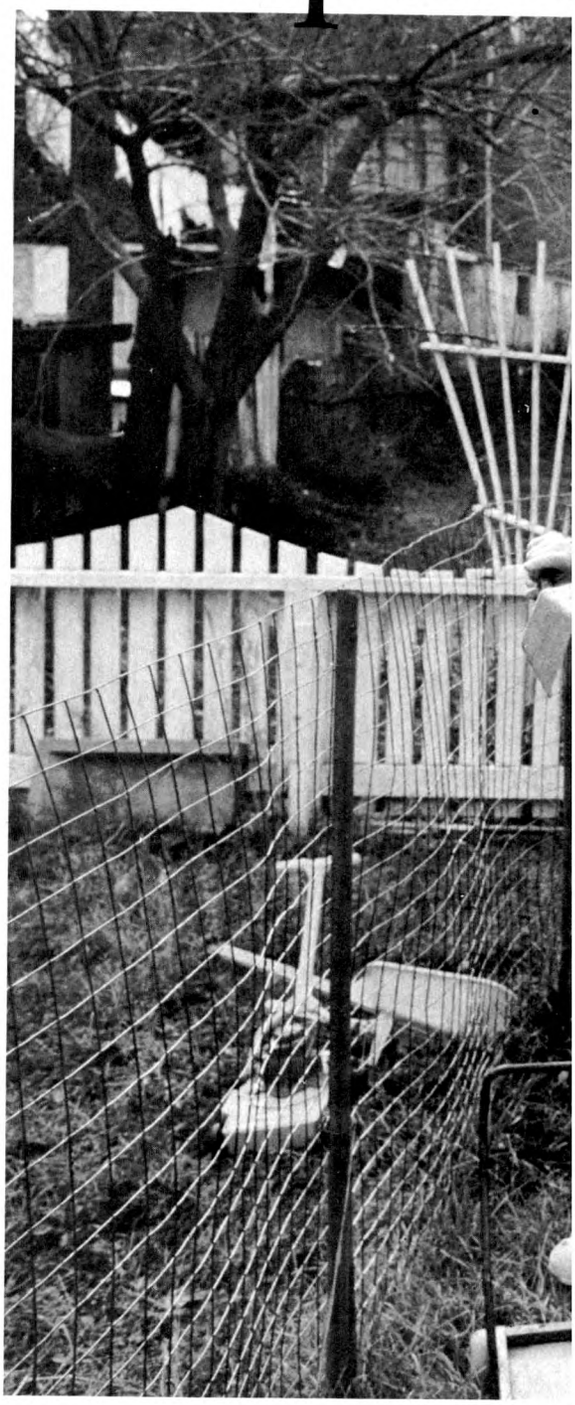
The reasons for acceptance or rejection of an oral contraceptive are many. Some are hers and some are yours.



In the main, her reasons for rejection, often highly subjective, are based on side effects—and side effects are only partially predictable from history and examination.

The ultimate test, then, of oral contraceptive acceptability must be what happens when she takes it since both your judgment and hers will be based on...

Real Life Experience

From real life...

A Woman satisfied her oral contraceptive

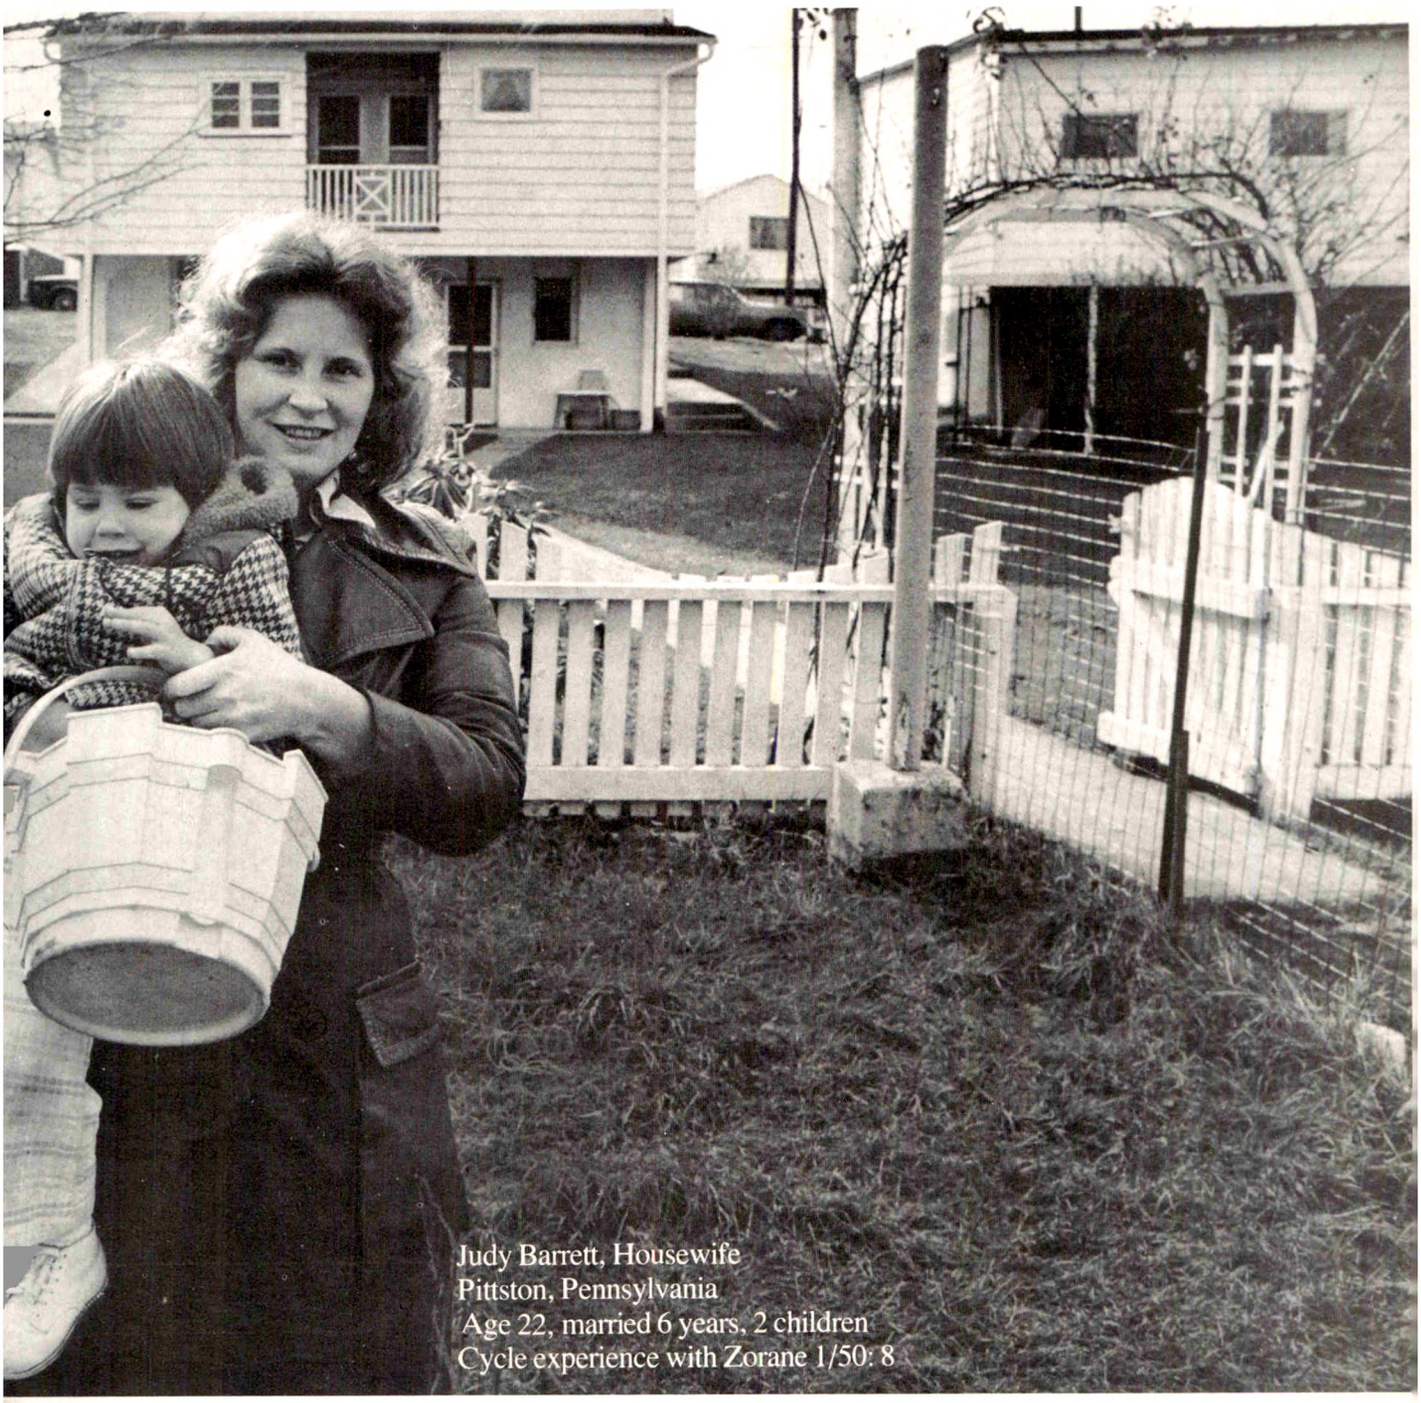
One important reason for patient satisfaction: Usually no G.I. discomfort

ZORANE 1/50 is a highly effective and generally well-tolerated oral contraceptive—providing the estrogen content and progestin:estrogen ratio that appears to be highly acceptable to the majority of women.

From clinical studies: In a study population of 1156 women, 25,983 cycles, the incidence of nausea and vomiting was 3.3%. Actual patient dropout rate* due to nausea and vomiting was 2.9% (33 subjects.) Overall patient dropout rate was 14.4% due to all adverse reactions. Serious reactions, as well as minor adverse reactions, have been reported following the use of all oral contraceptives. Before prescribing, the complete product information should be consulted for *special note, contraindications, warnings, precautions* and *adverse reactions*. Thereafter, the physician should remain alert to the earliest manifestations of any serious disorder. Should any occur or be suspected, the oral contraceptive should be immediately discontinued.

The woman profiled here is an actual ZORANE 1/50 user. However, not all women can be expected to have the same tolerance for side effects, should any occur. (Data on file, Lederle Laboratories)

*Dropout rates are based on total patient population (1,156); incidence reflects only those patients who completed one or more cycles (956).



Zorane® 1/50

Zorane 1/20 ♀ Norethindrone Acetate, 1 mg. and Ethinyl Estradiol, 20 mcg.

Special Note: Oral contraceptives have been marketed in the United States since 1960. Reported pregnancy rates vary from product to product. The effectiveness of sequential products appears to be somewhat lower than that of combination products. Both types provide almost completely effective contraception. The dropout rate for medical reasons, as observed in clinical trials, with ZORANE 1.5/30 appears to be the same as that of higher dose combination products. The dropout rate due to irregular bleeding was somewhat higher, but dropouts were equally split between irregular bleeding and other medical reasons attributable to the drug. (ZORANE 1/20 only: The effectiveness is somewhat lower than that of the higher dose combination products. Both provide almost completely effective contraception. Dropout rate for medical reasons appears to be somewhat higher than with higher dose combination products, due particularly to irregular bleeding.) An increased risk of thromboembolic disease associated with use of hormonal contraceptives has now been shown in studies conducted in both Great Britain and the United States. Other risks, such as those of elevated blood pressure, liver disease, reduced tolerance to carbohydrates, have not been quantitated with precision. Long-term administration of both natural and synthetic estrogens in subprimate animal species in multiples of the human dose increases the frequency for some animal carcinomas. These data cannot be transposed directly to man. Possible carcinogenicity due to the estrogens can neither be affirmed nor refuted at this time. Close clinical surveillance of all women taking oral contraceptives must be continued.

Indications: For control of conception.

Contraindications: Thrombophlebitis, thromboembolic disorders, cerebral apoplexy, or a past history of these conditions; markedly impaired liver function; known or suspected carcinoma of the breast; known or suspected estrogen-dependent neoplasia; undiagnosed abnormal genital bleeding; pregnancy.

Warnings: If early signs of thrombotic disorders (thrombophlebitis, cerebrovascular disorders, pulmonary embolism, retinal thrombosis) occur or are suspected, discontinue use of drug immediately. (Studies indicated a higher risk of these conditions with use of these drugs, not persisting after drug stoppage and not enhanced by long-term use.[1-4]) If sudden partial or complete loss of vision occurs, or if there is sudden onset of proptosis, diplopia or migraine; or if examination reveals papilledema or retinal vascular lesions, discontinue medication. Safety of use in pregnancy has not been established, therefore rule out pregnancy in any patient who has missed two consecutive periods before continuing contraceptive regimen; if prescribed schedule has not been adhered to, consider possibility of pregnancy with first missed period. A small fraction of hormonal agents has been identified in the milk of mothers receiving these drugs; long-range effect to the nursing infant has not yet been determined.

Precautions: Pretreatment and periodic physical examinations of breasts and pelvic organs should include Papanicolaou smear. (Estrogens have produced tumors, some malignant, in 5 species of subprimate animals.) If endocrine and liver function tests are abnormal in patients taking these drugs, repeat tests after drug withdrawal for 2 months. With use of these drugs, pre-existing uterine fibromyomata may increase in size; and some conditions (*i.e.*, epilepsy, migraine, asthma, cardiac or renal dysfunction) may be influenced by fluid retention; observe carefully for such. With use of ZORANE 1.5/30 or ZORANE 1/20, alteration in menstrual patterns may be induced. Since the amount and duration of flow and cycle length may vary, this must be considered in attempting to determine if cause of bleeding is organic. (ZORANE 1/50 only: In breakthrough bleeding or all cases of irregular bleeding per vaginam, keep in mind nonfunctional causes and take adequate diagnostic measures.) With history of psychic depression, discontinue drug if depression recurs to a serious degree. Possible influence of prolonged ZORANE therapy on pituitary, ovarian, adrenal, hepatic or uterine function awaits further study. A decrease in glucose tolerance has been seen in some patients on oral contraceptives; carefully observe diabetics on such therapy. Patient age is no absolute limiting factor, although these drugs may mask onset of climacteric. The pathologist should be advised of ZORANE therapy when relevant specimens are submitted. Susceptible women may have an increase in blood pressure following use of contraceptive steroids.

Adverse Reactions Observed in Patients Receiving Contraceptives: Statistically significant association demonstrated between use of oral contraceptives and: thrombophlebitis, pulmonary embolism, cerebral thrombosis. Suggestive evidence, neither confirmed nor refuted, between use and neuro-ocular lesions (*e.g.*, retinal thrombosis, optic neuritis). Known to occur: nausea, vomiting, G.I. symptoms (abdominal cramps, bloating), breakthrough bleeding, spotting, change in menstrual flow, amenorrhea during and after treatment, edema, chloasma or melasma, breast changes (tenderness, enlargement, secretion), weight change (increase or decrease), changes in cervical erosion and secretions, suppression of lactation when given immediately post-partum, cholestatic jaundice, migraine, allergic rash, rise in blood pressure in susceptible women, mental depression. Reported association with use, neither confirmed nor refuted: anovulation post treatment, premenstrual-like syndrome, changes in libido, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, fatigue, backache, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, itching. *May Alter Laboratory Results in:* hepatic function (increased sulfobromophthalein retention and other tests), coagulation tests (increase in prothrombin, Factors VII, VIII, IX, X), thyroid function (increase in PBI_1, and butanol extractable protein bound iodine, and decrease in T^3 uptake values), metyrapone test, pregnanediol determination.

GYNECOLOGY

Treatment of cervical carcinoma

CLAYTON T. BEECHAM, M.D.
DAVID D. BEILER, M.D.
Danville, Pennsylvania

A comparison of cervical carcinoma survival data is made between a large specialized cancer treatment center, M. D. Anderson, and a general regional medical center with 15,000 inpatient admissions and over 250,000 outpatient visits per year. End results are identical and did not depend on the percentage of time spent by the gynecologists or radiation therapists on problems of pelvic cancer.

AS REGIONALIZATION of cancer care receives increasing emphasis, certain prevailing concepts need validation or possible challenge. Among the criteria considered applicable to therapeutic cancer centers, where the best possible care is given, are (1) number of new cases treated per year and (2) clinical time gynecologists devote strictly to cancer work.

A comparative study of cancer survival figures should help reconcile the issue of optimum results and its relationship to the number of new cases treated per year. The other point is more subtle and cannot be directly measured; however, examination of these important issues in the context of survival figures is relevant.

Material and methods

In 1965 the authors[1] established a protocol for the treatment of invasive cervical carcinoma. According to plan, once the diagnosis is established, the care of patients is a team effort by gynecologists and therapeutic radiologists. They work together every step of the way. Administration of radiation follows the standards set by Fletcher[2] and, while some flexibility is permitted, a therapeutic design is carefully followed. If alterations seem indicated they are made jointly by gynecologists and radiologists. Decisions for the use of radical surgery as either primary or secondary component of the treatment plan are arrived at the same way. Taylor's[3] suggestion of "a mutually advantageous system of cooperation" is operational.

Staging of the disease is done in a conventional manner and always in consultation with at least one other therapeutic radiologist and two other gynecologists. Stage IV lesions are clearly established with positive biopsies from either the bladder or rectum or both.

Into this therapeutic environment 384 cases of cervical carcinoma have come during the period 1965-1972 (Table I). To answer our questions we have stud-

ied the 200 Stages I to IV patients treated entirely at Geisinger Medical Center—52 per cent of our cervical malignancy problem. These have been uniformly managed in accordance with our protocol for invasive cervical carcinoma.

The data have been collated and analyzed in accordance with the modified life table method for cancer staging and end-result reporting. In brief, "this method utilizes all survival information accumulated up to the closing date of the study and describes the manner in which the patient group was depleted during the total period of observation"[4] (see legends for Tables II to IV).

Results

The results for the series are given according to stage of disease in Tables II to V and for all stages, as a group, in Table VI. Summarizing the actuarial calculations, our 5 year survival rate is shown in Table VII. Computer-controlled graphs (Figs. 1 to 3) lend additional visibility to the data.* M. D. Anderson's results are compared with ours in Table VIII.

*Statistical analysis by D. J. Wright, Ph.D.

Comment

Symmonds,[5] in his paper entitled, "Where gynecologic cancer should be treated." dealt with the issues under discussion here. He summed up by stating that optimum results are achieved where there exists a "desirable combination of adequate facilities, cancer volume, and talented personnel." These characteristics—the mark of an acceptable cancer treatment center—leave little room for argument. Can we be more specific and examine each of Symmonds' categories more closely?

First, there is essentially no end-result difference when comparing the country's largest gynecologic cancer service, M. D. Anderson, and one of the nation's smaller, Geisinger Medical Center. Whether they are representative centers for large or small case loads cannot be categorically stated. From our work it is plain that a smaller institution can duplicate the survival rate of the larger. However, we are left with no definition of "small" or what constitutes an "adequate volume" of cervical cancer cases. The *Manual of Standards*[6] suggests "a minimum of 25 new cases of invasive cervical carcinoma."

The Wainright Tumor Clinic Association's 1967 survey of results in Pennsylvania Hospitals with tumor registries did not show a positive correlation between high case load and good results. In fact, an institution with 32 new cervical cases per year (the highest) reported an over-all 5 year survival rate of 18.6 per cent.

Second, "adequate facilities," as mentioned by Symmonds, must be taken for granted. To adequately care for women with cervical carcinoma, megavoltage equipment under the surveillance of a radiation physicist, backed up by computerized calculations, and operated by therapeutic radiologists is so basic to the issue that alternatives are truly hazardous.

Third, Symmonds' "talented personnel" requirement for involvement in successful oncologic treatment is an acceptable premise. Both gynecologist and radiologist must possess special oncologic knowledge while their experience and skills are enhanced by a full range of clinical activity—not just malignancy problems for the gynecologist nor only pelvic neoplasia for the therapeutic radiologist.

Our results show that both radiologists and gyne-

Stage IIIa	45.0	42.6
Stage IIIb	36.0	43.7
Stage IV	14.0	0

cologists possess optimum clinical expertise for dealing with cervical cancer. They do not need to spend their working life in any set percentage of pelvic oncology activity but rather maintain a full range of therapeutic action in their respective fields. This, and not percentages, is a more logical basis for achieving and maintaining diagnostic and therapeutic skills.

Clear-cell adenocarcinoma of the vagina and cervix: Survival data

KENNETH L. NOLLER, M.D.

Survival data on 36 patients with clear-cell adenocarcinomas are reported: seven with vaginal lesions and 29 with cervical lesions. Although the tumor responds to present treatment modalities, it tends to be associated with early lymph node involvement, thus making early diagnosis essential. Radiation as a primary therapeutic measure has often been followed by late recurrence, though many patients with these tumors were treated by older, low-energy modalities.

SEVERAL RECENT papers have reported an association between maternal synthetic estrogen treatment and the development of clear-cell adenocarcinoma of the vagina and cervix in young women.[1–5] Although the risk to those exposed in utero may be less than was earlier anticipated, about 200 such cases are now listed in the national registry, and the specter of cancer remains over all young women whose mothers were treated with diethylstilbestrol.[6]

Because the association of cancer and diethylstilbestrol has been reported only recently, no long-term survival results are available from the tumor registry, although a preliminary report has been published.[7] We thought it would be of benefit to report the survival statistics for our patients who had clear-cell cancer. Although most of these patients were older and were without a positive maternal hormone history, our experience may help in planning treatment for younger patients exposed to maternal diethylstilbestrol who have clear-cell tumors.

Materials and methods

A total of 675 patients with primary cervical adenocarcinoma were seen at the Mayo Clinic from 1910 through 1972. A review of slides from these cases revealed 29 in which the diagnosis of clear-cell (mesonephric) adenocarcinoma could be made. Likewise, 20 cases of primary vaginal adenocarcinoma have been diagnosed between 1930 and April 1, 1974. On review, seven of the 20 were clear-cell adenocarcinomas. Maternal history was obtained for patients with either vaginal or cervical malignancy of this type who were born since 1939, and this has been reported in detail elsewhere.[8] Of 10 patients born since the synthesis of diethylstilbestrol and previously reported, four patients (one with vaginal and three with cervical cancers) had had associated maternal synthetic estrogen treatment. Since the initial report, two additional patients with vaginal clear-cell cancer have been seen and both of these had associated maternal diethylstilbestrol treatment.

We used FIGO standards to establish the primary site of the tumor as well as its clinical stage. When no stage was assigned on initial work-up, staging was done retrospectively from the data in the records. Where differences between the clinical stage and the pathologic extent of the tumor were found, these are noted in the text.

Findings

Vaginal tumors. Seven patients with primary vaginal clear-cell adenocarcinomas were treated at the Mayo Clinic between 1930 and April 1, 1974 (Table I). Surgery was the treatment of choice for patients who

Total	29	

had Stage I tumors. One patient (Stage II lesion) required total exenteration 24 months after the completion of radiation therapy but is now tumor-free at 74 months of follow-up. Three of the seven patients are 5 year survivors and three others are alive and well 4, 10, and 51 months after operation. One patient with Stage IV disease died 9 months after diagnosis.

Cervical tumors. Sixteen patients had Stage I or II lesions and 13 had Stage III or IV lesions (Table II).

Although all five patients with Stage I disease had lesions confined to the cervix, three had clinically underdiagnosed lesions at surgery (Table III). In one patient the tumor extended to the vaginal wall; in another the iliac lymph nodes were positive. The third patient had had a malignant polyp removed by her local physician. She was referred to the Mayo Clinic where, at surgery, she had no residual tumor in the cervix or uterus but had several positive aortic nodes. This patient had a positive maternal history for diethylstilbestrol.

Eight of the 11 patients with Stage II lesions underwent exploratory laparotomy and definitive surgery (Table IV). Of the eight, three had positive lymph nodes and two of the three died of recurrent disease. Three patients received primary irradiation, two after biopsy only and the third was considered inoperable at exploration. All three patients treated with irradiation have died of disease, although two survived 5 years.

All nine patients with Stage III lesions were treated with primary irradiation (Table V). All nine had recurrent disease and seven have died. Three patients underwent exenteration for recurrence after irradiation and two of the three are alive more than 5 years after exenteration.

Three patients with Stage IV disease were seen in a preterminal state, and all three lived less than 1 month. A fourth patient received palliative irradiation and died 17 months after diagnosis.

Delay in therapy. Twenty-two patients had delay in diagnosis from the onset of irregular vaginal bleeding, which was the only presenting symptom (Table VI). The seven patients who had no delay were asymptomatic and the lesions were diagnosed by routine examination. For another seven patients the delay interval was not recorded. Two patients with Stage III cervical tumors were asymptomatic; for an additional three with Stage III lesions the delay to diagnosis was 6 months or less.

Tumors associated with maternal diethylstilbestrol. Three patients with vaginal and three (possibly four) with cervical tumors had had associated maternal diethylstilbestrol. The cervical tumors (with the exception of the cervical polyp) could represent extension of a primary vaginal tumor but would be considered "cervical" tumors under FIGO standards.

All seven patients were treated with radical hysterectomy; postoperative irradiation was given to the two patients who had positive lymph nodes (Table VII). In

addition to the radical hysterectomy, the patients with vaginal tumors underwent total vaginectomy and subsequent vaginal reconstruction during the postoperative period.

Comment

Although the conclusions that can be drawn from a small series such as ours are limited, the data indicate several trends that may be helpful in planning therapy. First, clear-cell adenocarcinoma confined to the vagina can be managed successfully with radical surgery. The prognosis seems to be better than that for patients with squamous-cell cancer of the same stage.[9] Second, because three patients with clinical Stage I and four with clinical Stage II clear-cell adenocarcinomas of the cervix were found at laparotomy to have lesions that

‡Associated maternal diethylstilbestrol treatment uncertain but suspected.

were "understaged," abdominal exploration would appear reasonable in all patients with clear-cell disease to determine more accurately the extent of the lesion; this will aid in the planning of appropriate and adequate therapy. Third, irradiation alone has been followed by late recurrence in all three patients who had Stage II cervical tumors treated by this modality. Generally, however, the patients who received irradiation were those who were seen earliest in this series, and this does not represent the results of the newer methods of delivering radiation therapy. Also, several of the patients who had surgery only have been followed less than 5 years, although four are long-term survivors. Fourth, irradiation was followed by recurrence in all nine patients with Stage III cervical tumors who were so treated. Because of this, exploratory laparotomy may be indicated, and an exenterative operation considered. Exenteration may provide prolonged or even permanent "salvage" in patients who have recurrent clear-cell disease (when the operation is still feasible). Fifth, no difference in survival was noted between patients who had clear-cell adenocarcinoma after maternal exposure to diethylstilbestrol and those who had clear-cell adenocarcinoma but were not exposed to maternal diethylstilbestrol.

Even when the "modern" techniques and dosages of radiation therapy are used, the vagina, bladder, and rectum sustain *some* permanent devascularization, fibrosis, and dysfunction. In the unfortunate young patient who has Stage I or II clear-cell disease, the treatment of choice appears to be primary radical hysterectomy, including total vaginectomy when indicated by the distribution of the malignancy. Satisfactory vaginal function can be provided by use of a split-thickness skin graft reconstruction, usually inserted 6 to 9 days after the initial operation.

A quantitative study of the pregnancy zone protein in sera of women taking oral contraceptives

M.-G. DAMBER
B. VON SCHOULTZ
F. SOLHEIM
T. STIGBRAND
Umeå, Sweden

By means of a single radial immunodiffusion the concentration of "the pregnancy zone protein" (PZ) was measured in sera from women taking oral contraceptive drugs. Women taking only 0.3 mg. of norethisterone were found not to induce measurable amounts of PZ, whereas women taking combined contraceptive drugs showed a significant rise in concentration of PZ. After six months' treatment, 1 mg. of norethisterone and 0.1 mg. of meastranol daily were found to give an average concentration of PZ amounting to 59 mg. per 100 ml., that is, approximately half of the concentration of PZ in sera from women during the last trimester of pregnancy. Different combined contraceptive pills gave rise to different concentrations of PZ.

THE PREGNANCY ZONE protein (PZ), recently purified with a molecular weight of 359,000[1, 2] is known to be found in sera of women during pregnancy.[3–8] In nonpregnant women or men PZ is generally not detectable by immunodiffusion test (less than 4 mg. per 100 ml.). This α_2-globulin, first described by Smithies,[9] has been found to have immunosuppressive properties.[10–12] During pregnancy PZ can be detected in increasing amounts from the end of the first trimester, and during the last trimester the average level is about 100 mg. per 100 ml. After delivery the concentration decreases rapidly.

Estrogen seems to be necessary for the induction of PZ.[2, 8] PZ is found not only in pregnant women but also in women taking oral contraceptive drugs[13–15] and in men treated with estrogen for prostatic cancer.[16, 17] Previous investigations[14, 15, 17] indicate that the occurrence of PZ is related to the composition of the drugs.

From the Departments of Obstetrics and Gynecology and Physiological Chemistry, University of Umeå.

Reprint requests: Dr. M.-G. Damber, Department of Obstetrics and Gynecology, University of Umeå, S 901-87 Umeå, Sweden.

The purpose of the present investigation was to measure quantitatively the variations of PZ in women treated with oral contraceptive drugs and to study the level of PZ in relation to the composition of the oral contraceptive drugs.

Material and methods

A total of 322 blood samples were drawn from 103 women prior to and during treatment with oral contraceptives. The blood samples were collected without anticoagulant. After coagulation the serum was decanted and stored at − 20° C. until use. All sera were coded and tested blindly.

Of the 103 women, 80 were specially selected according to certain criteria. They were all healthy and were not taking other drugs. They had not been pregnant and they had never been treated with oral contraceptives before the investigation. These 80 women were divided into two groups: twenty-two were treated with a combination of 1 mg. of norethisterone and 0.1 mg. of mestranol (Norinyl 1 + 100) and 58 women were treated with 0.5 mg. of norgestrel and 0.05 mg. of ethinyl estradiol (Ovral). Blood samples were obtained before treatment and then after one month, three months, and, in some women, also after six months of treatment.

In addition to these 80 women, a third group of 23 women were examined during treatment with low-dose progestin contraceptives. They had previously tried

Composition of drug	*Level of PZ mg. per 100 ml., (mean ± S.D.)*				*Per cent of women with increased amounts of PZ (> 10 mg. per 100 ml.) during treatment*
	Before	*After 1 month*	*After 3 months*	*After 6 months*	
Norethisterone, 0.3 mg. (Nor-Q.D.)	<4 ± 0 (23)	<4 ± 0 (21)	<4 ± 0 (21)	—	0
Norgestrel, 0.5 mg., ethinyl estradiol, 0.05 mg. (Ovral)	<4 ± 0 (58)	11 ± 17 (55)	17 ± 26 (43)	22 ± 29 (28)	59
Norethisterone, 1 mg., mestranol, 0.1 mg. (Norinyl 1 + 100)	<4 ± 0 (22)	22 ± 21 (21)	47 ± 37 (21)	59 ± 41 (19)	91

Numbers in parentheses are the numbers of patients.

combined oral contraceptives and wanted to change for various reasons. Pills containing 0.3 mg. of norethisterone (Nor-Q.D.) were used and blood samples were obtained after one and three months of treatment.

The serum concentration of PZ was measured by means of single radial immunodiffusion[18, 19] as described in a previous publication.[8] With this method the lowest concentration of PZ that could be accurately measured was 5 mg. per 100 ml.[8]

Results

Before treatment a measurable serum concentration of PZ (> 4 mg. per 100 ml.) was found in only six of 103 women, and there was no value exceeding 10 mg. per 100 ml.

Of the 80 women taking combined oral contraceptives, 54 were found to respond with elevated levels of PZ (> 10 mg. per 100 ml.) in the serum. The remaining 26 women on combined pills and the group of 23 women treated with progestin pills only showed no increase in the PZ concentration during the period of treatment.

Between the two groups of women taking combined pills there were marked differences. The frequency of individuals with increased amounts of PZ, that is, more than 10 mg. per 100 ml. was 91 per cent for women taking norethisterone, 1 mg., and mestranol 0.1 mg., while the corresponding figure for those taking norgestrel, 0.5 mg., and ethinyl estradiol, 0.05 mg. was 59 per cent (Table I). This difference was statistically significant ($p < 0.01$).

Furthermore, the mean values for the concentration of PZ as seen in Fig. 1 were higher in women taking Norinyl 1 + 100 than in women taking Ovral. The significance of difference after one, three, and six months was $p < 0.05$, $p < 0.05$, and $p < 0.05$, respectively. Also, when women with no detectable increase of PZ during treatment were excluded the mean value for the concentration of PZ after six months, was higher for women taking Norinyl 1 + 100, that is, 57 compared to 33 mg. per 100 ml. ($P < 0.05$).

The duration of treatment seemed to be of importance (Fig. 1 and Table I). Thus, the PZ concentration increased rapidly during the first month of treatment and thereafter the mean values were more stable and only slightly increasing. In both groups the increase of PZ was most pronounced during the first month of treatment (Norinyl 1 + 100, $p < 0.01$; and Ovral, $p < 0.01$). The further increase between one and three months was not statistically significant for Ovral, but that for Norinyl 1 + 100 was significant ($p < 0.05$). The increase between three and six months was not statistically significant for any group.

Comment

The present investigation confirms that induction of PZ is not exclusive to pregnancy but is found also during hormonal treatment, that is, combined contraceptive drugs. The mean concentration of PZ during this treatment was lower than that during pregnancy. In a previous investigation[8] the mean concentration during the last trimester of pregnancy was found to be about 100 mg. per 100 ml. The highest mean value now observed in this study (six months' treatment with Norinyl 1 + 100) was 59 mg. per 100 ml. (Table I)—approximately half the mean concentration during pregnancy. The inducing factor is most likely estrogen which is present in much higher concentrations during pregnancy than during treatment with modern contraceptive drugs. This explanation is supported by the present observation that none of the 23 women taking progestin only-contraceptives (norethisterone, 0.3 mg.) showed increased amounts of PZ. PZ is also found in men treated with estrogen.[16, 17]

There is an individual variation in the ability to produce increased amounts of PZ. In this investigation, as in previous studies, some individuals did not re-

act.[7, 8, 14] High mean values of PZ can be the result of both a high induction frequency (individual ability to react with PZ synthesis after exposure to a certain amount of estrogen) or a high induction level (the concentration of PZ may vary individually). The results in Table I show that both the induction frequency and the induction level are significantly affected by the type and dosage of the drug. The differences between the two groups of women taking Norinyl 1 + 100 and Ovral, respectively, are most likely due to the different composition of the drugs. It seems probable that the "total estrogen effect" is of fundamental importance for the induction of PZ. The lower concentrations found in women taking Ovral could be due to a straight estrogen dose response or interactions between estrogen and progestin components. Norgestrel has been reported to have an antiestrogen effect.[20]

The increased synthesis of PZ was pronounced during the first month of treatment. After the third month the increase in PZ concentration was still measurable but rather slow (Fig. 1). This is in agreement with the previous observation that no increase in the occurrence of PZ was found after six months of treatment with oral contraceptive drugs.[14]

The biological role of PZ is partly unknown but this protein is known to have immunosuppressive properties in physiologic concentrations, that is, PZ can inhibit the lymphocyte response to phytohemagglutinin[10] and also the mixed lymphocyte reaction.[11, 12] In the present investigation, PZ was found in increased amounts during treatment with combined oral contraceptives. The immunosuppressive properties of this protein may be related to the recently presented data that some viral diseases are more common in women taking oral contraceptives.[21] Furthermore, plasma from women treated with oral contraceptives has been reported to suppress the mixed lymphocyte reaction.[22]

It is possible that oral contraceptives may have an immunosuppressive effect in some but not all women.

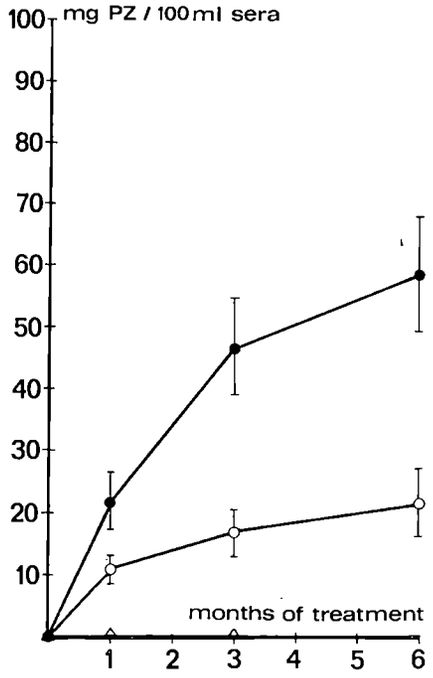

Fig. 1. Concentration of pregnancy zone protein (mean ± S.E.M.) in sera of women during treatment with oral contraceptive drugs. Δ, Norethisterone, 0.3 mg. (Nor-Q.D), ○, Norgestrel, 0.5 mg. ethinyl estradiol, 0.5 mg. (Ovral). ●, Norethisteron 1 mg., mestranol, 0.1 mg. (Norinyl 1 + 100).

These new aspects make it imperative to study in more detail the individual variations in PZ induction and also possible genetic factors controling variations in the individual response.

The increase of PZ during pregnancy both in women and in some animals[11, 23] certainly is a physiologic phenomenon. The increase of the same protein during hormonal treatment may be regarded as a side effect of unknown implications.

Our thanks are due to Professors L. Beckman and P. Lundström for stimulating criticism and advice.

The age of occurrence of gonadal tumors in intersex patients with a Y chromosome

MAY MANUEL, M.D., D.G.O.*
K. PAUL KATAYAMA, M.D., PH.D., F.A.C.O.G.**
HOWARD W. JONES, JR., M.D., F.A.C.O.G.
Baltimore, Maryland

A total of 320 intersex patients with a Y chromosome were classified into four groups; (1) gonadal dysgenesis, (2) asymmetrical gonadal differentiation, (3) virilizing male hermaphroditism, and (4) feminizing male hermaphroditism (testicular feminization syndrome). Of these 320 cases, 98 were from the files of The Johns Hopkins Hospital and the remainder from the literature. The incidence of tumors in relation to age and clinical classification was analyzed by computer. The results were plotted for each group. It was found that the percentage of tumors rose appreciably soon after the age of puberty in the first three groups, and it was concluded that the gonads were best removed before the age of puberty. In the case of testicular feminization patients, procrastination until the age of 25 could be considered, if one were willing to assume the risk of neoplasia of about 3.6 per cent until then.

AN INTERSEX patient with a Y chromosome can be encountered in at least four clinical situations: (1) gonadal dysgenesis, (2) asymmetrical gonadal differentiation, (3) virilizing male hermaphroditism, and (4) testicular feminization.

From the beginning of this century, it has been appreciated that gonadal tumors are more prone to occur in dysgenetic gonads.[1–7]

In recent times, the malignant potential of the dysgenetic gonads in the intersex patient with a Y chromosome has been stressed by many authors.[8–18]

The commonest tumors encountered in dysgenetic gonads have been the dysgerminoma and the gonadoblastoma. While the dysgerminoma can arise in women with normal ovaries, the gonadoblastoma almost always arises in women with dysgenetic gonads. The dysgerminoma, a term coined by Meyer,[19] is a tumor which most observers believe arises from the germ cells in the female and is thus analagous to the seminoma in the male.

The gonadoblastoma was first described by Scully[20] in 1953. It is a gonadal tumor composed of germ cells, sex cord derivatives resembling granulosa or Sertoli cells, and sometimes stromal elements resembling lutein or Leydig cells. This name was chosen by Scully because the neoplasm appeared to recapitulate gonadal development more completely than any other type of tumor. Scully[21] in 1970 reviewed 74 cases of gonadoblastomas and found that a Y chromosome was present in all but three of the cases where chromosomal analyses were available.

To some extent the frequency of neoplasia may be exaggerated since certain cases of gonadal dysgenesis with a Y chromosome might never be recognized except for the clinical appearance of a pelvic tumor and a resulting laparotomy. On the other hand, bilateral germ cell tumors may completely replace the gonadal streaks and the diagnosis of gonadal dysgenesis may be missed.[22]

Despite the documentation of a large number of females with a Y chromosome, dysgenetic gonads, and gonadal tumors, the data have been derived from several series with only a few cases. Therefore, it has not been possible to state the risk according to age. The present study, using cases from the literature and from

the files of The Johns Hopkins Hospital, was carried out to determine the expectancy of neoplasia in the gonads of these intersex patients with Y chromosome in relation to age. This is important in order to be able to state with some confidence the age by which dysgenetic gonads should be removed to avoid serious risk from tumor.

Materials and methods

A total of 320 intersex patients with a Y chromosome were classified into the following four groups: (1) gonadal dysgenesis, (2) asymmetrical gonadal differentiation, (3) virilizing male hermaphroditism, and (4) testicular feminization (complete type).

Many cases were available from the files of The Johns Hopkins Hospital and, whenever possible, pertinent series of cases from the literature were included, giving consideration to the following two criteria: (1) the age of the patient at laparotomy or when seen was available, and (2) chromosome studies were known.

For some categories, an unbiased and a biased series were derived. The cases were considered to be relatively unbiased for our purposes if they were ascertained on the basis of their gonadal or chromosomal abnormality. On the other hand, they were considered biased if the ascertainment was on the basis of the discovery of a tumor.

Group I(a): Gonadal dysgenesis, unbiased series. In the files of The Johns Hopkins Hospital there were 11 cases, of which two had tumors. One was in a 15-year-old girl with bilateral streaks which had gonado-

blastomas. Her karyotype was 45,X,-16, + t(16; Yp-)/46,X,Yq-,-16, + t(16;Yp-). The second patient was 16 years old with 46,XY chromosomes. The left streak had no tumor. On the right side was a gonadoblastoma with overgrowth of malignant germ cells, principally embryonal carcinoma and a focus of dysgerminoma. There was metastatic embryonal carcinoma in the omentum. She had a recurrence 12 months later in the cul-de-sac and the left lumbar gutter. This was found to be dysgerminoma with tubular Sertoli cell pattern and a focus of trophoblast. Her condition worsened in spite of chemotherapy.

Included were 62 pertinent cases from the literature where ascertainment seemed to be on the basis of gonadal dysgenesis rather than on tumors. There were 12 cases of tumors among these. Table I shows the type and distribution of these tumors. Table II shows the chromosomal complement of these 73 cases. The youngest patient without a tumor was 5.5 years old and the oldest was 56 (Fig. 1). The youngest patient with a tumor was 5 years old and the oldest was 24.

Group I(b): Gonadal dysgenesis, biased series. There were 41 tumor reports in this subseries where ascertainment was based on tumor rather than on dysgenesis (Fig. 2). Table III shows the type and distribution of tumors. Table IV shows the chromosomal complement of these 41 cases. The youngest patient with a tumor was 6 years old and the oldest was 43 (Fig. 1).

Group II(a): Asymmetrical gonadal differentiation, unbiased series. There were two cases in the files of The Johns Hopkins Hospital and neither had a tumor.

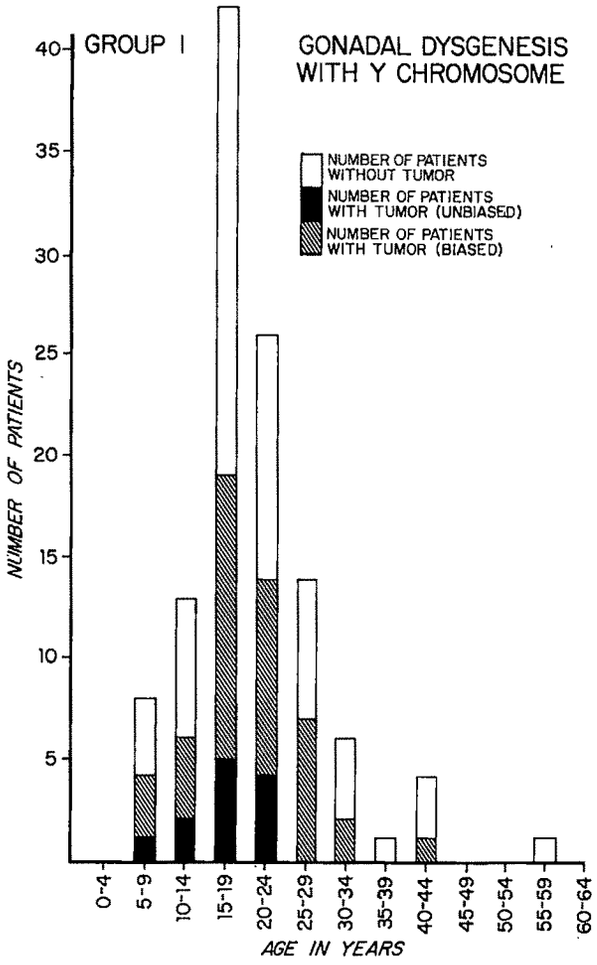

Fig. 1. The age distribution of patients without a tumor, with a tumor (unbiased), and with a tumor (biased) in Group I.

The karyotype of one was 46,XY and the other 45,X/46,X,Yq-. There were 49 pertinent cases from the literature, making a total of 51 cases in all; of these, two had tumors. Table V shows the type and distribution of these tumors. Table VI shows the chromosomal complement of these cases.The youngest patient in the series without a tumor was a newborn infant and the oldest was 47 years old. The youngest patient with a tumor was 19 years old, and the oldest was 21 (Fig. 2).

Group II(b): Asymmetrical gonadal differentiation, biased series. There were eight cases of tumors reported in the literature. Table VII shows the type and distribution of tumors. Table VIII shows the chromosomal complement of these eight cases. The youngest patient with a tumor was 9 years old, and the oldest was 26 (Fig. 2).

Group III: Virilizing male hermaphroditism. There were 62 cases in the files of The Johns Hopkins Hospital, of which two had tumors. Table IX shows the

type of these two tumors. The chromosomal complement of all of these patients was 46,XY. The youngest patient in the series without a tumor was 1 year old and the oldest was 46. The youngest patient with a tumor was 15 years old and the oldest was 38 (Fig. 3).

Group IV: Testicular feminization syndrome (complete type). There were 23 cases in our files and none of them had a tumor. There were 82 cases available from the literature, making a total of 105 cases. There were seven malignant tumors among them. Table X shows the type and distribution of these seven tumors.

The karyotype of these patients was usually 46,XY. The youngest patient without a tumor was 4 months old and the oldest was 70 years old. The youngest patient with a tumor was 14 years old and the oldest was 51 (Fig. 4).

Results

The data were computerized[48, 50] and the results were plotted with age on the abscissa and the expectancy of tumors on the ordinate. The sigmoid curves were applied to data points (Figs. 5 and 6).

Gonadal dysgenesis. In the unbiased series designated as SSY in Fig. 5 the expectancy of tumors is 2 per cent at the age of 10 years, 5 per cent at the age of 14, 16 per cent at the age of 20, and 27.5 per cent at the age of 30. If we include the biased series designated as SSY(b) the resultant curve in Fig. 5 rises more steeply than the unbiased curve SSY. The expectancy of tumors is four per cent at the age of 10 years, 10 per cent at the age of 15, 73 per cent at the age of 30, and 80 per cent at the age of 40 (Fig. 5).

Asymmetrical gonadal differentiation. In the unbiased series designated as STY in Fig. 5 the expectancy of tumors is 10 per cent at the age of 20 years and 19 per cent at the age of 30 years. In the biased series, designated as STY(b) the expectancy of tumors is 3 per cent at the age of 10 years, 10 per cent at the age of 13, 20 per cent at the age of 15, and 74.5 per cent at the age of 26 (Fig. 5).

Virilizing male hermaphroditism. The expectancy of tumors is 3 per cent at the age of 20 years but then rises sharply to 46 per cent at the age of 40 years (Fig. 6).

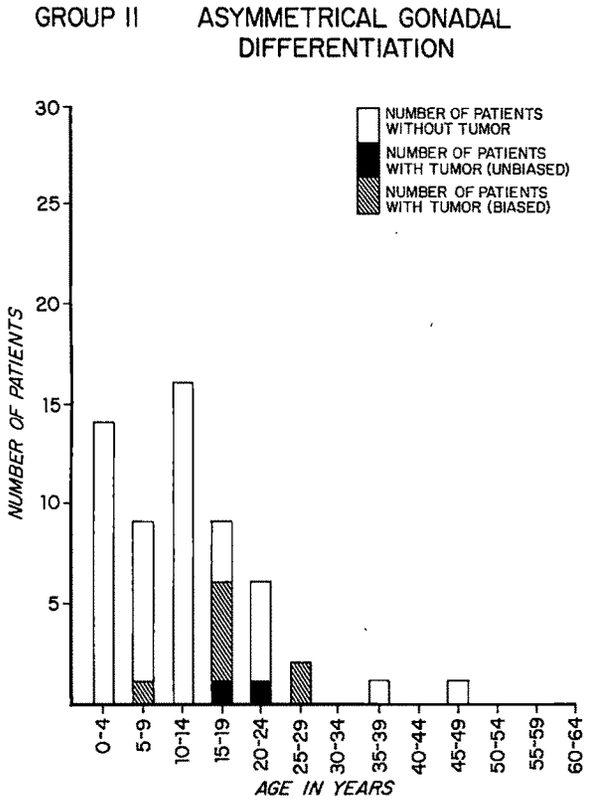

Fig. 2. The age distribution of patients without a tumor, with a tumor (unbiased), and with a tumor (biased) in Group II.

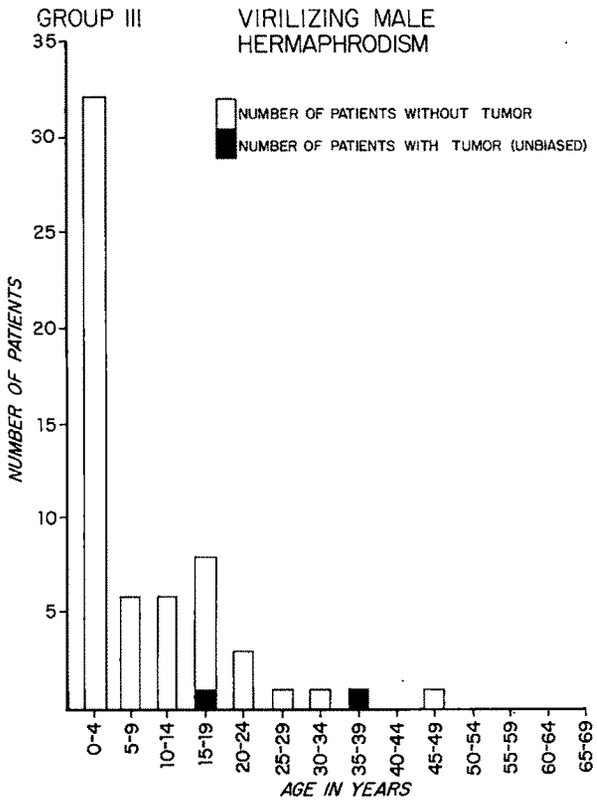

Fig. 3. The age distribution of patients without a tumor and with a tumor (unbiased) in Group III.

Testicular feminization (complete form). The expectancy of tumors is 3.6 per cent at the age of 25 years and this reaches 33 per cent at the age of 50. The curve here is shifted to the right as compared to the other categories of patients (Fig. 6).

Comment

It seems clear from the curves, obtained in Figs. 5 and 6 above, that the expectancy of tumors rises appreciably at about puberty in three groups of intersex patients with a Y chromosome: gonadal dysgenesis, asymmetrical gonadal differentiation, and male hermaphroditism. Hence, it may be concluded that the gonads are best removed from these patients by the age of puberty. Unfortunately, data are not available to further break down these groups, particularly male hermaphroditism, which is a heterogeneous group, so that for the moment nothing can be said about the various subgroups in these major groups with respect to tumor formation. In testicular feminization patients, on the other hand, if a risk of something less than 4 per cent is acceptable, delay in removal of the gonads may be entertained until approximately the age of 30. This has some advantages in allowing this type of patient to spontaneously feminize. This conclu-

sion is in line with that reached by Morris and Mahesh[10] who, in their review, found one malignant tumor in a teenage patient, two in those in their twenties, and 11 in 50 reported cases of 30 years or older. They thought that this 22 per cent incidence of malignancy was probably high, because the presence of the tumor was the indication for operation in many instances.

Dewhurst,[81] on the other hand, found no malignancies in 82 patients with this syndrome. However, 41 had had bilateral orchidectomy: six before puberty, 10 between the ages of 16 and 19, 16 between 20 and 29, and nine over the age of 30. From his personal experience and from a review of the literature, he suspected that the risk of tumor was approximately 5 per cent.

The data on which the discussion of the preceding paragraph was based were collected from patients who had a karyotype of 46,XY, or some minor variation thereof. The incidence of tumor in patients with the much more common 45,X karyotype associated with intersexuality is extremely rare.

Only a very few cases of intersexuality have been reported with a tumor and a karyotype without a definite Y chromosome. These cases have been with 46,XX karyotype,[88, 89, 91] 45,X,[29, 90] 45,X/46,X,?Xq-, 45,X/46,X, + m (m being a minute metacentric chromosome),[8] and 45,X/46,XX.[92] It is always possible that an XY cell line could have been missed in some of these patients, or that a fragment from a Y chromosome could have been translocated and not discovered by techniques in vogue at the time the case was reported.

This restudy of the literature stresses again the importance of removing the gonads of intersex patients with the Y chromosome because of the strong association of the genesis of tumor in the dysgenetic gonads with the presence of a Y chromosome. The number of gonadal tumors in intersex patients, without a Y chromosome, is so small that the possibility must be entertained that in these tumor cases, a restudy with the use of contemporary techniques would reveal the presence of a Y or a translocated fragment thereof.

Cyclic adenosine monophosphate–induced changes in the surface morphology of diapausing blastocysts and the effects on implantation

PAUL V. HOLMES, PH.D.
STAFFAN BERGSTRÖM, M.D.
Calgary, Alberta, Canada, and Uppsala, Sweden

Estrogen induces blastocyst implantation in diapausing female mice, increases uterine levels of adenyl cyclase and cyclic adenosine monophosphate (cyclic AMP), and stimulates synthesis of ribonucleic acid and protein in both the uterus and blastocyst. Furthermore, the surface ultrastructure of trophoblast cells seen with scanning electron microscopy (SEM) changes with activation of the diapausing blastocyst by estrogen. Cyclic AMP-activated blastocysts were investigated with the use of SEM and compared to blastocysts activated by estrogen. Intraperitoneal administration of cyclic AMP was generally ineffective, whereas administration of cyclic AMP intraluminally in the uterus effectively mimicked the early estrogen activation. These findings are discussed in relation to other known activation changes in preimplantation blastocysts and with regard to similar findings after administration of various antiestrogens.

THE ROLE OF estrogen in implantation of mouse and rat blastocysts is undisputed. This is evident in a recent review paper by McLaren[1] concerning activation of the blastocyst. For example, in diapausing female mice a single stimulus of estrogen induces trophoblast transformational changes,[2] activates tyrosine amino transferase in trophoblast cells while altering their surface coat properties,[3] and increases de novo ribonucleic acid (RNA) and protein synthesis in all blastocyst cells.[4–6] Further, the rapid estrogen activation of blastocysts is clearly demonstrated by the changes in trophoblast cell surface structure as seen in scanning and transmission electron microscopy.[7–9]

The relationship between estrogen, cyclic AMP, and adenyl cyclase in reproduction also appears firmly established. In 1967, Szego and Davis[10] reported that estrogen administration to rats acutely increases the uterine levels of cyclic AMP, and later Rosenfeld and O'Malley[11] demonstrated that estrogen stimulates uterine adenyl cyclase activity.

Since it appears that estrogen functions initially through the adenyl cyclase–cyclic AMP system, it should be possible to mimic estrogenic effects to some extent by cyclic AMP. Considerable work now shows that de novo RNA[5, 12, 13] and protein synthesis can be stimulated in the rat uterus by both estrogen and cyclic AMP.[14–17]

The present experiments were designed to determine whether the estrogen-induced trophoblast cell surface changes seen in the scanning electron microscope (SEM) could be reproduced with cyclic AMP and to determine if cyclic AMP is able to induce blastocyst implantation.

Material and methods

NMRI strain (Bethesda) albino mice were maintained under a controlled ten-hour night centered on midnight and fed a standard diet ad libitum. Virgin females weighing 20 to 25 grams were mated with fertile males and bilaterally overiectomized under sodium pentobarbital anesthesia on Day 3 of gestation, a vaginal plug having been found on Day 1. Fig. 1. Blastocyst in delay of implantation after intraluminal instillation of cyclic AMP. Signs of activation are obvious with bulging trophoblast cells, few remaining imprints, and distinct polarity, the abembryonic pole being to the left. ×750.

Table I. Single dose of cyclic AMP on Day 8

Cyclic AMP dosage	*Autopsy day*	*No. of mice*		*No. of blastocysts collected*
		Experimental	*Control*	
8M mole solution, 10 μl/uterine horn (intraluminal)	9	10	5	18 23
10 mg. in 0.5 ml./mouse (intraperitoneal)	9	5	3	24 13
5 mg. in 0.25 ml./mouse (intraperitoneal)	9	8	2	35 10

ovariectomy, 0.5 mg. of long-acting progesterone (Depo-Provera, The Upjohn Co., 50 mg. per milliliter) was administered subcutaneously producing experimental diapause.[18]

The first series of mice were treated with dibutyryl adenosine 3^1, 5^1-cyclic monophosphate (Sigma, Lot no. 42C-7540) either intraluminally in the uterus or intraperitoneally for 24 hours (Table I). In the former group the cyclic AMP or the control vehicle, sterile physiologic saline, was instilled by microsyringe into the uterine lumen on Day 8 at laparotomy after the cervix had been ligated to prevent leakage. The latter groups received intraperitoneal cyclic AMP in a single dose on Day 8 according to Table I. Effective doses of cyclic AMP were previously determined by Holmes and Bergström.[19]

At autopsy on Day 9, 24 hours later, the uteri were carefully excised, examined for implantation sites, and then flushed with 2.5 per cent glutaraldehyde in 0.1M Soerensen's phosphate buffer at pH 7.4. The blastocysts collected were rinsed in phosphate buffer, postfixed for at least 30 minutes in buffered one per cent OsO_4, rinsed in three baths of redistilled water, and prepared by freeze drying, as described previous-

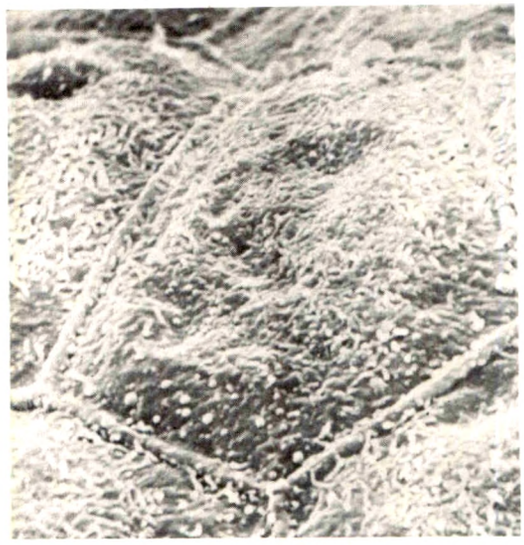

Fig. 3. Blastocyst in delay of implantation activated by 0.1 μg estradiol-17β and recovered 16 hours after estrogen was given. Abembryonic pole. Note distinct cell borders and vanishing shallow imprints on bulging trophoblast cells. ×3,000. (From Bergström, S., and Nilsson, O.: J. Reprod. Fertil. 44: 117, 1975, with due permission from the publisher.)

ly,[20] for observations in a Jeol JSM-U3 scanning electron microscope at 15 kv.

A second series of mice received 2.5 mg. of cyclic AMP in 0.25 ml. of sterile physiologic saline at pH 7.4 intraperitoneally every six hours for either 24 or 48 hours (Table II). The controls were administered 0.25 ml. of the saline vehicle only under identical conditions. The mice then were anesthetized and infused with 0.1 ml. of one per cent pontamine blue solution via the tail vein; five minutes later the uteri were observed for implantation sites. The uteri were excised carefully and flushed with glutaraldehyde to collect the blastocysts. These blastocysts also were processed as described above for scanning electron microscopy.

All observations made with SEM were done with the use of a double-blind method, and the blastocysts were judged according to characteristics previously described by Bergström.[7, 8]

Results

The results are summarized in Tables I and II, and all blastocysts observed by SEM were scored according to surface ultrastructure. The pontamine blue reaction seen early during normal implantation was not observed in any cyclic AMP–treated or control mice in this work.

The essential surface changes induced by cyclic AMP activation of blastocysts in delay of implantation (Figs. 1 and 2) were found to be similar to those seen after estrogen induction (Fig. 3). Examples of the unstimulated control blastocysts can be seen in Figs. 4 and 5. Therefore, the observed changes due to cyclic AMP activation were classified according to the features described for blastocysts activated by estrogen.[7, 8] Three categories were used: activated (bulging trophoblast cells, distinct intercellular borders, relative increase in microvilli, absence of imprints); inactive (signs of intimate proximity of the uterine epithelium to the blastocyst such as imprints, ridges, more or less masked intercellular trophoblast borders, and few microvilli); and, finally, an intermediate category of blastocysts falling between the two described.

Intraperitoneal administration of cyclic AMP was generally ineffective in producing an estrogen-like activation of the blastocyst. Even a dose of 10 mg. induced no visible surface changes in the blastocyst. A slight effect was obtained by dividing the 10 mg. into four doses of 2.5 mg. given every six hours. No additional effect was seen when the schedule was 2.5 mg. every six hours for 48 hours. Furthermore, there is always an insignificant fraction of spontaneously activated blastocysts seen in the control groups.

Intraluminal administration of cyclic AMP was clearly more effective in mimicking the activation changes induced by estrogen (Figs. 1 and 2). An evident change took place about 30 hours after an intraluminal dose of 0.025 mg., while little or no effect was seen after administration of the corresponding control vehicle.

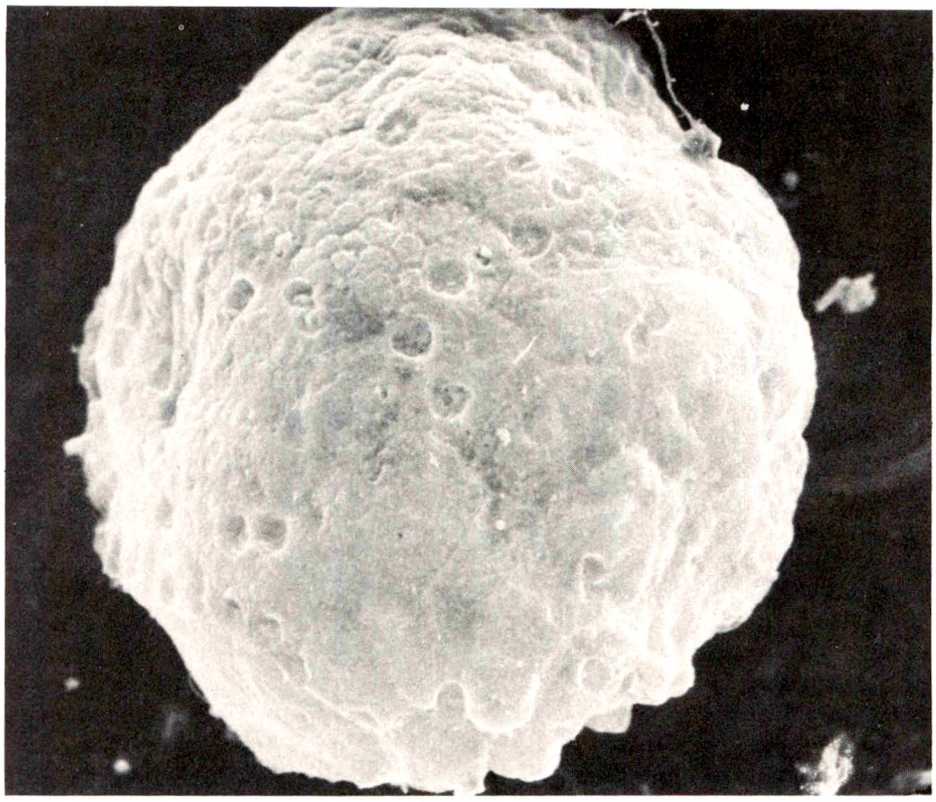

Fig. 4. Blastocyst in delay of implantation without any signs of activation. Note rough surface and multiple imprints. Some intercellular borders between trophoblast cells are barely visible. ×700.

Comment

A direct effect of estrogen on the blastocyst just before and during the implantation process as yet has not been demonstrated. We do know that estrogen stimulates uterine adenyl cyclase activity,[11] increases the uterine levels of cyclic AMP,[10] and therefore apparently functions in the uterus through the first and second messenger system referred to by Robison and Sutherland.[21] In addition, we know that estrogen, directly or indirectly, induces the blastocyst to implant[22] and, when doing so, induces numerous intra- and extracellular trophoblast changes.[3, 7] The present results demonstrate that some of these estrogen-induced changes can also be induced by cyclic AMP. Although it seems unlikely that the first and second messenger systems are not functional in blastocysts, it still cannot be shown that estrogen is the first messenger for blastocysts. However, the evidence is accumulating and other relationships would be clarified if a direct estrogen effect on blastocysts could be demonstrated and if the adenyl cyclase–cyclic AMP system was involved in the trophoblast cells.

Increased cell-to-cell attraction and adhesion can be induced under the stimulation of steroid hormones.[23] Thompson, Tomkins, and Curran[24] induced increased tyrosine aminotransferase (TAT) activity in cultured cells also with the use of steroid hormones. These two findings were linked by Ballard and Tomkins[25] who

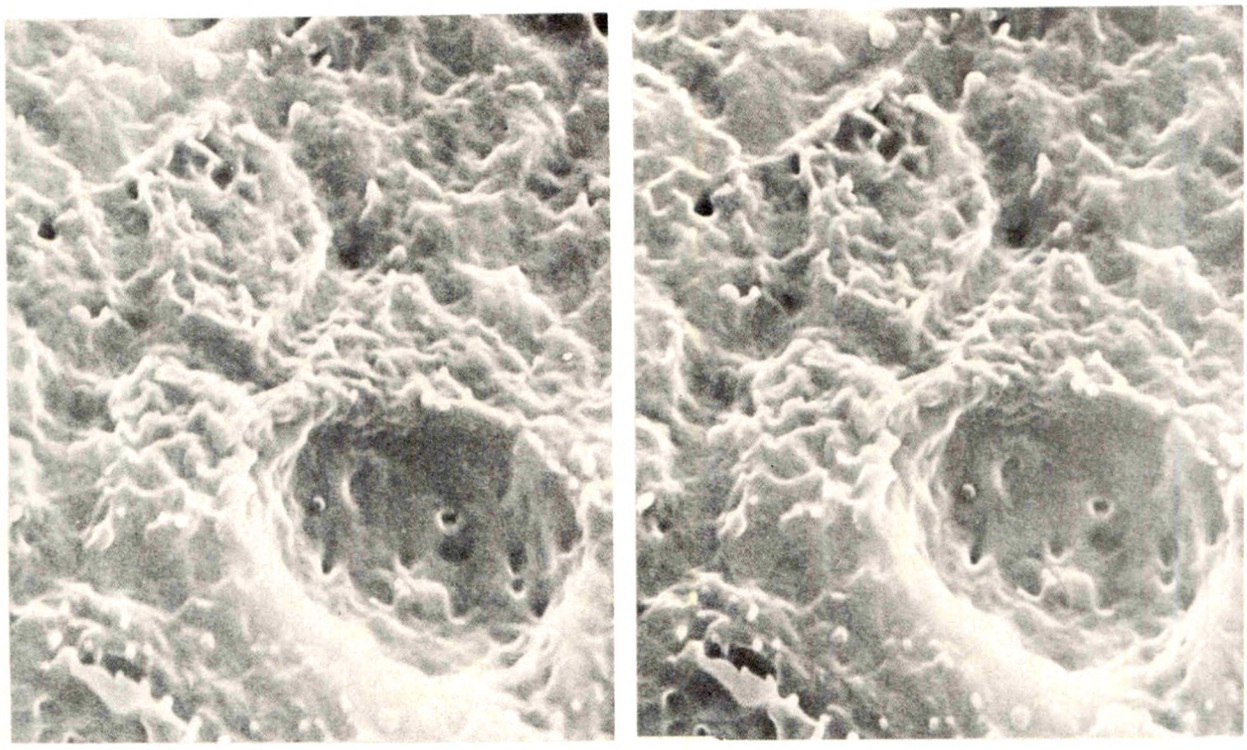

Fig. 5. Imprints on the specimen showed in Fig. 1. Stereo recording with six-degree tilt difference between the left and right figures. Note shallow imprint (upper left) due to uterine epithelial cell apices (polygonal shape) and crater-like imprint (lower right) due to fungus-like protrusion from the uterine epithelium (round shape). ×7,000.

induced both the increase in TAT activity in cell cultures along with the synthesis of a specific cell surface adhesive factor with the use of steroid hormones. Holmes and Dickson[3] proposed that these relationships existed in mouse blastocysts after demonstrating that, during the estrogen-induction of implantation, TAT activity increases in the trophoblast cells concomitant with changes in the electrochemical properties of the cell surface coat. Adding to this chain of action, Sahib, Jost, and Jost[26] recently induced TAT activity directly with cyclic AMP in cultured hepatoma cells, while Johnson and Pastan[27] also using cyclic AMP were able to increase the adhesion of fibroblasts to a substratum. All of these findings demonstrate a close relationship between cell surface adhesive properties, steroid hormones, cyclic AMP, and TAT, and all appear to function in the blastocyst during estrogen-induced activation.

The elimination of the inducing hormone by treatment with the second messenger, cyclic AMP, to achieve a similar result should be possible in this first and second messenger system. Indeed, this has been demonstrated clearly by increased incorporation of tritiated uridine into RNA synthesis in rat blastocysts induced by either estrogen[13] or cyclic AMP.[16] Furthermore, the changes in surface morphology of trophoblast cells accompanying blastocyst activation as seen by SEM now have been induced by either estrogen[7, 8] or cyclic AMP, as in the present results. Both morphologic and biochemical changes have been induced by cyclic AMP in cultured fetal rat brain cells.[28]

Intraperitoneal cyclic AMP appears to have a contraceptive effect on normal reproductive processes also. Ryan and Coronel[29] found that daily intraperitoneal injections of 5 mg. of cyclic AMP in normal female mice blocked the occurrence of pregnancy. Similar intraperitoneal treatment of mice with 5 and 10 mg. of cyclic AMP in the present results had no SEM activating effect, thus being consistent with the findings of Ryan and Coronel. To elucidate this contraceptive mechanism, Pearce and McClurg[30] conducted a histologic survey of the adrenal glands and reproductive organs after intraperitoneal cyclic AMP. They concluded that the contraceptive effect was mediated by changes in the ovaries, uterus, and vagina, indicative of a divergent hormonal effect. The activation effect induced by estrogen on the trophoblast cell surface was not present on blastocysts from mice

treated with intraperitoneal cyclic AMP, as mentioned above. In the present work, cyclic AMP activation of blastocysts apparently can be achieved only by local intraluminal administration of the nucleotide. Moreover, such a local intraluminal instillation of cyclic AMP in saline seems to mimic the effect of several contraceptive antiestrogens. Both produce estrogen-like activation of the blastocyst up to a point and later impede normal blastocyst proliferation and invasion of the stroma.[8] It seems that intraluminal cyclic AMP in saline is not enough to bring about a total estrogen effect, only the early changes. In this situation it has the effect on the blastocyst of an impeded estrogen.

Dr. Ove Nilsson, Professor and Chairman of the Department of Human Anatomy, Biomedical Centre, Uppsala, Sweden, provided the laboratory facilities for the investigation. The authors also are indebted to Ms. Barbro Petersson for her skilled technical assistance and to Ms. Bibi Karlsson for preparation of the manuscript.

Radiation exposure of ovaries during hysterosalpingography

HAMID HUSSAIN SHEIKH, M.D.*
MARVIN A. YUSSMAN, M.D.
Louisville, Kentucky

Radiation exposure to an area approximating the location of the ovaries was measured in 29 patients undergoing hysterosalpingography. A thermoluminescent crystal technique was used for some patients; a pocket dosimeter placed into the upper vagina was used for additional patients. Radiation dosage varied from 75 to 550 millirads. The weight of the patient did not affect the amount of radiation delivered to the gonads. The duration of fluroscopic time was the major factor increasing dosage. A discussion of hysterosalpingographic technique and suggestions for decreasing gonadal irradiation during hysterosalpingography are included.

THOUGH CONTROVERSIAL, there is evidence to indicate that genetic mutation may be induced by less than a single roentgen of irradiation.[1-4]

Muller,[5] the Nobel prize geneticist, states in regard to irradiation of the gonads that there is "no dose so small as to give no mutations at all; each individual ionization and probably each activation of an atom carries its definite chance of producing a mutation." On the average, each newly mutated gene, no matter how small the detriment it occasions, eventually takes its toll in the form of making a major contribution to the extinction of the line of descent.

Schwartz[6] found that the radiosensitivity of the recently fertilized ovum is greatest in the gastrula and morula stages and that it decreases gradually during fetal life. The evidence cited implies that prefertilization radiation or postfertilization exposure may have detrimental effects.[7, 8] Radiation damage to the germ cells is cumulative without regard to time. A mutation need not be a monstrosity, but it chances adding to the load of inherited human ills. High-level dosage, of course can result in sterility.[1]

With the advent of image-intensified fluoroscopy and cinematography, radiation exposure to the ovaries could have been decreased. Unfortunately, these techniques have been so used as to increase radiation exposure manyfold.[9, 10]

The aim of the current investigation is to determine if radiation exposure to the ovaries can be decreased during hysterosalpingography. We have approached this question by measuring the ovarian radiation exposure during hysterosalpingography (HSG) with fluoroscopy.

Material and methods

All the patients included in this study were undergoing either infertility investigation or hysterosalpingography following tubal sterilization (HSG follow-up of tubal sterilization is a separate study).

A Foley catheter technique[11, 12] was used for hysterosalpingography.

Parekh and associates[11] recommended this method and we confirm its convenience as long as uterine manipulation is not required. In the latter event, a suction cannula is used rather than the Foley catheter.[13]

After draping and insertion of a Graves speculum, the cervix and vagina were painted with an antiseptic solution. A No. 10 or 12 Foley catheter was introduced steadily into the uterus with the help of a ring or uterine forceps. The bulb of the Foley was distended with 2 to 4 ml. of air.

Radiation exposure was measured with either of the following two devices applied as close to the ovaries as possible:

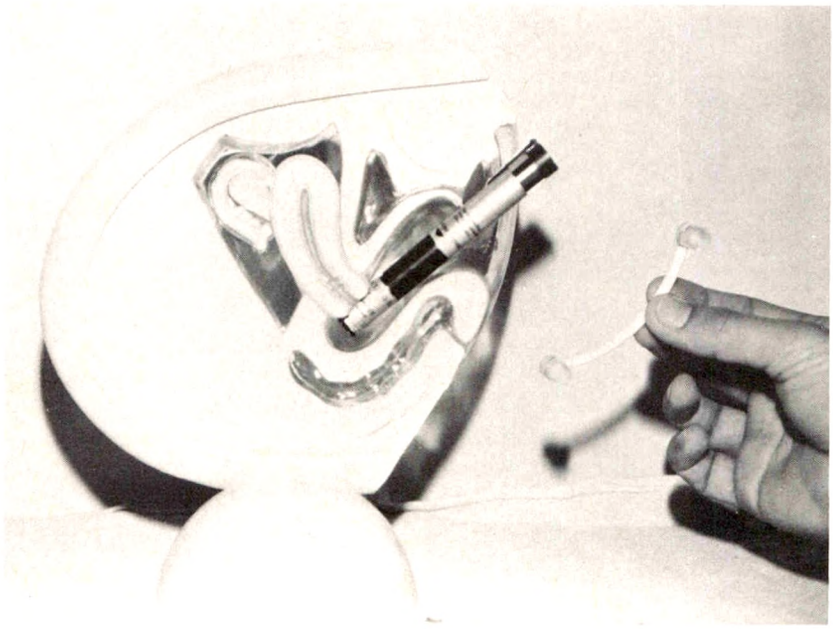

Fig. 1. Devices used for measuring radiation exposure to ovaries. Left, pocket dosimeter in model vagina; right, diaphragm device.

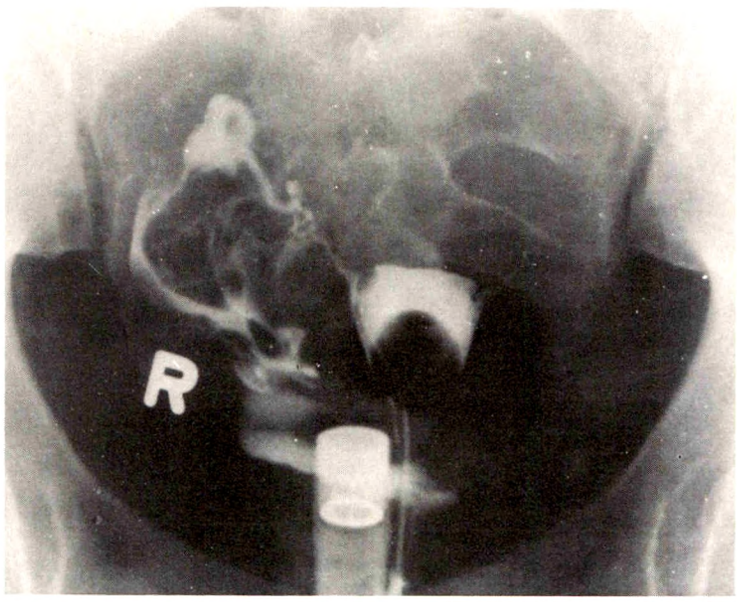

Fig. 2. Hysterosalpingography with the dosimeter in the vagina.

Thermoluminescent crystals (TLD principle) carried by small containers at the ends of an arc made from the curvature of a contraceptive diaphragm.[14, 15] The device was inserted into the vagina so as to place the crystals in the lateral fornices, thus measuring the radiation exposure in the vicinity of each ovary (Fig. 1). We were unable to continue using this device because of nonavailability of the dose-reading instrument.

An approximation of the irradiation exposure of the ovaries was obtained by a pocket dosimeter (Victoreen chamber principle).[15]

The dosimeter was placed in an empty surgical glove and inserted into the vagina so that the chamber was deeply placed in the posterior fornix. A hysterosalpingogram was performed, using fluoroscopy intermittently with minimum exposure time. All the procedures were carried out by the same operator, using the same x-ray machine (Westinghouse), with KVP kept

constant at 100. Fig. 2 is a hysterosalpingogram with the dosimeter in place. A No. 10 Foley catheter is in the uterine cavity. Fig. 3 is a hysterosalpingograph with two dosimeters in the vaginal canal. A second dosimeter with a finer scale was used to determine the accuracy of the original device.

Results

Table I details the information noted for each patient. The total number of patients was 29; 26 were poststerilization procedures and three were indicated for diagnostic purposes. It will be noted that the weight of the patient was not related to the amount of radiation exposure. Radiation dosage increased with the number of fluoroscopic views taken as well as the duration of fluoroscopic exposure. The tube/film distance remained as constant as possible. The radiation exposure of the gonads was identical for diagnostic and poststerilization hysterosalpingography.

Table II summarizes the data derived from this study.

Comment

Cooper and associates,[16, 17] measuring the amount of radiation delivered to the gonads by placing an ionizing chamber in a female cadaver close to the ovaries during HSG, found a mean value of 322 mrad. Martin[18] found a value of 2,500 mrad. measured from the level of the skin. Berman and Sonnenblick[19] used an intravaginal instrument to measure the radiation dose delivered to the gonads and found it to be 3.22 rads for six films. All the above series were carried out without the use of fluoroscopy. Figures as high as 27 roentgens for HSG are also reported.[19, 20]

Shirley,[14] measuring the gonadal dosage with two plane film techniques, reported 130 mrad. With his careful use of fluoroscopy, the dosage was 1,000 to 1,500 mrad; Parekh and co-workers[11] found it to be 525 mrad. with three exposures, with fluoroscopy, 231.5 and 365.7 mrad., respectively. Thus, there is little difference between our findings and those of Parekh and Arronett, perhaps because the Foley catheter technique was used in both series. DeVeechi[10] has shown that during roentgen cinematography the ovaries receive about 2 rads per minute. Schwartz[6] has shown that different diagnostic x-ray machines may deliver 60 to 200 rads per minute; with cobalt treatment the dose is of the order of 10 to 50 rads per minute and with radium it is approximately 0.1 to 0.2 rads per minute. Schwartz further measured the

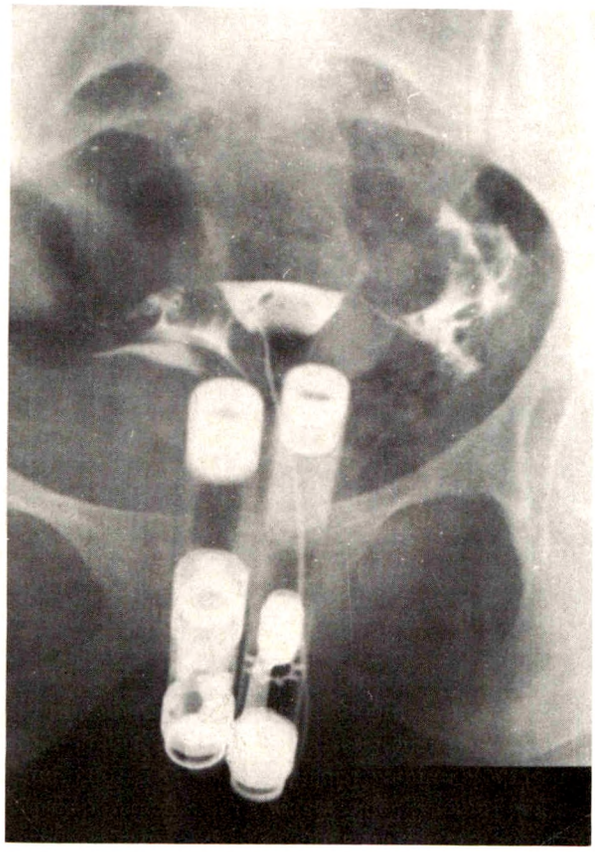

Fig. 3. Hysterosalpingography with two dosimeters in the vaginal cavity.

radiation given to the ovaries during such routine diagnostic procedures as intravenous pyelography, barium enema, and gastrointestinal series, at a total of 11 rads, higher than the maximum of 5 rads recommended radiation by the International Commission on Radiation Protection.[3] These figures represent quite high radiation exposures, and should be kept in mind

Table II. Summary of radiation data

Maximum Radiation (m.R.)	*Fluoroscopic view*	*Fluoroscopic time*
Maximum: Radiation 550	10	65
Minimum: Radiation 70	2	20

Average radiation with two exposures and fluoroscopy, 231.5 m.R.

Average radiation with three exposures and fluoroscopy, 365.7 m.R.

Average fluoroscopy time, 39.1 sec.

Average tube/film distance, 31.9 in.

Average fluoroscopic views, 4 (approximately).

Mean radiation for diagnostic HSG, 194 m.R.

before the decision is made to undertake a procedure on a fertile patient.

We feel that the current study confirms that (1) radiation exposure during hysterosalpingography can be decreased while retaining the efficacy of the procedure, and (2) hysterosalpingography can be simplified by the use of a Foley catheter technique.

Radiologic procedures involving gonad exposure, when indicated, should be done in the proliferative phase of the menstrual cycle, and radiologic exposure should be kept to a minimum.

We wish to thank Douglas M. Haynes, M.D., Professor of Obstetrics and Gynecology, and Curtis P. Sigdestad, M.D., Chief of Radiation Biology, for their critical review of the paper. We are indebted to John T. Queenan, M.D., Professor and Chairman, Department of Obstetrics and Gynecology, University of Louisville, for his encouragement in this project. Our appreciation to Mr. Ahren Jacobson, Radiation Physicist, for his technical advice and to the X-ray Department personnel for their cooperation in carrying out this study.

Varices of Pregnancy

Impending motherhood is a time for great expectation, and time for increased risk of varices in the lower extremities, especially with a second or subsequent pregnancy. The discomfort and disfigurement of varices are an unwelcome and perhaps unnecessary intrusion upon these special moments. Yet, increased intra-abdominal pressure, expanded blood volume and decreased physical activity may come to sharp focus during pregnancy predisposing to varices of the lower extremities.

Naturally, varicose veins become more severe in subsequent pregnancies and may reach the critical stage. Temporary valve incompetence associated with chronic venous distention lays the groundwork for vascular impairment of a very permanent nature, perhaps varicosities of the lower extremities for life.

A Jobst Pregnancy support applies external counter-pressures that oppose excessive venous pressures during pregnancy. Fatigue and discomfort are relieved. Edema is alleviated.[1] A Jobst support worn during the critical months of gestation, may prevent permanent damage to distended veins.[2]

Thompson reports, "We have preferred the Jobst stocking in our clinic. An elastic leotard produced by this company is particularly useful for varicose veins during pregnancy. Most patients are pleasantly surprised by the comforting support this garment gives."[3]

Write for the Jobst Program of Treatment for Varicosities Attendant to Pregnancy. You will receive a collection of clinical reprints on the subject and a full color, twelve-page monograph and bibliography describing the physiological fluid dynamics of external elastic compression. You might also like a twenty-eight-page patient education booklet, edited by a prominent obstetrician, entitled: Answering Your Questions About Varicose Veins During Pregnancy.

Microbiologic aspects of fertility...

The greatest potential for bacterial infection in the female genital tract exists during the fertile years. A large proportion of the potentially pathogenic microflora are anaerobic—particularly bacteroides and anaerobic streptococci. Isolation and identification present special problems.

"Pseudo-maturity"

Sterile at the time of birth, the female genitalia begin to develop an abundant bacterial flora within hours. But this maternally influenced flora, composed largely of the familiar gram-positive lactobacillus known as Döderlein's bacillus, disappears in just a few weeks. The vaginal secretions revert toward alkalinity and remain alkaline until puberty. A varied flora of staphylococci, streptococci (except pyogenes), coliforms and diphtheroid bacilli is present.

The healthy mature female

With the onset of menstruation, conditions within the vagina change appreciably. For example, the glycogen content of the vaginal epithelium is markedly increased under the influence of ovarian hormones. This, in turn, encourages the proliferation of Döderlein's bacilli. These lactobacilli create an acid environment which limits the growth of potential pathogens, and the role of lactobacilli in keeping the microflora in balance is vital throughout a woman's reproductive years.

The normal flora—anaerobes predominate

Certain other bacteria are also seen regularly in the vagina. With today's improved methods of culturing, it has been demonstrated that a large proportion of these bacteria are anaerobic—notably bacteroides and anaerobic streptococci. Other microorganisms that may be observed are the *Escherichia coli/Enterobacter aerogenes* group of coliforms, the anaerobic micrococci, group B streptococci, enterococci, diphtheroids, and *Hemophilus vaginalis.* The presence of any of these microorganisms may or may not be a matter of etiologic importance.

Disturbing influences—balance upset

Not all gynecologic infections are of endogenous origin. Changes in hormonal balance—for example, during pregnancy—nearly always influence the microbiological balance. Both

the resident bacterial population and potential invading pathogens may be affected. Either may be responsible for the occurrence of postpartum infections, postabortal infections, posthysterectomy infections, and the infections that occur concurrently with neoplastic disease. As pathogens ascend the reproductive tract from vagina to uterus to tubes, the risk to the patient is usually enhanced.

Forms of infection

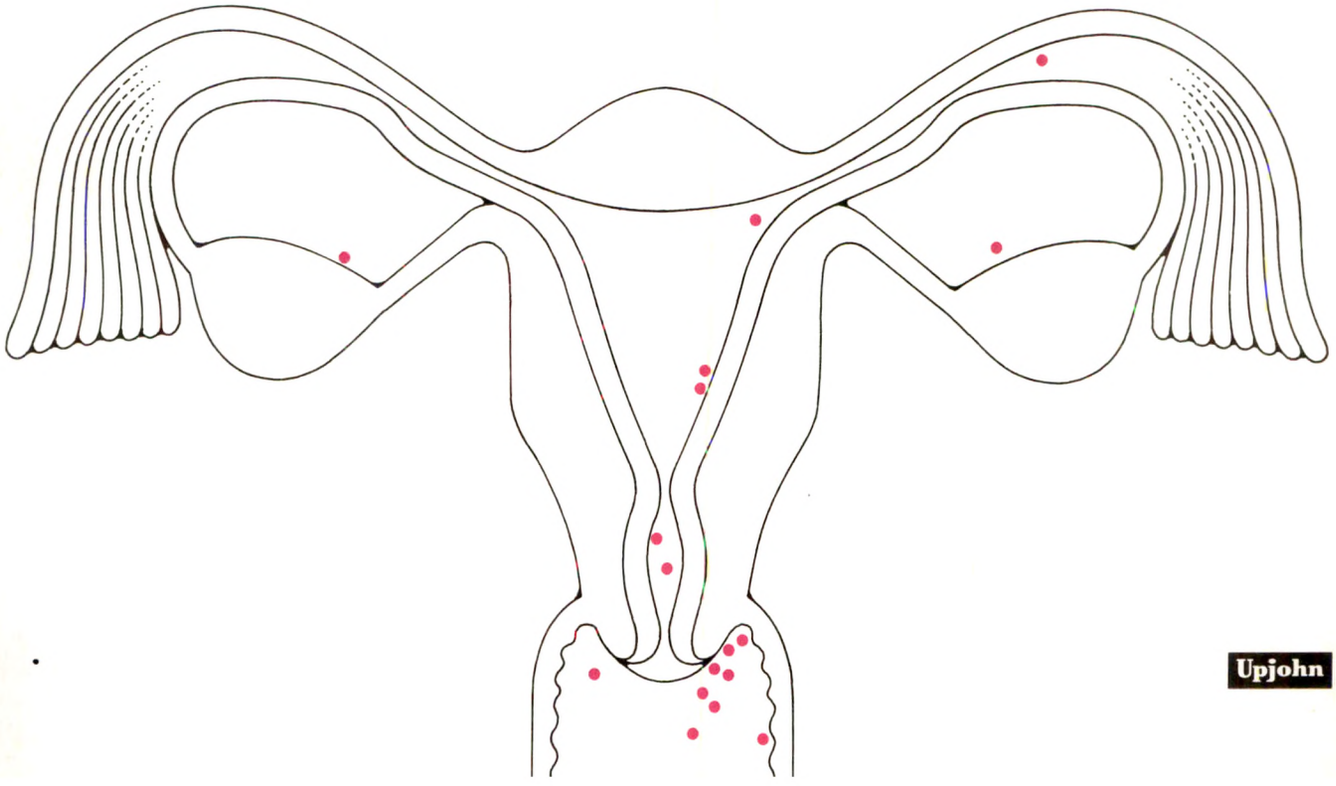
Gynecologists and surgeons alike are well acquainted with such infections: abscesses (whether tuboovarian, pelvic, vaginal, vulval, or Bartholin's gland infection), puerperal sepsis, salpingitis, endometritis, peritonitis of gynecologic origin, vaginal-cuff infection, chronic pelvic inflammatory disease—with each, the threat of possible septicemia. The need for immediate surgical intervention may be controversial, but certain of these infections often represent true gynecologic emergencies.

The problems anaerobes pose...culturing Improved culturing techniques have demonstrated that anaerobes—especially bacteroides and anaerobic streptococci—inhabit the vagina, as well as more remote genital areas. It has been reported that these usually foul-odor-producing anaerobic organisms may be isolated in three out of four cases of infections of the genital tract. In one series of patients, anaerobes alone were cultured in 37 percent of the cases. Many studies have shown that bacteroides are by far the most common of these organisms, but anaerobes such as peptococci, peptostreptococci and other anaerobic streptococci are also frequently observed. Mixed infections with multiple anaerobic species are not unusual.

Today many physicians suspect that the techniques of obtaining or incubating the culture may be at fault if no anaerobes at all are observed.

A new appreciation of pathogenicity Only recently has it been realized that anaerobes other than clostridia are pathogens of major significance in serious infections of the female genital tract. Exacting methods of culturing have helped to establish this. One investigation has shown that 44 percent of all anaerobic isolates obtained from a series of 400 patients of all types, not just gynecologic, were associated with infection. Bacteroides and anaerobic streptococci were the most prevalent, with clostridia occurring less frequently.

Whenever these organisms are seen on repeated occasions by Gram stain or isolated by culture—whether alone or combined with other bacteria—they should not be ignored.



Therapeutic measures

Selection of the most appropriate antibiotic—or antibiotics—is still a problem for the gynecologist in many instances, since many of the infections he deals with cannot be etiologically defined when first observed. Nevertheless, the seriousness of his patient's condition may demand immediate attention. Because there are numerous antibiotics effective against just certain potential pathogens, the physician's problem has been intensified. And for one aspect of his problem—anaerobic infections—there has been no easy answer.

Many gynecologists believe that, of all infections, these present one of today's most serious challenges.

For information on ONE ANTIBIOTIC OF SIGNIFICANCE in the treatment of serious anaerobic infections of the female reproductive tract, please turn page.

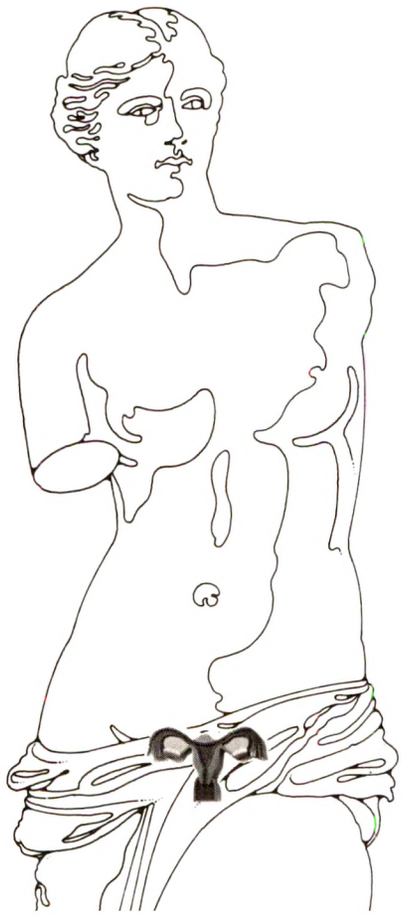
Therapeutic considerations...

Cleocin® Phosphate (clindamycin phosphate injection) has proved to be effective against susceptible anaerobic organisms (whether they are anaerobic cocci or anaerobic gram-positive or gram-negative rods). Specifically its activity has been established in serious infections of the female pelvis and genital tract such as endometritis, nongonococcal tubo-ovarian abscess, pelvic cellulitis, and postsurgical vaginal-cuff infection caused by susceptible strains of bacteroides, fusobacteria, peptococci, peptostreptococci, microaerophilic streptococci, or clostridia.* Furthermore, Cleocin PO_4 has proved successful in septicemia and in such nongynecologic conditions as serious intra-abdominal infections (peritonitis, intra-abdominal abscess), serious respiratory-tract infections (empyema, anaerobic pneumonitis, lung abscess), and serious infections of skin and soft-tissue caused by susceptible anaerobic organisms.

Since disc susceptibility testing with current methods is not reliable for anaerobes, *in vitro* dilution methods should be used to determine susceptibility to clindamycin.



Also of value in serious gram-positive infections The use of Cleocin PO_4 in serious nongynecologic infections caused by susceptible gram-positive organisms has been extensively investigated both bacteriologically and clinically. Because Cleocin PO_4 is a parenteral antibiotic, emphasis has been on evaluation of the drug in serious infections, and the appropriate patients for Cleocin PO_4 are those who are hospitalized with serious illnesses.

Diagnoses have included septicemia and septic shock, acute peritonitis, staphylococcal pneumonia, and massive wound infection. In many cases the infection was secondary to severe accidental trauma, major surgery, or debilitating disease.

Cleocin PO_4 has produced excellent results when the pathogens in these serious infections proved to be staphylococci, streptococci (except enterococci), or pneumococci. With rare exceptions, the organisms proved susceptible *in vitro* and were successfully eradicated from the clinical lesions, regardless of the severity of the infection. Its use in these infections should be reserved for penicillin-allergic patients for whom, in the judgment of the physician, a penicillin is inappropriate.

Other therapeutic considerations:

1) Cleocin PO_4 is clinically effective in serious infections caused by penicillin-resistant or penicillinase-producing staphylococci. However, staphylococcal strains resistant to clindamycin have been encountered, and susceptibility testing should be performed.

2) Cleocin is useful in patients who are sensitive to penicillin. Rare cases of sensitivity to Cleocin resulting in maculopapular rash and urticaria have been reported; as with all antibiotics, it should be used cautiously in atopic patients. Serious anaphylactoid reactions require emergency treatment with epinephrine. Oxygen and intravenous corticosteroids should also be administered as indicated. However, no actual cross-antigenicity with other antibiotics has been demonstrated, *except with lincomycin.*

Because of these two benefits, Cleocin PO_4 can fill a need both for penicillin-sensitive patients and those harboring penicillin-resistant organisms.

Cleocin PO_4 should be reserved for serious infections where less toxic antimicrobial agents are inappropriate, as described in the Indications Section of the brief summary on the following page.

WARNINGS: (See WARNING box on following page.)

If significant diarrhea or colitis occurs during therapy, this antibiotic should be discontinued. (See WARNING box and summary of prescribing information on following page.

Safety for use in pregnancy has not been established.

*Clostridia are more resistant than most anaerobes to clindamycin. Some species, e.g., *C. sporogenes* and *C. tertium*, are frequently resistant to clindamycin.

STERILE SOLUTION

...Cleocin® PO4

clindamycin phosphate injection, Upjohn

...OF MEDICINE ... LIBRARY ...

WARNING

Clindamycin can cause severe colitis which may end fatally. Therefore, it should be reserved for serious infections where less toxic antimicrobial agents are inappropriate, as described in the Indications Section. It should not be used in patients with nonbacterial infections, such as most upper respiratory tract infections. The colitis is usually characterized by severe, persistent diarrhea and severe abdominal cramps and may be associated with the passage of blood and mucus. Endoscopic examination may reveal pseudomembranous colitis.

When significant diarrhea occurs, the drug should be discontinued or, if necessary, continued only with close observation of the patient. Large bowel endoscopy has been recommended.

Antiperistaltic agents such as opiates and diphenoxylate with atropine (Lomotil®) may prolong and/or worsen the condition.

Diarrhea, colitis, and pseudomembranous colitis have been observed to begin up to several weeks following cessation of therapy with clindamycin.

Each ml contains:

clindamycin phosphate equivalent to. . . . . 150 mg clindamycin base

benzyl alcohol. . . . . 5 mg

disodium edetate. . . . . 0.5 mg

water for injection. . . . . qs

When necessary, pH adjusted with NaOH and/or HCl.

Indications: Clindamycin is indicated in the treatment of serious infections caused by susceptible anaerobic bacteria.

Clindamycin is also indicated in the treatment of serious infections due to susceptible strains of streptococci, pneumococci, and staphylococci. Its use should be reserved for penicillin-allergic patients or other patients for whom, in the judgment of the physician, a penicillin is inappropriate. Because of the risk of colitis, as described in the WARNING box, before selecting clindamycin the physician should consider the nature of the infection and the suitability of less toxic alternatives (e.g., erythromycin).

Anaerobes: Serious respiratory tract infections such as empyema, anaerobic pneumonitis and lung abscess; serious skin and soft tissue infections; septicemia; intra-abdominal infections such as peritonitis and intra-abdominal abscess (typically resulting from anaerobic organisms resident in the normal gastrointestinal tract); infections of the female pelvis and genital tract such as endometritis, nongonococcal tubo-ovarian abscess, pelvic cellulitis and postsurgical vaginal cuff infection.

Streptococci: Serious respiratory tract infections; serious skin and soft tissue infections; septicemia.

Staphylococci: Serious respiratory tract infections; serious skin and soft tissue infections; septicemia; acute hematogenous osteomyelitis.

Pneumococci: Serious respiratory tract infections.

Adjunctive Therapy: In the surgical treatment of chronic bone and joint infections due to susceptible organisms.

Indicated surgical procedures should be performed in conjunction with antibiotic therapy.

Bacteriologic studies should be performed to determine the causative organisms and their susceptibility to clindamycin.

Contraindications: History of hypersensitivity to clindamycin or lincomycin.

Warnings: (See WARNING box.) Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed promptly with fluid, electrolyte and protein supplementation as indicated. Systemic corticoids and corticoid retention enemas may help relieve the colitis. Other causes of colitis should also be considered.

A careful inquiry should be made concerning previous sensitivities to drugs and other allergens. Antagonism has been demonstrated between clindamycin and erythromycin *in vitro*. Because of possible clinical significance, these two drugs should not be administered concurrently.

Usage in Pregnancy: Safety for use in pregnancy has not been established.

Usage in Newborns and Infants: When clindamycin phosphate is administered to newborns and infants, appropriate monitoring of organ system functions is desirable.

Usage in Meningitis: Since clindamycin does not diffuse adequately into the cerebrospinal fluid, the drug should not be used in meningitis.

SERIOUS ANAPHYLACTOID REACTIONS REQUIRE IMMEDIATE EMERGENCY TREATMENT WITH EPINEPHRINE. OXYGEN AND INTRAVENOUS CORTICOSTEROIDS SHOULD ALSO BE ADMINISTERED AS INDICATED.

Precautions: Review of experience to date suggests that a subgroup of older patients with associated severe illness may tolerate diarrhea less well. When clindamycin is indicated in these patients, they should be carefully monitored for change in bowel frequency. Prescribe with caution in individuals with a history of gastrointestinal disease, particularly colitis.

Do not inject intravenously as an undiluted bolus; infuse as directed in package insert. Indicated surgical procedures should be performed in conjunction with therapy. Patients with very severe renal disease and/or very severe hepatic disease accompanied by severe metabolic aberrations should be dosed with caution and serum clindamycin levels monitored during high dose therapy.

Prescribe with caution in atopic individuals. During prolonged therapy, periodic liver and kidney function tests and blood counts should be performed. Use may result in overgrowth of non-susceptible organisms, particularly yeast. Should superinfection occur, adjust therapy as clinical situation dictates. Clindamycin has been shown to have neuromuscular blocking properties that may enhance the action of other neuromuscular blocking agents. Use with caution in patients receiving such agents.

Adverse Reactions: *Gastrointestinal:* Abdominal pain, nausea, vomiting and diarrhea. (See WARNING box.) *Hypersensitivity Reactions:* Maculopapular rash and urticaria have been observed. Generalized mild to moderate morbilliform-like skin rashes are the most frequently reported of all adverse reactions. Rare instances of erythema multiforme, some resembling Stevens-Johnson syndrome, have been associated with clindamycin. A few cases of anaphylactoid reactions have been reported. If a hypersensitivity reaction occurs, the drug should be discontinued. The usual agents (epinephrine, corticosteroids, antihistamines) should be available for emergency treatment of serious reactions. *Liver:* Jaundice and abnormalities in liver function tests have been observed during clindamycin therapy. *Hematopoietic:* Neutropenia, eosinophilia, agranulocytosis and thrombocytopenia have been reported; no direct etiologic relationship to concurrent clindamycin therapy has been made.

Local Reactions: Pain, induration and sterile abscess have been reported after intramuscular injection and thrombophlebitis after intravenous infusion. Reactions can be minimized or avoided by giving deep intramuscular injections and avoiding prolonged use of indwelling intravenous catheters.

How Supplied: Available as sterile solution with each ml containing clindamycin phosphate equivalent to 150 mg clindamycin base. Ampoules of 2 and 4 ml.

Caution: Federal law prohibits dispensing without prescription.

For additional product information see your Upjohn representative.

An effective low-dose oral contraceptive

©Ortho Pharmaceutical Corporation 19

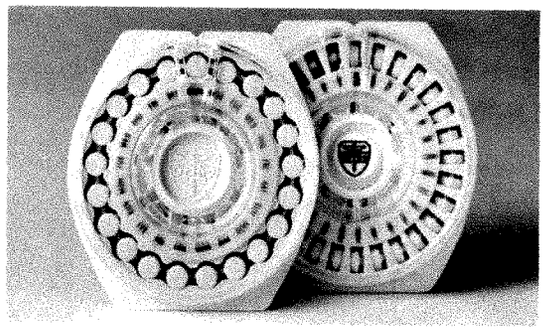
Ortho-Novum 1/50 □ 21

TRADEMARK

Each tablet contains 1 mg norethindrone and 0.05 mg mestranol.

A sensible way to start a woman on oral contraceptives is with an effective, low-dose combination like Ortho-Novum 1/50 □ 21. This combination offers a low dose of estrogen, 50 mcg of mestranol, and a low dose of progestin, 1 mg norethindrone, which can fulfill your contraceptive requirements and her contraceptive needs.

Ortho-Novum 1/50 □ 21 is usually a well-tolerated† combination; thus, in clinical studies, there is a low drug-related drop-out rate.



Add to this the simplicity of the dosage regimen — three weeks on and one week off — and the unique Dialpak* Tablet Dispenser, which helps reduce the chance of error or missed doses, and you have an effective combination that fits very nicely into their life-style...and their wor

†Serious as well as minor conditions have been reporte following the use of oral contraceptives. These conditi include thromboembolic disease. The physician should alert to the earliest manifestations of any symptoms of serious disease and discontinue oral contraceptive the when appropriate. The physician should be fully awar of the complete Prescribing Information for this produ

an effective low-dose oral contraceptive

Ortho-Novum 1/50□21 and 28

TRADEMARK

Ortho-Novum 1/50□21 and Ortho-Novum 1/50□28

Description: Each ORTHO-NOVUM 1/50□21 Tablet contains 1 mg of the progestational substance, norethindrone, together with 0.05 mg of the estrogenic compound, mestranol.

Each yellow ORTHO-NOVUM 1/50□28 Tablet contains 1 mg of the potent progestational substance, norethindrone, together with 0.05 mg of the estrogenic compound, mestranol. Each green tablet contains inert ingredients.

Actions: ORTHO-NOVUM 1/50□21 and ORTHO-NOVUM 1/50□28 act through the mechanism of gonadotrophin suppression, i.e., through the estrogenic and progestational actions of the ingredients. Alterations in cervical mucus and in the endometrium may also contribute to the efficacy of ORTHO-NOVUM 1/50□21 and ORTHO-NOVUM 1/50□28.

Special note: Oral contraceptives have been marketed in the United States since 1960. Reported pregnancy rates vary from product to product. The effectiveness of the sequential products appears to be somewhat lower than that of the combination products. Both types provide almost completely effective contraception.

The physician should consider a thorough discussion with each patient about the prescribing information, risks and benefits associated with oral contraceptives, taking into account various factors such as age and other physical conditions.

An increased risk of thromboembolic disease associated with the use of hormonal contraceptives has now been shown in studies conducted in both Great Britain and the United States. Other risks, such as those of elevated blood pressure and reduced tolerance to carbohydrates, have been reported and appropriate tests should be conducted to monitor these during oral contraceptive therapy. Liver disease has also been reported, and the physician should be alert to its earliest manifestations.

Long-term administration of both natural and synthetic estrogens in subprimate animal species in multiples of the human dose increases the frequency for some animal carcinomas. These data cannot be transposed directly to man. The possible carcinogenicity due to the estrogens can neither be affirmed nor refuted at this time. Close clinical surveillance of all women taking oral contraceptives must be continued.

Indication: Contraception.

Contraindications: 1. Thrombophlebitis, thromboembolic disorders, cerebral vascular disease, myocardial infarction, or a past history of these conditions. 2. Markedly impaired liver function. 3. Known or suspected carcinoma of the breast. 4. Known or suspected estrogen-dependent neoplasia. 5. Undiagnosed abnormal genital bleeding. 6. Known or suspected pregnancy.

Warnings: 1. The physician should be alert to the earliest manifestations of thrombotic and thromboembolic disorders, thrombophlebitis, cerebrovascular disorders including hemorrhage, pulmonary embolism and retinal thrombosis. Should any of these occur or be suspected, the drug should be discontinued immediately.

Retrospective studies of morbidity and mortality in Great Britain and studies of morbidity in the United States have shown a statistically significant association between thrombophlebitis, pulmonary embolism and cerebral vascular disease, occlusive or hemorrhagic, and the use of oral contraceptives. There have been three principal studies in Great Britain[1-3] leading to these conclusions and three in this country.[4-7] The estimate of the relative risk of thromboembolism in the study by Vessey and Doll[3] was about sevenfold, while the United States studies found relative risks of 4.4 to 11, meaning that the users are several times as likely to undergo thromboembolic disease without evident cause as nonusers.

In May, 1974, the Royal College of General Practitioners in England[8] issued an interim report of its continuing large-scale prospective study comparing a user group to a nonuser group. This study in its interim analysis states, "A statistically significant higher rate of reporting of cerebrovascular accidents in Takers is evident, but the numbers are too small to justify an estimation of the degree of risk." The study also reported a higher incidence of superficial and deep vein thrombosis in users as compared to nonusers. The risk of superficial and deep vein thrombosis was reported to be lower in women using 50 mcg estrogen preparations.

The Sartwell study[4] indicated that the risk did not persist after discontinuation of administration. Both the Sartwell and the Royal College studies indicated that the degree of risk was not associated with duration of treatment.

In a collaborative American study[5,6] of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the relative risk of thrombotic stroke was 4.1 to 9.5 times greater in users than in nonusers. A comparable estimate for hemorrhagic stroke was 2.0.

None of the American studies was designed to evaluate a difference between products. However, the Sartwell study[4] suggested that there might be an increased risk of thromboembolic disease in users of sequential products.

Other retrospective studies[9,10] have reported an increased risk of post-surgery thromboembolic complications in oral contraceptive users. It has been recommended that therapy be discontinued at least one month prior to elective surgery.

In May of 1975 two separate retrospective case control studies relating to fatal and nonfatal myocardial infarction in users and nonusers of oral contraceptives were reported.[11,12] The studies estimate that the increased risk of hospital admission for myocardial infarction associated with the use of oral contraceptives as compared to nonusers is 2.7 times in the 30-39 age group and 5.7 times in the 40-44 age group; and the risk of death associated with the use of oral contraceptives as compared to nonusers was increased 2.8 times for users in the 30-39 age group and 4.7 times in the 40-44 age group. One of these studies reported that oral contraceptive users who had myocardial infarction were more likely to be heavy smokers and have certain additional risk factors, i.e., treated hypertension and diabetes, pre-eclamptic toxemia, obesity and type II hyperlipoproteinemia.

2. Discontinue oral contraceptive medication if there is: gradual or sudden partial or complete loss of vision; proptosis or diplopia; onset or aggravation of migraine or development of headache of a new pattern which is recurrent, persistent or severe; papilledema; or any evidence of retinal vascular lesions.

3. Fetal abnormalities have been reported to occur in the offspring of women who have taken progestogens and/or estrogens during pregnancy.[13,14] The safety of ORTHO-NOVUM 1/50□21 or ORTHO-NOVUM 1/50□28 in pregnancy has not been demonstrated. Pregnancy should be ruled out before initiating or continuing the contraceptive regimen. Pregnancy should always be considered if withdrawal bleeding does not occur.

4. A small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The long-range effect to the nursing infant cannot be determined at this time.

5. Hepatic lesions (adenomas, hepatomas, hamartomas, regenerating nodules, etc.), occasionally fatal, have been reported in women on oral contraceptives. Such lesions may present as an abdominal mass or with the signs and symptoms of an acute abdomen. These lesions should be considered if the patient has abdominal pain or evidence of intra-abdominal bleeding. This has been reported in short-term as well as long-term users of oral contraceptives.

Precautions: 1. A thorough history and physical examination should be performed before prescribing oral contraceptives and periodically during their administration and should include special reference to breasts and pelvic organs, including Papanicolaou smear since estrogens have been known to produce tumors, some of them malignant, in five species of subprimate animals. 2. Endocrine and possibly liver function tests may be affected by treatment with ORTHO-NOVUM 1/50□21 or ORTHO-NOVUM 1/50□28. Therefore, if such tests are abnormal in a patient taking ORTHO-NOVUM 1/50□21 or ORTHO-NOVUM 1/50□28, it is recommended that they be repeated after the drug has been withdrawn for two months. 3. Under the influence of estrogen-progestogen preparations, pre-existing uterine fibromyomata may increase in size. 4. Because these agents may cause some degree of fluid retention, conditions which might be influenced by this factor, such as epilepsy, migraine, asthma, cardiac or renal dysfunction, require careful observation. 5. In breakthrough bleeding, and in all cases of irregular bleeding per vaginam, nonfunctional causes should be borne in mind. In undiagnosed bleeding per vaginam, adequate diagnostic measures are indicated. 6. Patients with a history of psychic depression should be carefully observed and the drug discontinued if the depression recurs to a serious degree. 7. Any possible influence of prolonged ORTHO-NOVUM 1/50□21 or ORTHO-NOVUM 1/50□28 therapy on pituitary, ovarian, adrenal, hepatic or uterine function awaits further study. 8. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. The mechanism of this decrease is obscure. For this reason, diabetic patients should be carefully observed while receiving ORTHO-NOVUM 1/50□21 or ORTHO-NOVUM 1/50□28 therapy. 9. The age of the patient constitutes no absolute limiting factor, although treatment with ORTHO-NOVUM 1/50□21 or ORTHO-NOVUM 1/50□28 may mask the onset of the climacteric. 10. The pathologist should be advised of ORTHO-NOVUM 1/50□21 or ORTHO-NOVUM 1/50□28 therapy when relevant specimens are submitted. 11. Susceptible women may experience an increase in blood pressure following administration of contraceptive steroids. 12. Cholestatic jaundice has been reported in users of oral contraceptives. If this occurs, ORTHO-NOVUM 1/50□21 or ORTHO-NOVUM 1/50□28 should be discontinued. This condition is more likely to occur in patients who have experienced cholestatic jaundice of pregnancy. Patients with a history of cholestatic jaundice of pregnancy should be carefully observed during ORTHO-NOVUM 1/50□21 or ORTHO-NOVUM 1/50□28 therapy.

Adverse reactions observed in patients receiving oral contraceptives: A statistically significant association has been demonstrated between use of oral contraceptives and the following serious adverse reactions: thrombophlebitis, pulmonary embolism, cerebral thrombosis and hemorrhage, myocardial infarction, gallbladder disease.

Although available evidence is suggestive of an association, such a relationship has been neither confirmed nor refuted for the following serious adverse reactions: neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis; hepatic lesions with or without intra-abdominal bleeding.

The following adverse reactions are known to occur in patients receiving oral contraceptives: nausea, vomiting, gastrointestinal symptoms (such as abdominal cramps and bloating), breakthrough bleeding, spotting, change in menstrual flow, amenorrhea during and after treatment, edema, chloasma or melasma, which may persist, cholestatic jaundice, migraine, rash (allergic), mental depression, change in weight (increase or decrease), breast changes (tenderness, enlargement and secretion), changes in cervical erosion and cervical secretions, suppression of lactation when given immediately post-partum, rise in blood pressure in susceptible individuals.

Although the following adverse reactions have been reported in users of oral contraceptives, an association has been neither confirmed nor refuted: anovulation post-treatment, which tends to occur more frequently in women with a history of menstrual disorders, premenstrual-like syndrome, changes in libido, changes in appetite, cystitis-like syndrome, headache, intolerance to contact lenses, nervousness, dizziness, fatigue, backache, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruptions, itching, vaginitis.

The following laboratory results may be altered by the use of oral contraceptives: hepatic function—increased sulfobromophthalein retention and other tests; coagulation tests—increase in prothrombin, Factors VII, VIII, IX and X; decrease in anti-thrombin III; increase in platelet aggregability; thyroid function—increase in PBI, and butanol-extractable protein-bound iodine and decrease in T^3 uptake values; metyrapone test; pregnanediol determination.

Case of vesico-vaginal fistula, successfully treated by an operation

GEORGE HAYWARD
American Journal of Medical Sciences, vol. 24, pp. 283-288, 1839

250 Hayward's *Case of Vesico-vaginal Fistula.*

some degree of morbid sensibility in the lining membrane of the vagina, so that an examination was quite painful.

I told her that an operation for the difficulty had been several times successful; that it had more frequently failed, and that in a few instances it had been followed by very serious consequences. At the same time, I regarded her case on the whole as a favourable one, and if, after this explanation, she wished for an operation, I would cheerfully undertake it. She at once consented, and it was fixed for the next day but one, May 10th, 1839, when it was performed in the following manner, in the presence of my friends Drs. Channing, C. G. Putnam and J. B. S. Jackson.

The patient was placed on the edge of a table, in the same position as in the operation for lithotomy. The parts being well dilated, I introduced a large bougie into the urethra and carried it back as far as the fistula. In this way I was able to bring the bladder downwards and forwards, so that the opening was brought fairly into view. The bougie being then taken by an assistant, I made a rapid incision with a scalpel around the fistula about a line from its edges, and then removed the whole circumference of the orifice. As soon as the bleeding, which was slight had ceased, I dissected up the membrane of the vagina from the bladder all around the opening, to the extent of about three lines. This was done partly with the view of increasing the chance of union, by presenting a larger surface, and partly to prevent the necessity of carrying the needles through the bladder. I then introduced a needle, about a third of an inch from the edge of the wound, through the membrane of the vagina and the cellular membrane beneath and brought it out at the opposite side at about an equal distance. Before the needle was drawn through, a second and a third were introduced in the same way, and there being found sufficient to close the orifice, they were carried through, and the threads tightly tied. Each thread was left about three inches in length. I should have remarked, that I found no difficulty in introducing the needles by the hand, the fistulous opening having been brought so low down and so fairly in view.

A short silver catheter constructed for the purpose was then introduced into the bladder, and the patient was conveyed to the bed and laid on her right side, to prevent any urine from coming in contact with the wound. I found her in the evening, eight hours after the operation, quite comfortable. She had had some smarting for two or three hours; but this was soon gone; she complained a little of the catheter; all the water flowed through it and was received upon cloths. She was directed to live on thin arrow root, milk and water and a solution of gum arabic.

In the morning I removed the catheter, lest it might become obstructed, and after cleansing replaced it. No water had escaped through the wound. The patient had slept some in the night; her pain had been slight and all her sufferings she referred to the instrument. Her pulse was good and she

The first report of successful closure of vesicovaginal fistula in America. Although the case of John P. Mettauer occurred the previous year (1838), it was not reported until the following year (Boston Med. Surg. J. 22: 154, 1840). In a later article, Hayward observed, regarding this first case, "I had never seen the operation done, till I did it myself, nor could I find any description of the mode which others had adopted, that was sufficiently clear and explicit to be of much service. I had, therefore, to take such a course as I thought safe, and at the same time likely to effect the object. . . ." The patient, age 34, had developed the fistula following delivery of her first child 15 years previously. Subsequently, she aborted 11 times. Hayward, Professor of Surgery at Harvard University and surgeon at the Massachusetts General Hospital, used a whalebone bougie inserted through the urethra to bring the fistulous opening into view, excised the cicatrix around the opening, widely dissected the bladder from the vagina, and closed the opening with three silk threads through the outer wall of the bladder (see left). A silver retention catheter was left in place for one week. Hayward concluded, "I have ventured to make these suggestions, which I do with great diffidence, with regard to the mode of operating, because there is no case in surgery in which a successful operation gives more complete relief . . . or relieves a greater amount of wretchedness, and because it is by no means settled what is the best mode of treating this distressing infirmity." In all, Hayward operated on nine patients (Boston Med. Surg. J. 44: 209, 1851). In three patients the results were entirely successful; four gained considerable relief but still had some incontinence, and two received no benefit.

CURRENT DEVELOPMENTS

Developments in mammography

JOHN N. WOLFE, M.D.

Detroit, Michigan

Mammography is presented for the primarily nonradiologic audience. A brief historical review calls attention to some of the milestones in mammography and how it has changed. Xeroradiography is discussed, as it is one of the newer developments and is rapidly gaining broad acceptance in the United States. Clinical applications are included, with a discussion of the various entities which the radiologist can identify on the mammogram. Although the mammographic examination can be extremely accurate in the hands of interested examiners, some carcinomas will not be identified; of these, some can be discovered by routine physical examination. If mammography is made to stand alone, without a physical examination, some women with breast cancer will not be identified and will not receive prompt, adequate treatment. Mammography is an adjunct and a complement to the physical examination. Breast cancer screening appears to be effective in finding small, nonpalpable tumors, many very early in their growth. Definitive evidence is now available that early diagnosis of breast cancer leads to prolonged survival. There is promise of further developments in the field of mammography.

RADIOGRAPHIC examination of the breast, or mammography, has a long history and one could characterize that history by dividing it into segments. The first part would be the era of early experimentation, which took place during the 1930's. The next era was one of limited clinical application of mammography and this lasted until the late 1950's. Beginning in the late 1950's and extending until the present time there has been an accelerated acceptance and utilization of this diagnostic examination for breast cancer detection. The present era is one of widespread application on a day-to-day clinical basis, trials in large-scale screening of asymptomatic women, and a rapidly accelerating technology with a constant search for new and better methods of either carrying out the examination or interpreting the images.

From the Department of Radiology, Hutzel Hospital.

Reprint requests: John N. Wolfe, M.D., Department of Radiology, Hutzel Hospital, 432 E. Hancock Ave., Detroit, Michigan 48201.

This communication presents mammography in the following order: a brief historical review, newer developments in the technique of examination, including those being used in practice and those still experimental, breast cancer screening, and, finally, the development of criteria for assigning patients to risk categories for breast cancer.

Historical review

This historical review is very brief; it only touches on some of the highlights. Many important contributions are not listed. Before 1950 several well-known investigators were carrying out mammography as an everyday clinical examination. Notable among these were Gershon-Cohen of the United States, Willemin of France, and Leborgne of Uruguay.

In the United States, the subject did not receive much acceptance or application prior to Egan's report of work done at the M. D. Anderson Hospital in Houston. Egan reported excellent results with the use of a "new technique" embodying a soft x-ray beam with

low filtration and an extremely high-detail x-ray film. This work incited the United States Public Health Service to enter into training programs and stimulated many radiologists in the United States to begin work in this field of diagnostic radiology.

Investigators were not completely satisfied with the techniques available and a concerted search has always been carried out for a better one. One of the most significant changes concerned the utilization of a molybdenum anode x-ray tube instead of the conventional tungsten anode tube. The molybdenum tube afforded a spectrum of radiation energy which is quite different and resulted in improved contrast on the mammograms. This work was carried out by Gros and is considered a significant advance by many workers in the field.

Another innovative technique concerned xeroradiography. This technique of examining the breast by ionizing radiation was first tried in the early 1950's, but then it was more or less abandoned by the investigators and the Xerox Corporation, which manufactured the equipment.

A further development has been the acceptance by some members of the radiologic community of a combination of a relatively fast x-ray film and screen combination. This technique has the advantage of a relatively low dosage of radiant energy to the breast.

Other innovations concern the application of computer technology to the interpretation of the mammograms, whether on film or xeroradiograph, and some work has been done showing that perhaps this might be feasible. Many techniques of image enhancement have been tried and are now being developed in an attempt to extract more information from the radiographic image. Without question, newer methods of imaging will be tried and perhaps even better and more precise ones will be developed.

This author has been deeply involved in the research, development, and application of xeroradiography as a method of breast cancer detection and that subject will be treated at length.

Xeroradiography

One of the problems in breast cancer diagnosis is the "dense" or dysplastic breast. It is difficult to identify a small cancer in this type of breast by either radiographic means or physical examination. This is the type of breast in which the film mammogram often fails.

Xeroradiography, which is a photoelectric system of recording the radiographic image, has an inherent physical phenomenon called edge enhancement. Because of this phenomenon, small disparities in density, especially if they are sharp discontinuities, have an exaggerated contrast; this is why it is believed that xeroradiography succeeds more frequently in the difficult breast than do the usual film techniques. In addition, there is no doubt that calcifications are imaged better on the xeroradiograph (XR), especially in the dense breast, and this is another area where film, especially if coupled with a molybdenum anode tube, fails.

Xeroradiography is an outgrowth of the science of xerography, or the duplication of graphic material, which was discovered by Chester Carlson in 1938. In 1948 it was found that the xerographic plates would also respond to ionizing radiation and, therefore, the feasibility of applying this method to the recording of radiographic images was demonstrated.

Early attempts to apply this technique to medicine appeared to fail or, at least, were not astoundingly successful. Work began at Hutzel Hospital in 1966 on this science. Preliminary results were encouraging to many of the radiologic community concerned with breast cancer diagnosis and the Xerox Corporation reopened its research and development in this science. There followed a 4 year period of development and machine construction and today there are many xeroradiographic machines functioning throughout the United States and other parts of the world.

Xeroradiographic process

Xeroradiography is a photoelectric imaging system. The most fundamental and unique part is the xeroradiographic plate. It is a sheet of aluminum which measures about 9 by 14 inches. On the surface is coated a thin layer of selenium—an amorphous, enamel-like substance which is a photoconductor.

In brief, a voltage is placed on the selenium surface and the part to be examined is x-rayed. Where x-rays strike the selenium, photoconduction is produced, causing the differential dissipation of the voltage previously placed on the plate in amounts proportional to the absorption of the x-ray.

By means of photoconduction, a latent electrostatic image is created on the plate's surface. This is made visible by conventional xerographic development: a cloud of finely divided, blue plastic particles is brought into proximity to the plate's surface in a dark enclosure. The particles have an electrostatic charge and they form a powder image on the plate's surface. The powder image is then transferred to a sheet of paper, again in the conventional xerographic manner, and that image, permanently fused on the paper, is available to the radiologist for interpretation.

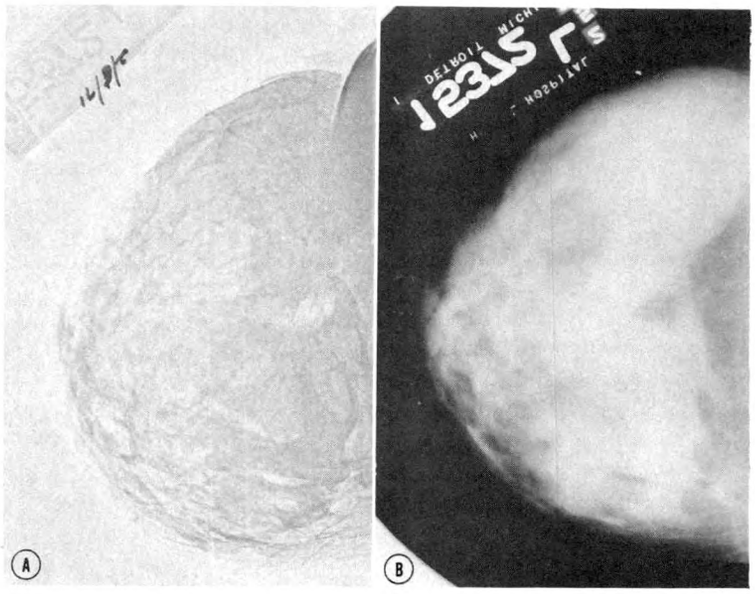

Fig. 1. *(A)* Caudal projection of the breast of a 35-year-old woman involved severely with mammary dysplasia by xeroradiography. *(B)* Caudal projection of the same breast utilizing film mammography. Note how much more detail is visible on the xeroradiograph as compared to the conventional film mammogram.

The images obtained by xeroradiography are believed to have some distinct advantages over film mammography; there is very good resolution. One of the important diagnostic features of breast carcinoma is microcalcifications and there is evidence to support the fact that microcalcifications are more readily identified on the XR image than on the conventional film image. Another advantage of xeroradiography is the wide latitude of structures recorded on one image. That is to say, the nipple and skin and deep structures within the breast are recorded in such a manner that it is easy for the radiologist to extract information. Film does not exhibit this wide latitude.

The edge enhancement enables the XR to "break up" dense structures within the breast into individual components (Fig. 1). This enables small architectural changes, such as spicules around the margin of a mass, to be more readily identified on the XR than on the conventional film. In addition, the xeroradiograph is considered to be highly accurate—more accurate in the hands of this author than conventional film techniques. The technician's work is facilitated in that a darkroom is not required and there is less chance for error in selection of radiographic techniques.

Technique of examination

The technique of examination of the breast radiographically is fairly standard, whether one utilizes xeroradiography or a film system. Physically, the women is examined in two projections at right angles to each other. With conventional radiographic equipment, usually the lateral projection is made with the patient supine, lying on the side to be examined, and the direction of the x-ray beam is mediolateral. A second projection obtained is termed the caudal or cephalocaudal; that is made with the patient sitting, and the direction of the x-ray beam is superoinferior.

Numerous special mammographic machines have been manufactured, each of which is a little different. In some of them the patient stands for the complete examination, in others she sits for the entire examination. Most of these machines, for the lateral projection, will employ an x-ray beam the direction of which is lateromedial. This is considered by some to be disadvantageous in that neither the tail of the breast nor the axilla are routinely imaged and at times some of the deeper structures near the chest wall are not visible on this projection. Not all of the special mammographic machines have this restriction in the way the lateral must be produced. With some the lateral can be produced in the usual mediolateral beam direction, which enables the technologist to image not only the breast but a portion of the chest wall and the axilla. Needless to say, there are advocates of all types of equipment and all types of projections. The choice depends on the radiologist's experience and what he deems to be important to visualize.

The amount of radiation required for mammog-

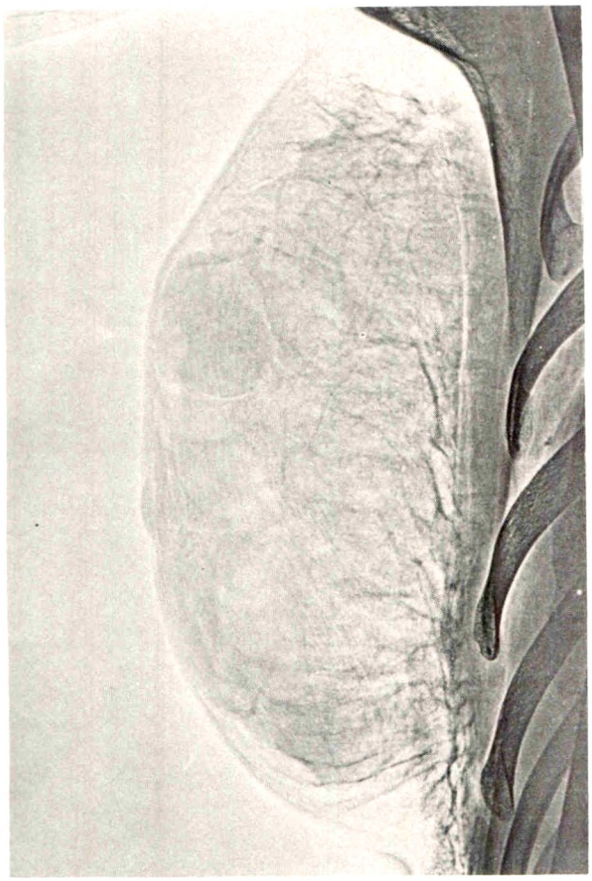

Fig. 2. Lateral projection of the breast of a 27-year-old woman with a palpable mass. The well-defined tumor, bulging the skin located superficially slightly above the level of the nipple, is considered very characteristic of a fibroadenoma.

Fig. 3. Lateral projection of a 62-year-old woman with slight thickening palpable in both breasts. The beaded appearance of the parenchyma is considered very characteristic of a prominent duct pattern.

raphy is modest and it is questioned seriously if the levels utilized in this diagnostic procedure are important as to their carcinogenic effect. To begin, there is an immeasurable dose to the abdomen and neck in our experience. The beam is always tangential to the body except in the occasional axillary view, when it is perpendicular to that area. Dosimetry at the low kVp. level utilized in mammography is difficult to obtain as opposed to dosimetry in general radiography, where higher dose levels are utilized. Therefore, there is not now a lot of confidence in the levels.

Some concept of the dose levels may be gained from the following chart:

	r/exposure
Low kVp. industrial x-ray film (Egan technique)	3-7
Molybdenum anode x-ray tube and medium-speed film	3-12
Molybdenum anode x-ray tube, single intensifying screen, and fast film	<0.75-4
Molybdenum anode x-ray tube and xeroradiography	3-5
Tungsten target x-ray tube and xeroradiography	<0.5-1

Great care must be taken in evaluating radiation dose and consequent information content of the image. In general, with radiographic images, as one diminishes the dose, the information content changes drastically. For example, one could do mammography with very fast screen-film combinations where the dose would be only a small fraction of that usually required. Unfortunately, the information is also but a portion of that obtainable by accepted techniques.

One must also be careful in evaluating data supplied by manufacturers. For example, one manufacturer may state that a system may have a resolution of 10 line pairs per millimeter, which, as a measure of resolution, is considered only acceptable. The important question is: Under what situations does this resolution exist—in

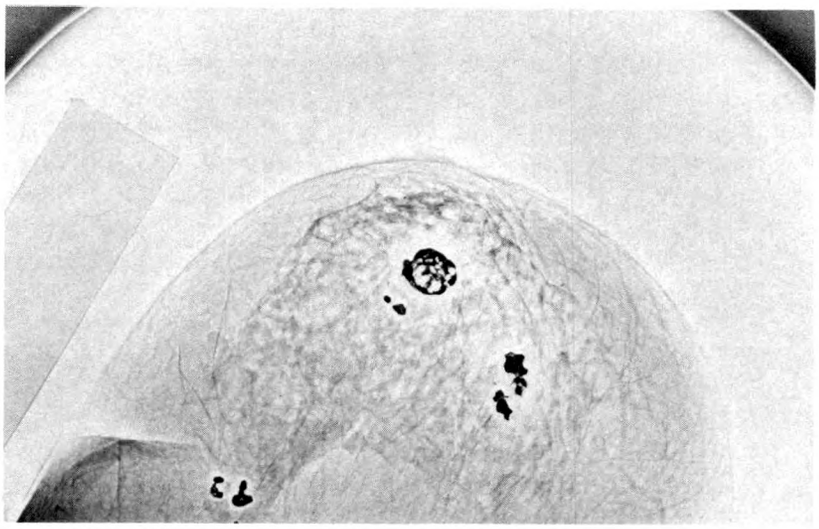

Fig. 4. Caudal projection of a 49-year-old woman with masses palpable in both breasts. The densely calcified masses within the caudal projection of this breast are very characteristic of fibroadenomas. The opposite breast contained four similar tumors.

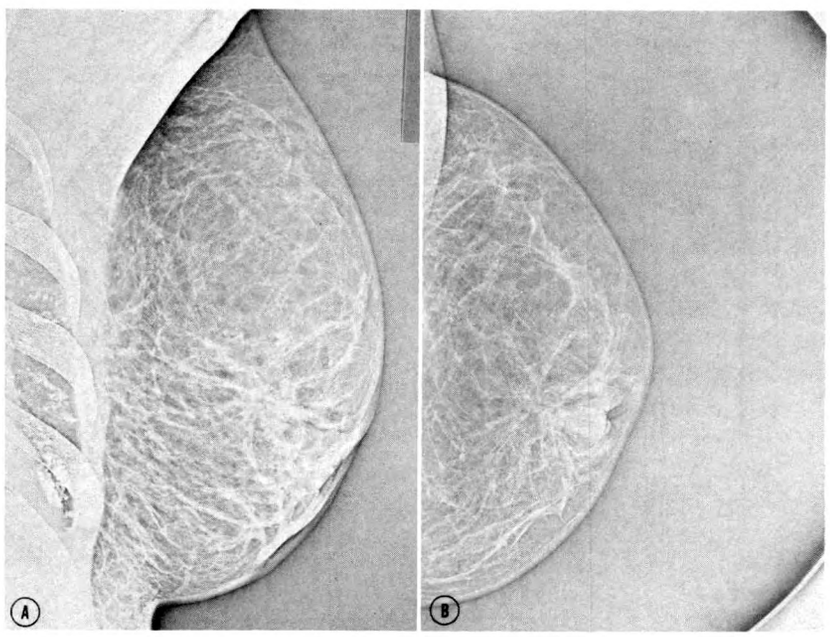

Fig. 5. Both projections of the breast of a 33-year-old woman with a history of chronic breast abscess. She has had an incision and drainage in the subareolar area several times in the past. The deformity of the parenchyma of the breast in the subareolar area is considered characteristic for scarring from a chronic breast abscess.

mammography or some artificial measuring device that bears no relationship to mammography?

The reader is requested to refer to the section on breast screening for a further discussion of dosimetry.

Clinical application

The role of mammography in the symptomatic woman is twofold: to confirm the physical findings and to contribute its own unique information. The physical and mammographic examinations of the breast must be regarded as complementary and should be considered together in decision making but, at the same time, each mode of evaluation must be strongly considered independently. Each mode can, in itself, direct the surgeon toward or away from biopsy. When these methods of examination are not utilized thus,

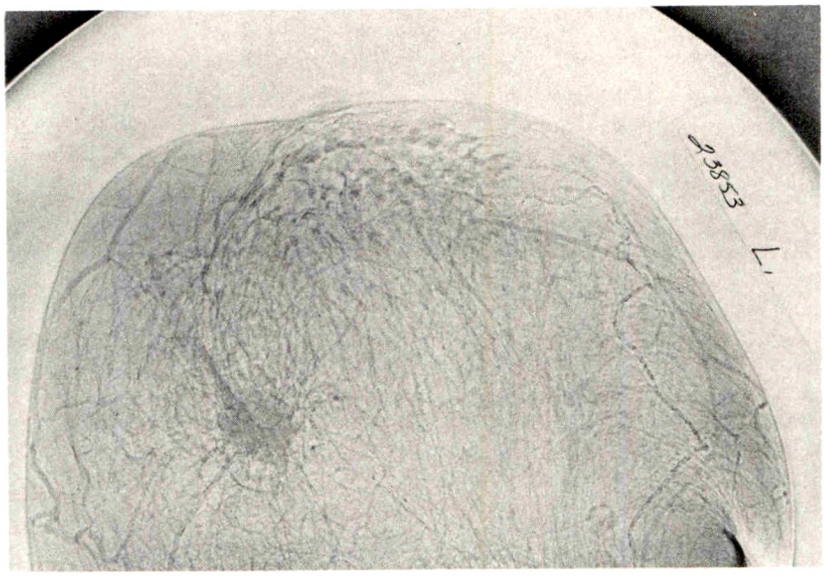

Fig. 6. Caudal projection of the left breast of a 62-year-old woman who had a palpable mass in the medial aspect. The mass with irregular margins is considered very characteristic of a scirrhous carcinoma. In the subareolar area some prominent ducts are also noted.

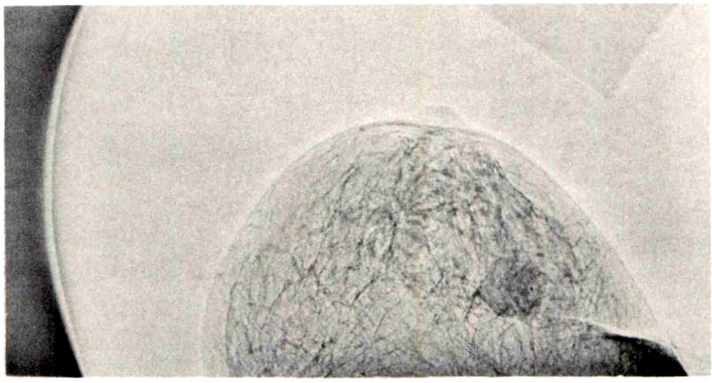

Fig. 7. Caudal projection of the breast of a 46-year-old woman with a palpable mass in the axillary portion. The poorly limited tumor is considered characteristic of a medullary carcinoma.

then certain carcinomas of the breast may suffer from late treatment.

Radiographically, the following divisions of breast conditions can be identified.

1. Normal breast
2. Benign conditions
   a. Mammary dysplasia
   b. Neoplasms
   c. Effects of stasis
   d. Effects of aging
   e. Inflammations
   f. Trauma
   g. Miscellaneous benign conditions
3. Malignancies
   a. Carcinoma
   b. Sarcoma

The normal breast is interesting to the radiologist in that the pathologist rarely tells him it exists and he uncommonly sees images which are regarded as completely normal. The usual patient in whom the radiologist will judge the breasts as normal is the multiparous one, especially if she is near the menopause and slightly obese. Even in that case, there is the risk that the pathologist will describe histologic findings of dysplasia. The very high incidence of connective tissue hyperplasia together with microcyst formation and adenosis, even in the very young girls' breasts (90 to 95 per cent), indicate the developmental nature of these "dysplasias" which one must consider as "normal" (Fig. 2).

Another very interesting observation to be made

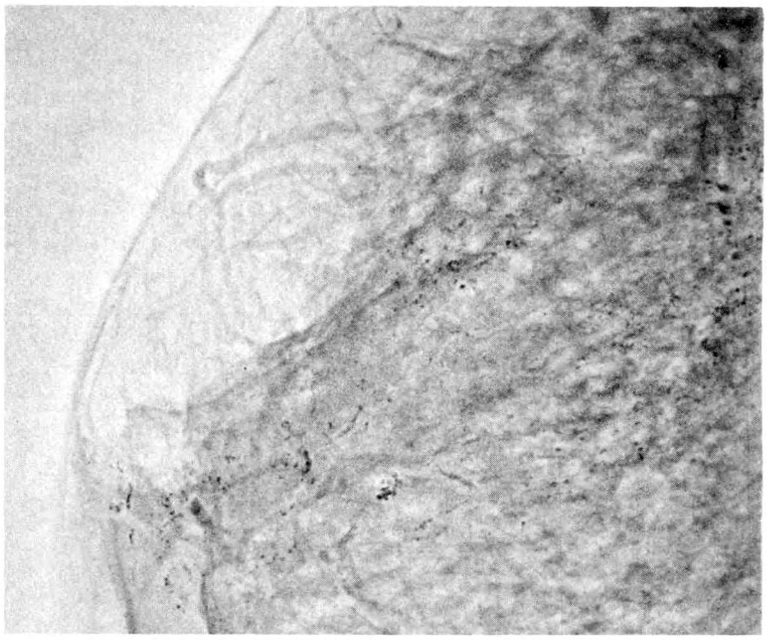

Fig. 8. Photographic enlargement from a portion of the caudal projection of the breast of a 39-year-old woman with no particular palpable abnormality other than slight thickening in both breasts. The calcific deposits are considered very characteristic for a comedocarcinoma. Note that there is widespread involvement and, in spite of the extent of the disease, the tumor was not palpable.

from the radiographic examination of the breast is periductal hyperplasia, or "prominent duct pattern," which has some association with most breast cancers and is also associated most frequently with postmenopausal, nulliparous women. Although cancer of the breast occurs in women without this gross and histologic change, the majority will exhibit radiographically and histologically varying degrees of connective tissue hyperplasia around the circumference of ducts. Indeed, in certain cases, the only radiographic evidence of some breast carcinomas will be an asymmetrical, unilateral prominence of ducts (Fig. 3). The cancer often will be too small to be observed on the mammogram. (See later section on risk factors.)

Many of the benign conditions of the breast have perfectly characteristic radiographic features. A good example is a densely calcified fibroadenoma. In the experience of thousands of these tumors, there has never been a mistake in diagnosis. They have a characteristic lobulated appearance and as myxomatous degeneration occurs they become progressively calcified. These tumors are not confused with carcinoma insofar as their radiographic appearance is concerned (Fig. 4). Some other benign conditions which can produce masses and have rather characteristic radiographic features, especially when coupled with the historical facts of the case, are inflammations of the breast and the effects of trauma (Fig. 5).

The radiographic signs of carcinoma of the breast can be divided into primary and secondary, as shown in the following tabulation.

Primary signs:
- Mass
- Tumor calcifications
- Localized prominent ducts

Secondary signs:
- Thickening of the skin and/or areola
- Retraction of the skin
- Increased vascularity

From the primary signs the radiologist often is capable of being almost 100 per cent confident that a carcinoma exists in the breast when the features are well developed. That is to say, given a mass with a spiculated border and skin retraction, it would be extremely unusual if a finding such as that does not represent a carcinoma (Fig. 6). On the other hand, the radiologist is less confident when encountering a medullary carcinoma (Fig. 7). The differential diagnosis between a medullary carcinoma and a cyst or uncalcified fibroadenoma is exceedingly difficult.

Tumor calcifications when perfectly characteristic can lead to a very firm, positive diagnosis of carcinoma.

Unfortunately, many other benign diseases of the breast also calcify and at times calcify in a manner which may simulate carcinoma. In fact, one of the problems in mammographic diagnosis is diagnosing collections of calcifications, which are in reality associated with benign disease, as being associated with a carcinoma (see Fig. 8).

Regarding secondary signs of carcinoma, skin retraction is exceedingly valuable as a secondary sign but one must be extremely careful that the skin retraction is not deformity of the skin due to previous biopsy. This problem is further complicated by the fact that carcinomas do occur at the site of previous biopsies so at times a radiologist is incapable of coming to a reasonable, accurate decision as to whether or not a particular stellate density is due to previous surgery or a carcinoma.

Another area which can be extremely valuable for identifying some advanced carcinomas is thickening of the skin (see Fig. 9). Here again, however, there are benign conditions which produce skin thickening, especially inflammatory disease. Skin can also be thickened in cases of extensive congestive failure. Areolar thickening should be approached with great caution because low-grade inflammatory diseases of the nipple and areola are exceedingly common and a change of the areolar shadow, such as thickening, is not in itself sufficient for a diagnosis of carcinoma. There is a temptation by some to overread simple areolar thickening as an indication of Paget's carcinoma of the breast. Paget's carcinoma should be accompanied, for a confident radiographic impression, by calcifications in the subareolar area, or somewhere within the breast, indicating the presence of an intraductal carcinoma. Increased vascularity of one breast is the least reliable sign of carcinoma and should be used only to focus greater attention on the breast having the increased vascularity.

A radiologist very often can be firm and decisive in his opinion, but sometimes he cannot. In cases such as that, close cooperation is needed between the radiologist and the referring physician. An example of such cases is illustrated in Fig. 10. The solitary mass, which on physical examination appears smooth and freely movable and which on radiographic examination appears homogeneous, discrete, and circumscribed, is typically a cyst, most likely, or fibroadenoma, with some slight preference being possible on the basis of the patient's age and the general appearance of the breast. These discrete tumors, however, can represent circumscribed forms of carcinoma.

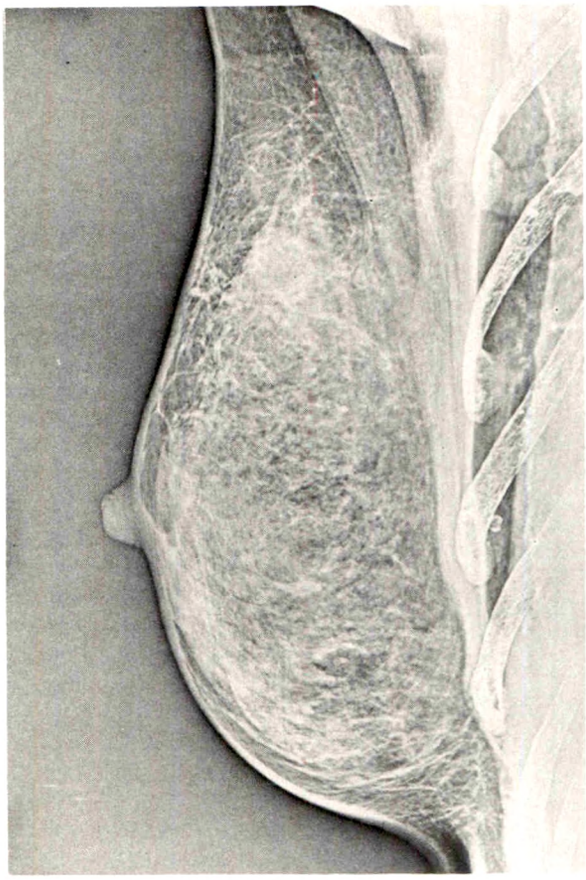

Fig. 9. Lateral projection of the breast of a 52-year-old woman with a palpable mass in the upper portion of the breast. The irregular tumor seen superior to the nipple is considered characteristic of a carcinoma. There is very early involvement of the skin, evidenced by slight thickening in the area of the tumor and, on close inspection, direct continuity between the abnormality of the skin and the tumor could be seen.

These are the sorts of masses that require close cooperation between surgeon and radiologist. Ideally, if the mass is of sufficient size, the surgeon will attempt aspiration of the contents and, if it is cystic and the fluid content is usual, the treatment of that clinical problem is simplified. If the tumor is solid, however, then one must excise it.

There are many instances when the radiologist has to call upon the physical examination for help, either to evaluate a suspected radiographic observation by a directed repeat physical examination or to permit the radiologist to re-examine the patient at short intervals to satisfy himself that an abnormality thought to be benign can be demonstrated to be static in its growth (or regressive) over varying periods of time. This is especially helpful in the case of cysts, as they fluctuate greatly over short periods of time.

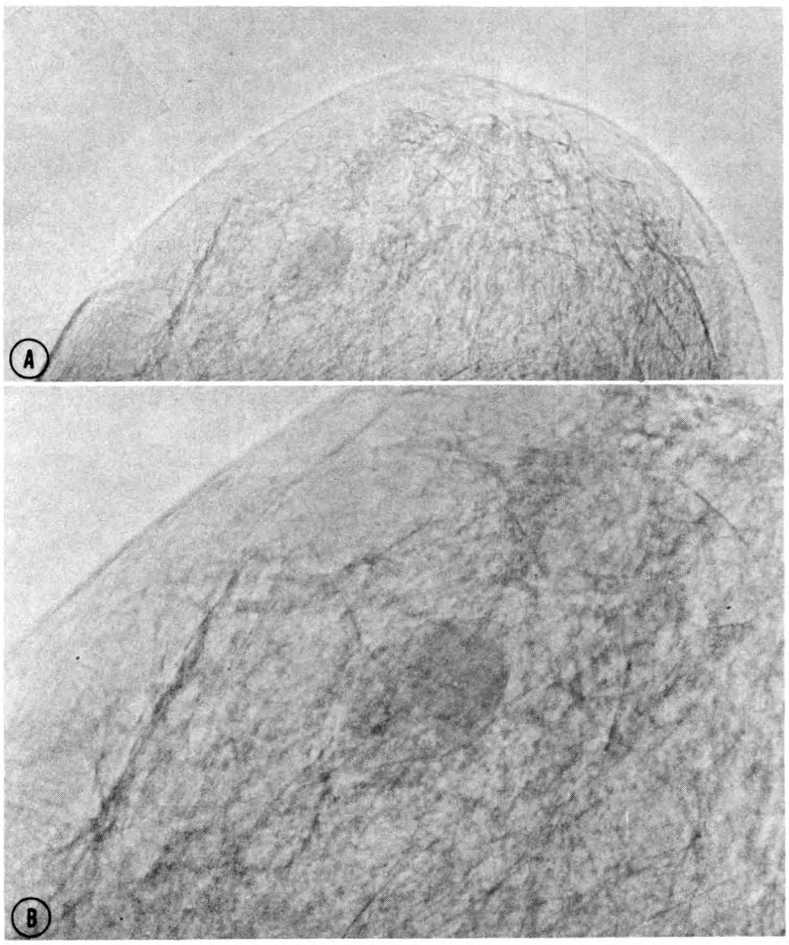

Fig. 10. *(A)* Caudal projection of the breast of a 40-year-old woman with a palpable mass in the axillary quadrant. *(B)* Photographic enlargement of the tumor. This illustrates one of the difficulties in mammography: the inability to differentiate some benign tumors from malignant ones. The tumor was interpreted as representing perhaps a circumscribed carcinoma; it is a fibroadenoma.

Results

The index of success of a mammographic technique is the number of occult carcinomas found and the size of the cancers diagnosed correctly. The over-all accuracy is variable and not a good index of the efficacy of a technique, in that it can be too strongly influenced by the type of case material. Similarly, the presence or absence of metastatic disease in axillary nodes is no longer valid as an index because the type of operative procedure varies so much from institution to institution and the zeal of the pathologist in searching for the nodes varies. It is simple to measure the area of involvement from the mammogram and tumor size relates in a large proportion of cases to stage of disease. One can also make a reasonable judgment as to whether the cancer was occult to physical examination and certainly this is an index of the worth of the procedure.

A total of 462 carcinomas of the breast were observed by xeroradiography at Hutzel Hospital during a 4 year period. These occurred in a referral-type practice which today has an incidence of carcinoma of a little less than 2 per cent of those examined. A true positive rate of 95.3 per cent was attained, while maintaining a false-positive rate of about 5 per cent. The age distribution was significant in that 35 per cent of the patients were less than 50 years of age. The tumor size was even more remarkable in that 31 per cent were judged 1.0 cm. or less.

The most interesting aspect of the analysis concerned the group of carcinomas judged "occult." Typically they were small, 59 per cent of the cases being 1.0 cm. or less in diameter, which is not surprising. Carcinomas in young women tended to be more often occult than those in older women: 30 per cent for the entire group and 43.2 per cent of cancer in

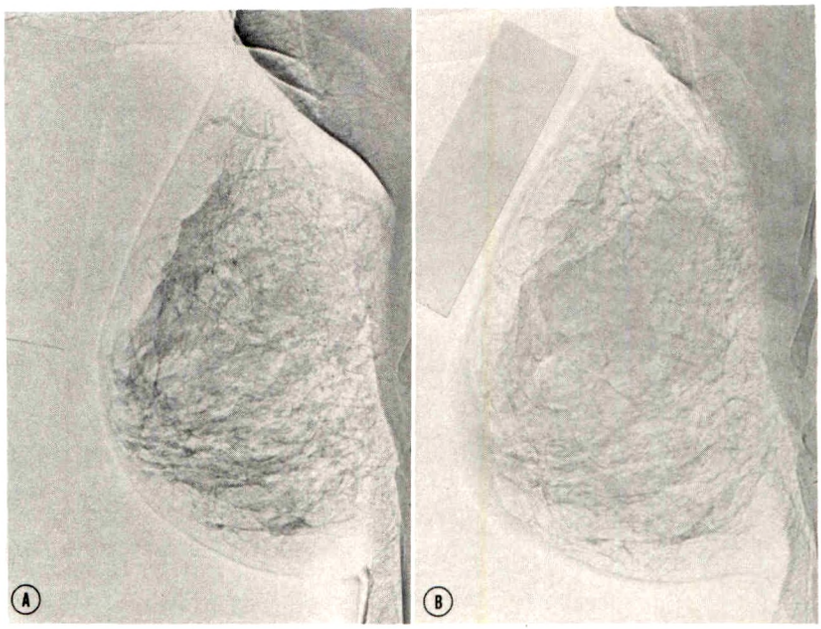

Fig. 11. *(A)* Lateral projection of the breast of a 43-year-old woman who had slight thickening palpable in the upper quadrants of both breasts. The interpretation was benign mammary dysplasia and no evidence of carcinoma. *(B)* The same patient on repeat examination 6 months later. There is now a very large carcinoma occupying an area of approximately 3 by 4 cm. with marked edema of the areola and the skin. At the time of operation, many lymph nodes were palpable.

the age group 31 to 40, vs. 18.7 per cent for women over the age of 71. The high incidence of occult cancer in young women is not too surprising when one considers that their breasts are much more difficult to examine by palpation as compared to the breasts of older, postmenopausal women.

Occult cancers, if they are represented as a mass, are typically small, some of 2 and 3 mm. being observed. These are uncommonly observed, however, in the absence of calcifications characteristic of carcinoma. Some carcinomas attain a size of 6 to 8 cm. and are still nonpalpable. Typically these are comedocarcinomas in dysplastic breasts which are still "early" in their invasive growth and have not evoked a connective tissue response within the neoplastic region.

The type of breast in which the radiologist is most likely to err in his diagnosis is the small, dense one, involved severely with connective hyperplasia either in association with cystic disease and adenosis or periductal connective tissue hyperplasia. In addition, the cancers most often "missed" are probably rapidly growing ones that do not form distinct masses or develop tumor calcifications (Fig. 11).

Breast cancer screening

At the time of this writing there are 27 Breast Cancer Screening Centers in operation throughout the United States operated conjointly by the National Institute of Health and the American Cancer Society. Mammography has demonstrated an effectiveness in discovering small tumors long before they become palpable. It has long been believed by most people that early diagnosis of a breast cancer should lead to an improved cure rate. This seems to have been settled decisively by the study conducted by the Health Insurance Plan of Greater New York, where it was found that, when a population was divided into two groups and half were screened and half were not, the mortality rate from breast cancer was greater in the nonscreened group.

It is likely that, until a better method of finding the small, early breast cancer is discovered, screening by mammography will become more and more popular and should be successful in the limited amount of the population it can be applied to.

Breast cancer screening centers may be aided greatly by the discovery of risk groups for breast cancer, so that the population then can be restricted insofar as annual examinations are concerned. To sum up this work, there is a good chance that this may occur in that two groups of patients have been identified, of which one has an incidence of developing breast carcinoma 22 times greater than the other.

Some fear that repeated screenings of the breast may produce more cancer than those that are found. The

only basis for such feeling is that several groups of patients exposed to high doses of radiation subsequently showed an increased incidence of breast cancer. The first of these were the women who were exposed to radiation during the atomic bombings in Japan; the second, groups of women who had repeated fluoroscopic examinations of the chest for pneumothorax therapy in the treatment of tuberculosis.

One must keep in mind the effect of radiation and its relationship to dose and time. For example, a high dose over a very short period of time is much more effective in terms of radiation therapy or destruction of tissue than the same amount of radiation given over a protracted period of time. This is the corollary one might apply to the relatively high doses received by women who were victims of the bombings and those who received the fluoroscopic examinations. They were high doses over a short period of time. Mammography at most is a low dose to a small volume of tissue over a very long period of time (30 years) rather than instantaneous, as in the case of the bombings, or over a 1 or 2 year period, as in the repeated fluoroscopies. In addition, and equally important, it is likely that present-day techniques in mammography, especially as practiced in the United States, deliver considerably less radiation than the dosages received in mammography as it was practiced 5 or 10 years ago.

Future developments

Mammography has changed a great deal in the last 15 years in the United States. It continues to change as more and more of the x-ray manufacturers are devoting considerable amounts of money to equipment and to new film techniques. In addition, methods of extracting information from the film, as by image enhancement techniques, are being developed. In the film industry a combination of film and intensifying screen is now available for the use of those who find it satisfactory and providing sufficient information for their needs. Xeroradiography is changing in that some newer techniques permit a dosage level reduction by about 60 per cent.

ITEMS

Fourth Annual Newborn Symposium: Major Dilemmas in Neonatal Pediatrics

On April 20 and 21, 1976, Methodist Hospital, Indianapolis, Indiana, once again will host its annual Newborn Symposium, "Major Dilemmas in Neonatal Pediatrics." Among topics to be discussed are the adoptive neonate, dilemmas of maternal-infant interaction, phototherapy hazards, and long-range follow-up of both the congenitally deformed child and the survivors of neonatal intensive care. Guest faculty will include Dr. T. Berry Brazelton (Harvard), Dr. Murray Feingold (Tufts), Dr. Gerard Odell (Johns Hopkins), Dr. Henry Seidel (Johns Hopkins), and Dr. Philip Sunshine (Stanford).

For further details, please write: Dr. Richard S. Baum, The Newborn Center, Methodist Hospital, 1604 N. Capitol Ave., Indianapolis, Indiana 46202. Telephone: (317) 924-8174.

Recent Advances in Reproductive Immunology

The Department of Obstetrics and Gynecology of the University of Iowa College of Medicine announces a postgraduate course entitled, "Recent Advances in Reproductive Immunology," to be held April 29 and 30, 1976. It will include a review of basic immunologic mechanisms as well as a survey of the latest developments in immunologic aspects of infertility, pregnancy problems, and gynecologic oncology by physicians specializing in each field. The registration fee is $125.00 (residents $75.00). For registration and information, contact: Office of Continuing Medical Education, The University of Iowa College of Medicine, 101 CMAB, Iowa City, Iowa 52242.

Symposium on Women at Work

A symposium on Women at Work will be held at the City of Hope Medical Center in Duarte, California, September 29 and 30 and October 1, 1976. The increasing number of working women and emphasis on equality of opportunity at the work site raise important questions about the risk potential to women in the occupational environment.

The conference will address itself to: (1) the current state of knowledge with respect to anatomic, physiologic, psychologic, sociologic, reproductive, legal, and legislative facets of women in the workplace; (2) important sex differences which must be analyzed; (3) the generation of recommendations for employers, labor groups, and governmental agencies with respect to health-care policies.

Those wishing to present papers should submit an abstract by March 1, 1976, to: Dr. E. R. Plunkett, City of Hope Medical Center, Section on Occupational Health, 1500 E. Duarte Rd., Duarte, California 91010.

National Foundation–March of Dimes Symposium on Inborn Errors of Metabolism

The National Foundation–March of Dimes Symposium on Inborn Errors of Metabolism will be held Wednesday, March 24, 1976, at the William Penn Hotel in Pittsburgh, Pennsylvania. Participants include Barton Childs, M.D., R. J. Desnick, Ph.D., M.D., Prof. Dr. Hans. Galjaard, William J. Mellman, M.D., Elizabeth F. Neufeld, M.D., Leon E. Rosenberg, M.D., and Harvey L. Sharp, M.D. For information or registration forms, please write or call: Mr. Robert McFarland, Greater Pittsburgh Chapter, National Foundation–March of Dimes, 1310 Fulton Bldg., Pittsburgh, Pennsylvania 15222. Telephone: (412) 391-3193.

Fourth Annual Breast-feeding Seminar for Physicians

La Leche League International is sponsoring its Fourth Annual Breast-feeding Seminar for Physicians on March 13, 1976, at the San Francisco Hilton Hotel from 9:00 A.M. to 4:30 P.M. For further information, contact: Carol Kolar, R.N., Coordinator, Continuing Medical Education, La Leche League International, Inc., 9616 Minneapolis Ave., Franklin Park, Illinois 60131. Telephone: (312) 455-7730.

Seminars for health professionals

The Women's Health Care Training Programs and Family Planning Clinic of the Department of Obstetrics and Gynecology, Harbor General Hospital, Torrance, California, is sponsoring a series of twelve seminars for nurse practitioners, registered nurses, physicians, and other health professionals. The seminars will be held January 8, February 19, March 11, April 8, May 13, June 10, July 8, August 12, September 9, October 14, November 11, and December 9, 1976. Fee: $100.00 for

all twelve seminars or $15.00 per seminar. These seminars are approved by the California Medical Association (Category 1) for up to three hours of credit in Continuing Education per seminar. The Course Chairman is J. Robert Bragonier, M.D., Ph.D. For information and registration, write to: Ms. Ellen Woolfson, Continuing Education Coordinator, Professional Staff Association, 1124 W. Carson St., Torrance, California 90502. Telephone: (213) 775-7711, extension 1373.

Gynecologic Endocrinology: A postgraduate education course for the practicing physician

The Department of Obstetrics and Gynecology at the University of Tennessee Center for the Health Sciences, Memphis, Tennessee, will sponsor a three-day postgraduate course for clinicians on "Gynecologic Endocrinology," at the Hilton Inn-Memphis Airport, March 11, 12, and 13, 1976. The diagnosis and management of the major gynecologic endocrine disorders will be discussed by 11 visiting faculty and 10 local faculty. Guest faculty include: Drs. Carl E. Cassidy, Charles Flowers, Joseph W. Goldzieher, Robert B. Greenblatt, Jerome M. Hershman, Ronald K. Kalkhoff, Janet W. McArthur, Robert L. Rosenfield, Pentti K. Siiteri, Leon Speroff, and Michael Y. Yannone. An interesting and informative program is also planned for wives, including a pilgrimage to restored antebellum homes. For furthur information and registration, contact: James R. Givens, M.D., 800 Madison Ave., Memphis, Tennessee 38163.

New nomenclature for vulvar disease

The only purpose for a uniform terminology of any group of diseases is to enable a physician to diagnose a condition utilizing a term which indicates the biological behavior of the disease and characterizes its clinical significance. Such prediction of behavior is based on the documented experience of others and will have validity and reliability in porportion to the uniformity, comparability, and volume of that documentation.

At the present time, the diagnosis of many vulvar diseases is imprecise because of lack of a standard terminology, making the available data confusing and the experience nonadditive.

Therefore, it is essential that an international language be developed and employed in all future reports and, insofar as possible, that all past publications be reviewed and reconsidered in the light of this new schema. Only by so doing can meaningful data be obtained.

Use of the new nomenclature* will permit simple and rapid grouping of cases. If a large enough number of cases in any single group show a unique pattern of biological behavior different from other cases within the same group and identifiable as such—then further subdivision of the group may be warranted.

The following terms have been deleted from the vocabulary of vulvar diseases because of the confusion associated with their use: lichen sclerosus et atrophicus, leukoplakia, neurodermatitis, leukeratosis, Bowen's disease, erythroplasia of Queyrat, carcinoma simplex, leukoplakic vulvitis, hyperplastic vulvitis, and kraurosis vulvae.

To replace these terms, the International Society for the Study of Vulvar Disease adopted the new nomenclature outlined in the following classification. This outline is not intended to be a complete discussion of the various entities but rather defines them with a new and simplified terminology.

Vulvar dystrophies. The term "dystrophy" characterizes the many disorders of epithelial growth and nutrition which result in otherwise unclassified alterations of the surface architecture. Included within the general classification of the vulvar dystrophies are those vulvar changes variously described in the past as leukoplakia, kraurosis, atrophic dystrophy, hyperplastic vulvitis, leukoplakic vulvitis, neurodermatitis, etc. The gross changes seen on the vulva may be diffuse or localized and may be seen as thickened or thinned. White or red color changes may be evident. These lesions should be specifically classified according to their microscopic features as follows:

I. Hyperplastic dystrophy
   a. Without atypia
   b. With atypia
II. Lichen sclerosus
III. Mixed dystrophy (lichen sclerosus with foci of epithelial hyperplasia)
   a. Without atypia
   b. With atypia

Vulvar atypia. Atypia (dysplasia, atypical hyperplasia) is further categorized as mild, moderate, or severe, depending upon the extent of the change and may exist:

a. Without dystrophy
b. With dystrophy

Paget's disease of the vulva. Paget's disease of the vulva should be recognized as a distinct clinicopathologic entity with a pathognomonic histologic appearance. Cases of Paget's disease of the vulva should not be considered together with squamous cell carcinoma in situ, since the biological behavior and significance of these two diseases are distinctly different.

Squamous cell carcinoma in situ. Carcinoma in situ may present clinically at any age as papules or macules, coalescent or discrete, single or multiple. Such lesions

*Proposed and adopted by the International Society for the Study of Vulvar Disease at the Second International Congress, January 10, 1975, Key Biscayne, Florida.

may be hyperpigmented (dark), lichenified and hyperkeratotic (white), eczematoid and scaly (pink), or erythroplastic (red), depending on their location (mucous or cutaneous surface) and prior treatment, as well as local hygiene. These varieties of clinical appearance do not warrant the separate titles and subdivisions applied in the past (Bowen's disease, erythroplasia of Queyrat, carcinoma simplex).

Histopathologic definitions.

Dystrophy.

I. Hyperplastic dystrophy

a. Without atypia—epithelial hyperplasia is present. There is acanthosis with elongation of the epithelial folds which may also exhibit blunting and slight edema. Varying degrees of hyperkeratosis are present. Chronic inflammation within the dermis will vary from mild to severe. No atypia is present.

b. With atypia—mild, moderate, or severe. (See definitions of atypia.)

II. Lichen sclerosus

There are variable degrees of thinning of the squamous epithelium with progressive loss of the epithelial folds (rete ridges). Vacuoles may be noted in the basal layer of cells. The dermis just beneath the squamous epithelium has a characteristic acellular, homogeneous appearance. Edema may be present in this area. Deep to the homogeneous zone, infiltration with lymphocytes and plasma cells may vary from mild to severe. Hyperkeratosis may be present.

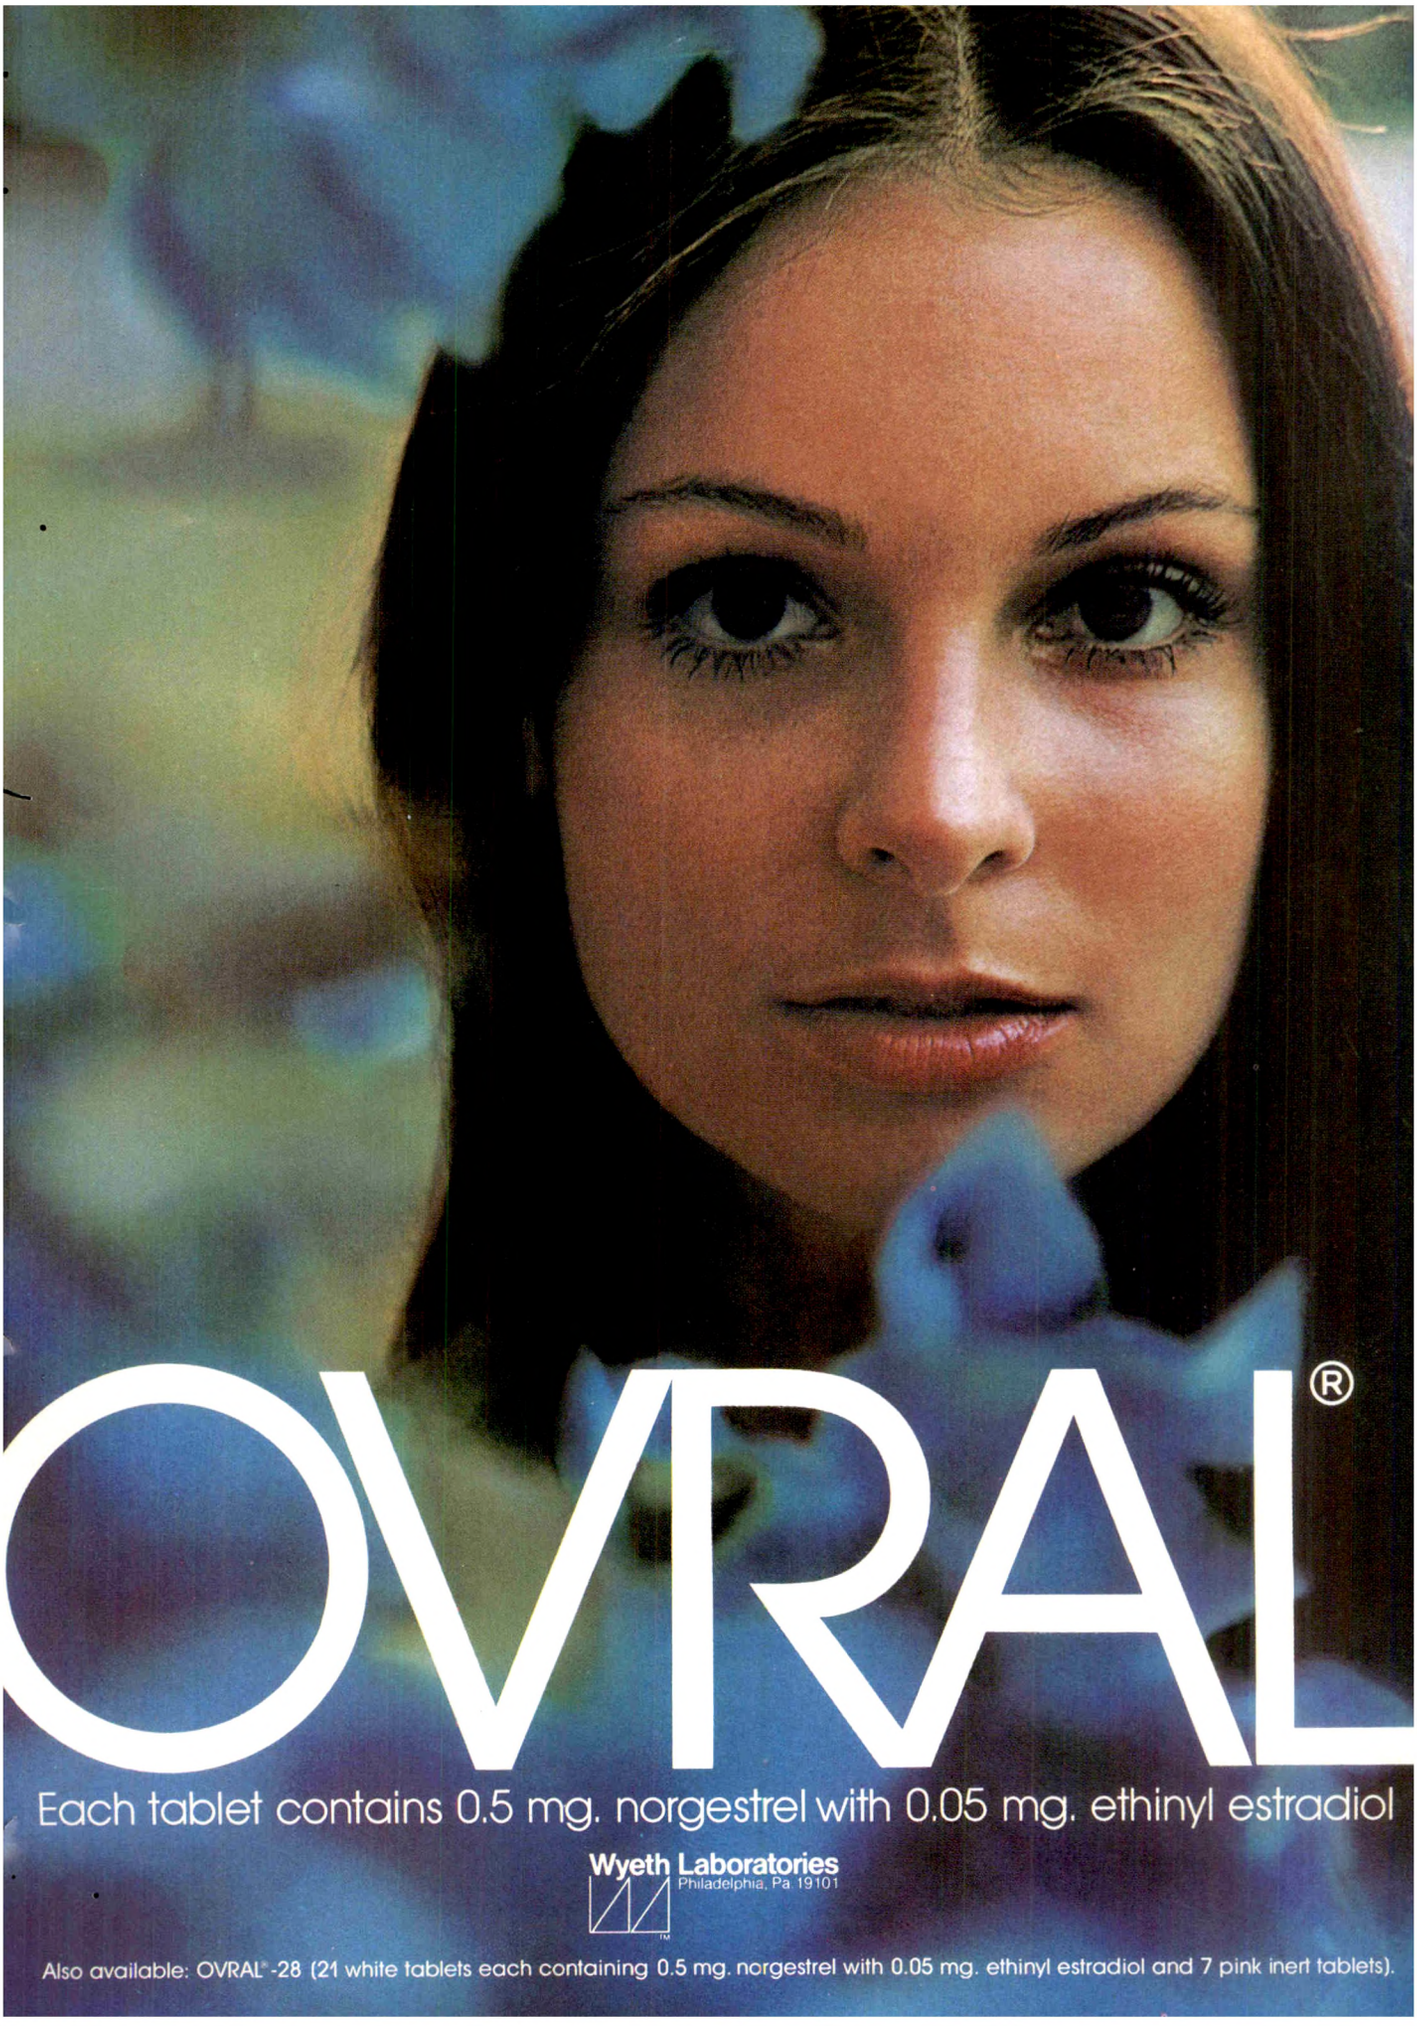
III. Mixed dystrophy

a. Without atypia—the mixed dystrophy consists of changes consistent with those of lichen sclerosus but with areas of epithelial hyperplasia as described under "Hyperplastic dystrophy" above.

b. With atypia—mild, moderate, or severe. (See definitions of atypia.)

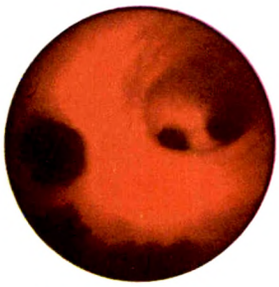
Atypia.

MILD ATYPIA. There is an excessive proliferation of squamous cells, some of which contain nuclei that are enlarged and hyperchromatic and show fine chromatin clumping. The cytoplasm around the nuclei shows a normal maturation process so that as the surface is approached the nuclei become more widely separated from one another. Individually keratinized cells and mitotic figures above the basal layer are rare.



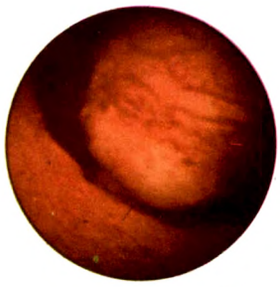
MODERATE ATYPIA. A moderate number of enlarged nuclei are seen which are hyperchromatic and irregular with fine to moderately coarse chromatin clumping. There is partial cytoplasmic maturation of the cells so that as the surface is approached the nuclei show some degree of increased separation from each other due to increased quantities of cytoplasm around each nucleus. As a result of these changes, the appearance is given of increased cellularity and cellular disarray extending through approximately two thirds of the thickness of the epithelium. Individually keratinized cells and mitotic figures above the basal layer are infrequent.

SEVERE ATYPIA. A marked discrepancy in the nuclear/cytoplasmic ratio is present. Nuclei are enlarged and hyperchromatic and show chromatin clumping that may be moderately coarse and irregular. There is little maturation of the cytoplasm so that cells of the parabasal type reach almost to the surface. As they approach the surface, however, some cytoplasmic maturation is seen such that the nuclei appear to be further separated, one from the other, when compared to the deeper layers of the epithelium. The cells in the upper layers are horizontally oriented. Some pyknosis of the surface nuclei may be seen. The appearance is given of cellular atypia extending through more than two thirds of the full thickness of the epithelium with just the upper layers of the epithelium demonstrating cytoplasmic and nuclear maturation. Individually keratinized cells and mitotic figures above the basal layer are seen occasionally.



Note: Varying degrees of hyperkeratosis and parakeratosis may be seen in all grades of atypia.

Paget's disease of the vulva. The pathognomonic Paget cells are present. These are large cells which have a clear, vacuolated cytoplasm that can be shown to contain mucopolysaccharides. These characteristic cells are noted initially in the basal layers of the epidermis but later may involve the full thickness of the epithelium as well as the underlying skin adnexa.



Squamous cell carcinoma in situ. The histologic appearance of squamous cell carcinoma in situ is characterized by disorientation and a loss of epithelial architecture which extends throughout the full thickness of the epithelium (not including the most superficial layers in tissue from keratinized surfaces). Giant cells, multinucleated cells, abnormalities of the nuclear/cytoplasmic ratio, dyskeratosis, individual-cell keratinization, corps rond formation, abnormal mitoses, mitotic figures above the basal layer, and an increased density of cell population may all be seen in varying degrees. Less commonly, full-thickness change is not present but intraepithelial squamous "pearls" are present at the tips of the rete pegs, associated with loss of the normal basal cell layer.

OVRAL®
Each tablet contains 0.5 mg. norgestrel with 0.05 mg. ethinyl estradiol
Wyeth Laboratories
Philadelphia, Pa. 19101
Also available: OVRAL®-28 (21 white tablets each containing 0.5 mg. norgestrel with 0.05 mg. ethinyl estradiol and 7 pink inert tablets).

PRESCRIBING INFORMATION

HYSKON® HYSTEROSCOPY FLUID

32% (W/V) dextran 70 in dextrose

DESCRIPTION: Hyskon Hysteroscopy Fluid is a clear, viscid, sterile, non-pyrogenic solution of dextran 70 (32% W/V) in dextrose (10% W/V). Dextran 70 is that fraction of dextran, a branched polysaccharide composed of glucose units, having a weight average molecular weight of 70,000. The fluid is electrolyte-free and non-conductive. At room temperature Hyskon Hysteroscopy Fluid has a viscosity of 220 cSt.

Hyskon has a tendency to crystallize when subjected to temperature variations or when stored for long periods. If flakes of dextran are present, heat at 100°-110° C until complete dissolution is achieved.

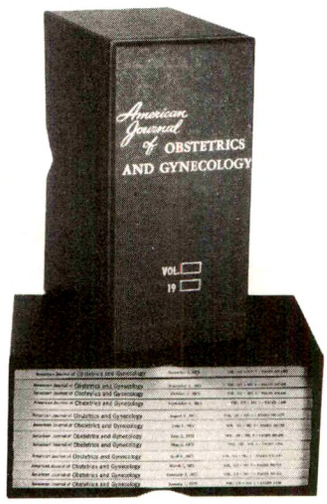
INDICATIONS: Hyskon Hysteroscopy Fluid is indicated for use with the hysteroscope as an aid in distending the uterine cavity and in irrigating and visualizing its surfaces.

CONTRAINDICATIONS: Hyskon Hysteroscopy Fluid should not be instilled in patients known to be hypersensitive to dextran. All other contraindications are those relative to the hysteroscopic procedure itself, such as pregnancy, endometrial carcinoma, etc.

WARNINGS: It is not known whether systemic absorption of dextran 70 occurs from the uterine and peritoneal cavities. Because of the possibility that absorption can occur, the physician should familiarize himself with the systemic effects of this drug. The most alarming are severe, sometimes fatal anaphylactoid reactions, which are quite rare. Other noteworthy effects include plasma volume expansion and transient prolongation of bleeding time.

ADVERSE REACTION: Undesirable effects directly attributable to the use of Hyskon Hysteroscopy Fluid have not been reported. However, the physician should be mindful of the fact that adverse reactions are known to occur with the intravenous administration of dextran 70 (MACRODEX 6% W/V). Such reactions have included: allergic phenomena (anaphylactoid reactions, urticaria, nasal congestion, wheezing, tightness of chest and mild hypotension), nausea, vomiting, fever and joint pains.

DOSAGE AND ADMINISTRATION: The amount of Hyskon Hysteroscopy Fluid required per patient depends on a number of factors, such as the type and length of the diagnostic procedure, whether or not manipulation or surgery is performed, etc. Most often, however, the amount of Hyskon instilled into the uterus will be between 50 and 100 milliliters.



Hyskon should be introduced into the uterine cavity through the cannula of a hysteroscope under low pressure (approximately 100 mm Hg) until the uterus is sufficiently distended to permit adequate visualization. During the hysteroscopic examination, Hyskon should be infused at a rate that keeps the cavity suitably distended. To avoid injection of the fluid into the tissues of the uterus and parametria and to avoid having unnecessary amounts of the fluid pass into the peritoneal cavity and backwards along the side of the hysteroscope, infusion pressures greater than 150 mm Hg should not be used.

HOW SUPPLIED: Hyskon Hysteroscopy Fluid (32% W/V dextran 70 in 10% W/V dextrose) is available as a sterile, nonpyrogenic solution in 100 ml bottles packed 12 to a carton.

PERSONALIZED LIBRARY CASES

Keep your personal copies of AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY in these specially designed library file cases. Two files hold an entire year's issues. Designed to keep your journal copies near at hand in your office, library, or home.

Your case is heavy bookbinder's board in a rich red Kivar cover. Files are scuff-resistant and washable.

Lettering is stamped in gold leaf and the cases make a fit companion for the most costly binding.

Files are reasonably priced—only $4.25 each, postpaid (3 for $12., 6 for $22.). Add $1.00 postage per case for orders outside U. S. Satisfaction unconditionally guaranteed or your money back! Use the coupon for prompt shipment.

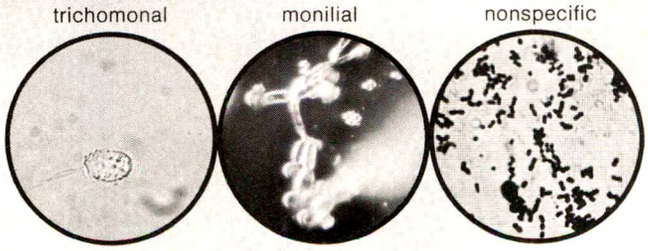
Infectious vaginitis!
monilial?
trichomonal?
nonspecific?

a microbicidal douche
for triple target therapy
of infectious vaginitis



BETADINE® douche

Infectious vaginitis often involves a mixed infection. Systemic or topical therapy directed against a single pathogen may miss or encourage another.

BETADINE DOUCHE is a broad-spectrum topical microbicide that promptly kills trichomonads, monilia and bacteria. It is active in the presence of blood, pus or vaginal secretions, and is virtually nonirritating to vaginal mucosa. Low surface tension assists penetration into vaginal crypts and crevices.

Suggested regimen for therapeutic use: In the office, swab the cervix and vulvovaginal area with BETADINE SOLUTION. Prescribe BETADINE DOUCHE: Two (2) tablespoonfuls to a quart of lukewarm water once daily, preferably before bedtime, through the entire menstrual cycle. If further therapy is warranted, douching may be continued through the next cycle. The patient may be instructed to return for an office visit following two weeks of therapy.

Directions for routine cleansing: One (1) tablespoonful to a quart of lukewarm water once or twice a week.

Supplied: 8 oz. and 1 gal. plastic bottles; 1/2 oz. packettes (6 per carton).

RETIRED, RETIRING GYNECOLOGIST

Some past experience in cytology. Part time, Southern California.

A useful, valuable retirement—can you recommend a candidate?

Write or phone Pat Kleiman, DSA Medical Group, 6440 Coldwater Canyon Avenue, North Hollywood, California, (213) 877-5336.

CHAIRMAN
DEPARTMENT OF OBSTETRICS AND GYNECOLOGY

Applications are invited for the position of Chairman of the Department of Obstetrics and Gynecology, Vanderbilt University School of Medicine.

The School of Medicine is one of several schools which comprise Vanderbilt University. The Chairman of the Department of Obstetrics and Gynecology is responsible for the development of service, educational, and research programs.

The applicant should be board certified in Obstetrics and Gynecology and should have experience in administration and teaching in an academic setting, as well as substantial experience in the clinical practice of Obstetrics and Gynecology.

Applications and nominations should be directed to:

James A. O'Neill, Jr., M.D.
Chairman, Search Committee for Chairman of Obstetrics and Gynecology
Department of Pediatric Surgery
Room T-2113
Vanderbilt University Hospital

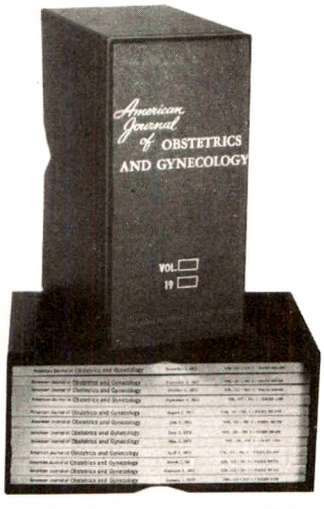
THE DEPARTMENTS OF OBSTETRICS AND GYNECOLOGY OF THE FACULTIES OF MEDICINE OF THE UNIVERSITIES OF THE PROVINCE OF QUEBEC

ANNOUNCE:



A SYMPOSIUM ON FETAL MONITORING

The Symposium will be held at the Château Frontenac in Quebec City, Canada, from Wednesday, April 21st to Saturday, April 24th 1976. The three days will be devoted to the study of recent advances in monitoring the fetal heart and uterine contraction. Internationally known experts in these fields will be giving presentations. Lectures and workshops have been organised for physicians and nurses interested in the subjects.

Official languages will be English and French with simultaneous translation available.

Registration will be closed April 1st 1976. The regular fee will be: physicians, one hundred and fifty canadian dollars ($150.00); nurses, fifty dollars ($50.00), including three breakfasts and two lunches at the Château Frontenac. For registration after April 1st, the fee will be: physicians, two hundred dollars ($200.00); nurses, seventy-five dollars ($75.00). Cheques should be made payable to: Symposium de monitorage foetal, Département d'Obstétrique-Gynécologie, Faculté de Médecine, Cité Universitaire, Québec, Canada, G1K 7P4.

For further information write to: Adrien Bastide M.D., Hôpital Saint-Francois d'Assise, 10 de l'Espinay, Québec, Canada, G1L 2H1 or call (418) 688-8710.

Breast self-examination:

KEY ROLE OF THE PHYSICIAN

item:	**Breast cancer is a major concern of American women, according to a recent Gallup study conducted for the American Cancer Society.**
item:	**Although aware that early discovery improves the chances of cure, and that BSE can lead to early discovery, *fewer than 1 in 5* women practice BSE, and *only half* have an annual breast examination by a physician.**
item:	**Only 35% of all women polled reported that a *physician* had ever raised the subject of breast self-examination, and only 24% had received instruction from the physician on how to do it. Even among women who regularly see a gynecologist, only 34% had been instructed on BSE.**
item:	***But*, among women who received personal instruction from their physicians, the overwhelming majority *(92%)* practiced BSE during the preceding year.**

The Gallup study revealed that, far more important than increasing awareness of breast self-examination, is the problem of inducing women to practice it regularly. The physician plays a key role in this—by teaching women the correct technique, and instilling in them the confidence that will assure their continued practice of BSE.

The American Cancer Society gives major emphasis to breast cancer through research and a vast array of public educational materials, designed to give women life-saving information about the disease. Our latest approach is via a pioneering television film starring Jennifer O'Neill, "Breast Cancer: Where We Are." Where we *will* be in a few years will certainly hinge on our joint efforts.

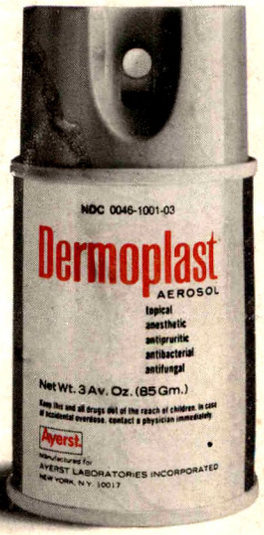
Happy homecoming for the new mother



For continued relief of postepisiotomy discomfort, send her home from the hospital with DERMOPLAST® Aerosol

What DERMOPLAST starts doing to relieve postepisiotomy discomfort in the hospital, it can keep doing at home—to help make the new mother's first days with her baby as enjoyable as they should be. DERMOPLAST permeates the suture line without affecting sutures, and relieves itching that accompanies tissue regeneration and hair regrowth.

It will not dry or macerate the skin, and is easily removed with soap and water. DERMOPLAST is easy to apply—sprays from any angle. Available in three sizes, including convenient 3-oz. size that is especially designed for self-administration by the patient.

DERMOPLAST Aerosol Spray contains: Benzocaine, w/w 4.5%; benzethonium chloride, w/w 0.1%; menthol, w/w 0.5%; oxyquinoline benzoate, w/w 1.2%; and methylparaben, w/w 2.0%. Inactive ingredients, vegetable oils and propellant. Also contains 1.9% isopropyl alcohol.

For additional indications, full directions for use, and warnings, see label copy on DERMOPLAST Aerosol Spray can.

For her private world...

She's a well-balanced, healthy young woman with an uncomplicated life-style. You've gained her confidence ...she wants the pill. Start her on Demulen. Low in estrogen (only 50 mcg.). It might well be the pill she'll start with and stay with. It's from Searle, where "the Pill" began.

Low-Dose Demulen®

ethynodiol diacetate 1 mg.
ethinyl estradiol 50 mcg.

See next page for brief summary of prescribing information.

SEARLE

Actions—Demulen®acts to prevent ovulation by inhibiting the output of gonadotropins from the pituitary gland. Demulen depresses the output of both the follicle-stimulating hormone (FSH) and the luteinizing hormone (LH).

Special note—Oral contraceptives have been marketed in the United States since 1960. Reported pregnancy rates vary from product to product. The effectiveness of the sequential products appears to be somewhat lower than that of the combination products. Both types provide almost completely effective contraception.

An increased risk of thrombotic, thromboembolic and cerebral vascular disease associated with the use of hormonal contraceptives has been shown in studies conducted in both Great Britain and the United States. British studies have shown an increased risk of myocardial infarction. Other risks, such as those of elevated blood pressure and reduced tolerance to carbohydrates, have been reported and appropriate tests should be conducted to monitor these during oral contraceptive therapy. Liver disease has also been reported, and the physician should be alert to its earliest manifestations.

Long-term administration of both natural and synthetic estrogens in subprimate animal species in multiples of the human dose increases the frequency of some animal carcinomas. These data cannot be transposed directly to man. The possible carcinogenicity due to the estrogens can be neither affirmed nor refuted at this time. Close clinical surveillance of all women taking oral contraceptives must be continued.

Indication—Demulen is indicated for oral contraception.

Contraindications—Patients with thrombophlebitis, thromboembolic disorders, cerebral vascular disease, myocardial infarction or coronary thrombosis, or a past history of these conditions, markedly impaired liver function, known or suspected carcinoma of the breast, known or suspected estrogen-dependent neoplasia, undiagnosed abnormal genital bleeding and known or suspected pregnancy.

Warnings—The physician should be alert to the earliest manifestations of thrombotic and thromboembolic disorders, thrombophlebitis, cerebrovascular disorders including hemorrhage, pulmonary embolism, retinal thrombosis, myocardial infarction or coronary thrombosis. Should any of these occur or be suspected, the drug should be discontinued immediately.

Retrospective studies of morbidity and mortality in Great Britain and studies of morbidity in the United States have shown a statistically significant association between thrombophlebitis, pulmonary embolism and cerebral vascular disease, occlusive or hemorrhagic, and the use of oral contraceptives. There have been three principal studies in Great Britain[1-3] leading to these conclusions and three[4-7] in this country. The estimate of the relative risk of thromboembolism in the study by Vessey and Doll[3] was about sevenfold, while studies in the United States found relative risks of 4.4 to 11, meaning that the users are several times as likely to undergo thromboembolic disease without evident cause as nonusers.

In one British study[8] it was estimated that users of oral contraceptives are 3 to 6 times more likely than nonusers to develop nonfatal myocardial infarction. In another British study[9] it was estimated that users of oral contraceptives between the ages of 40 and 44 were 4 to 5 times more likely to have fatal myocardial infarction than nonusers. Below the age of 40 the relative risk was estimated to be 2 to 3 times as high for users as for nonusers of oral contraceptives. The annual estimated aggregate rate of fatal plus nonfatal myocardial infarction in the 30- to 39-year age group is 4 per 100,000 in nonusers and 11 per 100,000 in users. In the 40- to 44-year age group the aggregate rates are about 22 per 100,000 and 112 per 100,000, respectively. (These estimates are based on British vital statistics, which show acute myocardial infarction death rates 2 to 3 times less than in the U.S. for women in these age groups.) The reports indicate that women with additional risk factors (hypertension, hypercholesterolemia, diabetes, cigarette-smoking, etc.) have a greater risk than the average.

In May 1974 the Royal College of General Practitioners in England[10] issued an interim report of its continuing large-scale prospective study comparing a user group with a nonuser group. This study in its interim analysis states, "A statistically significant higher rate of reporting of cerebrovascular accidents in Takers is evident, but the numbers are too small to justify an estimation of the degree of risk." The study also reported a higher incidence of superficial and deep vein thrombosis in users as compared to nonusers. The Sartwell study[4] indicated that the risk did not persist after discontinuation of administration. Both the Sartwell and the Royal College studies indicated that the degree of risk was not associated with duration of treatment. In a collaborative American study[5,6] of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the relative risk of thrombotic stroke was 4.1 to 9.5 times greater in users than in nonusers. A comparable estimate for hemorrhagic stroke was 2.0. None of the American studies was designed to evaluate a difference between products. However, the Sartwell study suggested that there might be an increased risk of thromboembolic disease in users of sequential products. Other retrospective studies[11,12] have reported an increased risk of postsurgery thromboembolic complications in oral contraceptive users. It has been recommended that therapy be discontinued at least one month prior to elective surgery.

Discontinue medication if there is gradual or sudden partial or complete loss of vision; proptosis or diplopia; onset or aggravation of migraine or development of headache of a new pattern which is recurrent, persistent or severe; papilledema; or any evidence of retinal vascular lesions.

Fetal abnormalities have been reported to occur in the offspring of women who have taken progestogens and/or estrogens during pregnancy.[13-15] The safety of Demulen in pregnancy has not been demonstrated. Pregnancy should be ruled out before initiating or continuing the contraceptive regimen. Pregnancy should always be considered if withdrawal bleeding does not occur.

A small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The long-range effect on the nursing infant cannot be determined at this time.

Hepatic lesions (adenomas, hepatomas, hamartomas, regenerating nodules, etc.), occasionally fatal, have been reported in women on oral contraceptives. Such lesions may present as an abdominal mass or with the signs and symptoms of an acute abdomen. These lesions should be considered if the patient has abdominal pain or evidence of intra-abdominal bleeding. This has been reported in short-term as well as long-term users of oral contraceptives.

Precautions—A thorough history and physical examination should be performed before prescribing oral contraceptives and periodically during their administration and should include special reference to breasts and pelvic organs, including Papanicolaou smears since estrogens have been known to produce tumors, some of them malignant, in five species of subprimate animals. Endocrine and liver function tests may be affected by treatment with Demulen. Therefore, if such tests are abnormal in a patient taking Demulen, it is recommended that they be repeated after the drug has been withdrawn for two months. Under the influence of progestogen-estrogen preparations, preexisting uterine fibromyomas may increase in size. Because these agents may cause some degree of fluid retention, conditions which might be influenced by this factor, such as epilepsy, migraine, asthma, cardiac or renal dysfunction, require careful observation. In breakthrough bleeding, and in all cases of irregular bleeding per vaginam, nonfunctional causes should be borne in mind. In undiagnosed bleeding per vaginam, adequate diagnostic measures are indicated. Patients with a history of psychic depression should be carefully observed and the drug discontinued if the depression recurs to a serious degree. Any possible influence of prolonged Demulen therapy on pituitary, ovarian, adrenal, hepatic or uterine function awaits further study. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. The mechanism of this decrease is obscure. For this reason, diabetic patients should be carefully observed while receiving Demulen therapy. The age of the patient constitutes no absolute limiting factor, although treatment with Demulen may mask the onset of the climacteric. The pathologist should be advised of Demulen therapy when relevant specimens are submitted. Susceptible women may experience an increase in blood pressure following administration of contraceptive steroids. Cholestatic jaundice has been reported in users of oral contraceptives. If this occurs Demulen should be discontinued. This condition is more likely to occur in patients who have experienced cholestatic jaundice of pregnancy. Patients with a history of cholestatic jaundice of pregnancy should be carefully observed during Demulen therapy.

Adverse reactions observed in patients receiving oral contraceptives—A statistically significant association has been demonstrated between use of oral contraceptives and the following serious adverse reactions: thrombophlebitis, pulmonary embolism, cerebral thrombosis and hemorrhage, myocardial infarction and coronary thrombosis, and gallbladder disease.

Although available evidence is suggestive of an association, such a relationship has been neither confirmed nor refuted for the following serious adverse reactions: neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis, and hepatic lesions with or without intra-abdominal bleeding.

The following adverse reactions are known to occur in patients receiving oral contraceptives: nausea, vomiting, gastrointestinal symptoms (such as abdominal cramps and bloating), breakthrough bleeding, spotting, change in menstrual flow, amenorrhea during and after treatment, edema, chloasma or melasma, which may persist, breast changes (tenderness, enlargement and secretion), change in weight (increase or decrease), changes in cervical erosion and cervical secretions, suppression of lactation when given immediately post partum, cholestatic jaundice, migraine, rash (allergic), rise in blood pressure in susceptible individuals, and mental depression.

Although the following adverse reactions have been reported in users of oral contraceptives, an association has been neither confirmed nor refuted: anovulation post treatment, which tends to occur more frequently in women with a history of menstrual disorders, premenstrual-like syndrome, changes in libido, changes in appetite, cystitis-like syndrome, headache, intolerance to contact lenses, nervousness, dizziness, fatigue, backache, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, itching and vaginitis.

The following laboratory results may be altered by the use of oral contraceptives: hepatic function: increased sulfobromophthalein retention and other tests; coagulation tests: increase in prothrombin, Factors VII, VIII, IX, and X; decrease in anti-thrombin III; increase in platelet aggregability; thyroid function: increase in PBI and butanol extractable protein bound iodine, and decrease in T_3 uptake values; metyrapone test and pregnanediol determination.

Double trouble: Acute painful cystitis

FOR THE PAIN

Early relief of painful symptoms such as burning and pain often associated with urgency and frequency.

FOR THE PATHOGENS

Effective control of susceptible pathogens such as *E. coli, Klebsiella-Aerobacter, Staph. aureus, Proteus mirabilis* and, less frequently, *Proteus vulgaris.*

Appropriate antibacterial therapy: Up to 3 days' therapy with Azo Gantrisin, 4 to 6 tablets *Stat.*, then 2 tablets *q.i.d.;* then 11 days with Gantrisin (sulfisoxazole) may be considered.

Relieve the pain while you eliminate the pathogens

Azo Gantrisin®

(0.5 Gm sulfisoxazole and 50 mg phenazopyridine HCl)

Before prescribing, please consult complete product information, a summary of which follows.

Indications: In adults, urinary tract infections complicated by pain (primarily cystitis, pyelitis and pyelonephritis) due to susceptible organisms (usually *E. coli, Klebsiella-Aerobacter, Staphylococcus aureus, Proteus mirabilis,* and, less frequently, *Proteus vulgaris*) in the absence of obstructive uropathy or foreign bodies.

Important Note: Carefully coordinate *in vitro* sulfonamide sensitivity tests with bacteriologic and clinical response. Add aminobenzoic acid to culture media for patients already taking sulfonamides. Increasing frequency of resistant organisms currently is a limitation of the usefulness of antibacterial agents including the sulfonamides. Blood levels should be measured in patients receiving sulfonamides for serious infections, since there may be wide variations with identical doses; 12 to 15 mg/100 ml is considered optimal for serious infections; 20 mg/100 ml should be the maximum total sulfonamide level, as adverse reactions occur more frequently above this level.

Contraindications: Children below age 12; sulfonamide hypersensitivity; pregnancy at term and during nursing period. Contraindicated in glomerulonephritis, severe hepatitis, uremia, and pyelonephritis of pregnancy with gastrointestinal disturbances, because of phenazopyridine HCl component.

Warnings: Safe use in pregnancy has not been established. Teratogenicity potential has not been thoroughly investigated. Deaths from hypersensitivity reactions, agranulocytosis, aplastic anemia and other blood dyscrasias have been reported; clinical signs such as sore throat, fever, pallor, purpura or jaundice may be early indications of serious blood disorders. Complete blood counts and urinalysis with careful microscopic examination should be performed frequently during sulfonamide therapy.

Precautions: Use with caution in patients with impaired renal or hepatic function, severe allergy, bronchial asthma and in glucose-6-phosphate dehydrogenase-deficient individuals. In the latter, hemolysis may occur. Maintain adequate fluid intake to prevent crystalluria and stone formation.

Adverse Reactions: *Blood dyscrasias:* Agranulocytosis, aplastic anemia, thrombocytopenia, leukopenia, hemolytic anemia, purpura, hypoprothrombinemia and methemoglobinemia. *Allergic reactions:* Erythema multiforme (Stevens-Johnson syndrome), skin eruptions, epidermal necrolysis, urticaria, serum sickness, pruritus, exfoliative dermatitis, anaphylactoid reactions, periorbital edema, conjunctival and scleral injection, photosensitization, arthralgia and allergic myocarditis. *Gastrointestinal reactions:* Nausea, emesis, abdominal pains, hepatitis, diarrhea, anorexia, pancreatitis and stomatitis. *C.N.S. reactions:* Headache, peripheral neuritis, mental depression, convulsions, ataxia, hallucinations, tinnitus, vertigo and insomnia. *Miscellaneous reactions:* Drug fever, chills, toxic nephrosis with oliguria and anuria, polyarteritis nodosa and L.E. phenomenon. Due to certain chemical similarities with some goitrogens, diuretics (acetazolamide and thiazides) and oral hypoglycemic agents, sulfonamides have caused rare instances of goiter production, diuresis and hypoglycemia. Cross-sensitivity with these agents may exist.

Dosage: Usual adult dosage for acute, painful phase of urinary tract infections is 4 to 6 tablets initially, then 2 tablets four times daily for up to 3 days. If pain persists, causes other than infection should be sought. After relief of pain has been obtained, continued treatment of the infection with Gantrisin (sulfisoxazole) may be considered.

Note: Patients should be told that the orange-red dye (phenazopyridine HCl) will color the urine soon after ingestion.

How Supplied: Tablets, each containing 0.5 Gm sulfisoxazole and 50 mg phenazopyridine HCl—bottles of 100 and 500.

Thief.

When baby takes more iron than mother can afford to give, *iron deficiency anemia of pregnancy* is a likely consequence.

Stolen iron can be replaced with a single formulation. **Tabron.**

Throughout pregnancy and the postpartum period, one Tabron tablet per day can usually fill her iron requirements. Tabron can also supply her with folic acid, a fecal softener, vitamin B_{12}, ascorbic acid, and other vitamins she's likely to need.

FILMSEAL®

Tabron®

a comprehensive hematinic... restores the iron and more

Each Tabron Filmseal represents: 304.2 mg ferrous fumarate (represents 100 mg of elemental iron); 500 mg ascorbic acid; 6 mg thiamine mononitrate; 6 mg riboflavin; 5 mg pyridoxine hydrochloride; 25 mcg cyanocobalamin, crystalline; 1 mg folic acid; 30 mg niacinamide; 10 mg calcium pantothenate; 30 I U vitamin E (*dl*-alpha tocopheryl acetate); 50 mg dioctyl sodium sulfosuccinate.

Caution: Folic acid may obscure pernicious anemia; the peripheral blood picture may revert to normal while neurological manifestations remain progressive.

KOROSTATIN
...(Nystatin Tablets U.S.P.)

Vulvovagir
Candidia

There are a lot of reasons why Korostatin is the better way to eliminate a serious problem.

- NO REFRIGERATION NEEDED...Eliminates possible loss of potency at room temperature
- EFFICACY...A proven specific
- ECONOMY...Dramatically less expensive than miconazole nitrate cream
- ADDITIONAL BENEFITS...Korostatin is nonstaining, it can be used throughout pregnancy, it is well tolerated and available in convenient 14 and 28 tablet packages, with reusable applicator.

DESCRIPTION: KOROSTATIN (Nystatin) Vaginal Tablets, U.S.P. is in an oblong shaped vaginal tablet, each containing 100,000 units of Nystatin, U.S.P. Inactive ingredients include: starch, lactose, polyvinylpyrrolidone, sorbitol and magnesium stearate.

INDICATIONS FOR USE: KOROSTATIN (Nystatin) Vaginal Tablets U.S.P. are indicated in the local treatment of vulvovaginal candidiasis.

CONTRAINDICATIONS: All Nystatin preparations are contraindicated in patients with a history of hyper-sensitivity to Nystatin.

ADVERSE REACTIONS: Nystatin, U.S.P. is virtually nontoxic and nonsensitizing and is well tolerated by all age groups, even on prolonged administration. If irritation during intravaginal use should occur, discontinue the medication.

For full prescribing information, consult package insert.

KOROSTATIN is manufactured under Holland-Rantos specifications by the American Cyanamid Company.

The causes of vaginitis are multiple

You can depend on AVC... therapy that combats major vaginal pathogens and provides rapid symptomatic relief.*

***Indications:** Based on a review of AVC by the National Academy of Sciences–National Research Council and/or other information, FDA has classified the indications as follows:

"Probably" effective: For the relief of symptoms of vulvovaginitis where isolation of the specific organism responsible (usually *Trichomonas vaginalis, Candida albicans,* or *Hemophilus vaginalis)* is not possible.

NOTE: When the offending organism is known, treatment with a specific agent known to be active against that microorganism is preferred.

"Possibly" effective: For the treatment of trichomoniasis, vulvovaginal candidiasis, and vaginitis due to *Hemophilus vaginalis* or other susceptible bacteria.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Known sensitivity to sulfonamides.

Precautions/Adverse Reactions: The usual precautions for topical and systemic sulfonamides should be observed because of the possibility of absorption. Burning, increased local discomfort, skin rash or other manifestations of sulfonamide toxicity are reasons to discontinue treatment.

Dosage: 1 applicatorful (about 6 g.) or 1 suppository intravaginally once or twice daily.

Supplied: Cream–4 ounce tube with applicator. Suppositories–Box of 16 with inserter.

Announcing

Senokot® S

(standardized senna concentrate and dioctyl sodium sulfosuccinate) **Tablets**

a unique natural laxative plus a classic stool softener

Provides a unique natural laxative—standardized senna concentrate... virtually colon-specific ...effectiveness documented in numerous published studies comprising thousands of patients.

Provides a classic stool softener—DSS... complementing the laxative action by softening the stool for smoother and easier passage.

Comfortable, predictable evacuation... a bedtime dose of SENOKOT S Tablets usually induces comfortable evacuation the next morning, allowing uninterrupted sleep. SENOKOT S Tablets aid in rehabilitation of the constipated patient by facilitating regular elimination.

Indications: SENOKOT S Tablets offer welcome relief in functional constipation when combined neuroperistaltic stimulation plus stool softening is indicated, especially for: the aged; postpartum and postoperative patients; drug-induced constipation; cardiovascular patients and those with hemorrhoids. **Dosage** (preferably at bedtime): Adults: Initial Dosage: 2 tablets (max. dose—4 tablets b.i.d.). Children (above 60 lb.): 1 tablet (max. dose—2 tablets b.i.d.). To meet individual requirements, dosage may be decreased or increased by 1 tablet (up to maximum) until the most effective dose is established. **Supplied:** Bottles of 30 and 60 tablets.

better beginnings thanks to better monitoring...

Honoring its commitment to better fetal, neonatal and maternal care, Roche Medical Electronics introduces a new fetal monitor with dramatically expanded capabilities.

The Fetasonde® 2104 is capable of continuous fetal and/or maternal monitoring throughout labor and delivery. The improved counting circuits and displays of the Fetasonde 2104 provide more meaningful data, for a broader range of patients than ever before.[1]

Only Fetasonde 2104 combines outstanding accuracy, flexibility and ease of use with these important technological advantages:

- Choice of indirect or direct fetal heart rate monitoring.
- Unique multi-crystal cloverleaf transducer.
- Ultrasonic ranging for accurate counting.
- Beat-to-beat heart rate and ECG recording for mother, fetus or neonate, for examination of short term variability patterns and arrythmias.
- Full clinical range of fetal heart rate counting in both direct and indirect modes.
- Unique credence and poor-signal verification logic, increases data reliability.
- Automatic Arteriosonde® 1216 maternal blood pressure monitoring and permanent record with the 2104.

ROCHE ... improving patient care through technology.

Roche offers reliable, high performance instruments for obstetrics, pediatrics, cardiology, surgery and intensive care. The stringent standards we apply to the development, manufacture and clinical testing of all Roche instruments assure you of providing your patients with the very best care.

For advanced application consultation, system planning, operational training or service, Roche is ready to supply immediate professional and skilled assistance.

ROCHE people and products...on call or in attendance, around the clock, seven days a week.

For more information, write for literature. Or phone your Roche Medical Electronics representative today.

In serious respiratory tract infections...*

*due to indicated susceptible organisms

Until th[illegible] start with 'ANCEF'

Serious respiratory tract infections usually require immediate treatment. In these cases, prudent medical judgment and the use of 'Ancef', when appropriate, can save valuable time while waiting for lab results. 'Ancef' offers:

• Broad coverage of major respiratory pathogens

Streptococcus pneumoniae (formerly *D. pneumoniae*), *Klebsiella* species, *Hemophilus influenzae*, *Staphylococcus aureus* (penicillin-sensitive and penicillin-resistant), and group A beta-hemolytic streptococci.

• High and prolonged serum levels

Single 1 gram IV injections in healthy adult volunteers produced average peak serum levels of 190.0 mcg/ml. At four hours, levels of 16.5 mcg/ml were still present.

• Convenient IV or IM administration at same dosage schedule

When lab tests return, if indicated organism is sensitive to 'Ancef'—and chances are it will be—therapy is already under way. If it isn't sensitive, then 'Ancef' should be discontinued and an appropriate antibiotic should be selected.

Injectable benzathine penicillin is considered the drug of choice in treatment and prevention of streptococcal infections, including prophylaxis of rheumatic fever.

Adverse Reactions

Reported adverse reactions include pain on injection, rash, G.I. symptoms, pruritus and phlebitis. For a complete list of adverse reactions, please see next page.

Warning: In penicillin-sensitive patients, cephalosporins should be used cautiously because of evidence of cross-allergenicity of the penicillins and cephalosporins.

Please see next page for a brief summary of the prescribing information.

SK&F **Smith Kline & French Laboratories**
Division of SmithKline Corporation, Philadelphia, Pa.

ANCEF® IV IM

brand of sterile

CEFAZOLIN SODIUM

(LYOPHILIZED)

Injection: 250 mg, 500 mg, and 1 gram vials

ANCEF® IV IM

brand of sterile

CEFAZOLIN SODIUM

(LYOPHILIZED)

Injection: 250 mg, 500 mg, and 1 gram vials

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

DESCRIPTION

Ancef® (sterile cefazolin sodium, SK&F) is a semi-synthetic cephalosporin for parenteral administration. It is the sodium salt of 3-{[(5-methyl-1,3,4-thiadiazol-2-yl)thio]methyl}-8-oxo-7-[2-(1H-tetrazol-1-yl) acetamido]-5-thia-1-azabicyclo[4.2.0]oct-2-ene-2-carboxylic acid. The sodium content is 46 mg. per gram of cefazolin.

ACTIONS

Microbiology: *In vitro* tests demonstrate that the bactericidal action of cephalosporins results from inhibition of cell wall synthesis. 'Ancef' is active against the following organisms *in vitro*:

Staphylococcus aureus (penicillin-sensitive and penicillin-resistant)

Group A beta-hemolytic streptococci and other strains of streptococci (many strains of enterococci are resistant).

Streptococcus pneumoniae (formerly *D. pneumoniae*)
Escherichia coli
Proteus mirabilis
Klebsiella species
Enterobacter aerogenes
Hemophilus influenzae

Most strains of *Enterobacter cloacae* and indole positive Proteus (*P. vulgaris, P. morgani, P. rettgeri*) are resistant. Methicillin-resistant staphylococci, serratia, pseudomonas, mima, herellea species are almost uniformly resistant to cefazolin.

INDICATIONS

Ancef (sterile cefazolin sodium, SK&F) is indicated in the treatment of the following serious infections due to susceptible organisms:

Respiratory tract infections due to *Streptococcus pneumoniae* (formerly *D. pneumoniae*), *Klebsiella* species, *Hemophilus influenzae*, *Staphylococcus aureus* (penicillin-sensitive and penicillin-resistant), and group A beta-hemolytic streptococci.

Injectable benzathine penicillin is considered to be the drug of choice in treatment and prevention of streptococcal infections, including the prophylaxis of rheumatic fever. 'Ancef' is effective in the eradication of streptococci from the nasopharynx; however, data establishing the efficacy of 'Ancef' in the subsequent prevention of rheumatic fever are not available at present.

Genitourinary tract infections due to *Escherichia coli, Proteus mirabilis, Klebsiella* species, and some strains of enterobacter and enterococci.

Skin and soft-tissue infections due to *Staphylococcus aureus* (penicillin-sensitive and penicillin-resistant) and group A beta-hemolytic streptococci and other strains of streptococci.

Bone and joint infections due to *Staphylococcus aureus*.

Septicemia due to *Streptococcus pneumoniae* (formerly *D. pneumoniae*), *Staphylococcus aureus* (penicillin-sensitive and penicillin-resistant), *Proteus mirabilis, Escherichia coli*, and *Klebsiella* species.

Endocarditis due to *Staphylococcus aureus* (penicillin-sensitive and penicillin-resistant), and group A beta-hemolytic streptococci.

Appropriate culture and susceptibility studies should be performed to determine susceptibility of the causative organism to 'Ancef'.

CONTRAINDICATIONS

Ancef (sterile cefazolin sodium, SK&F) is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS

BEFORE CEFAZOLIN THERAPY IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE CONCERNING PREVIOUS HYPERSENSITIVITY REACTIONS TO CEPHALOSPORINS AND PENICILLIN. CEPHALOSPORIN C DERIVATIVES SHOULD BE GIVEN CAUTIOUSLY IN PENICILLIN-SENSITIVE PATIENTS.

SERIOUS ACUTE HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

There is some clinical and laboratory evidence of partial cross-allergenicity of the penicillins and the cephalosporins. Patients have been reported to have had severe reactions (including anaphylaxis) to both drugs.

Any patient who has demonstrated some form of allergy, particularly to drugs, should receive antibiotics cautiously. No exception should be made with regard to 'Ancef'.

Usage in Pregnancy: Safety of this product for use during pregnancy has not been established.

Usage in Infants: Safety for use in prematures and infants under 1 month of age has not been established.

PRECAUTIONS

Prolonged use of cefazolin sodium may result in the overgrowth of nonsusceptible organisms. Careful clinical observation of the patient is essential.

When 'Ancef' is administered to patients with low urinary output because of impaired renal function, lower daily dosage is required (see dosage instructions). A false positive reaction for glucose in the urine of patients on 'Ancef' has occurred with Clinitest® tablets solution.

ADVERSE REACTIONS

The following reactions have been reported.

Hypersensitivity: Drug fever, skin rash, vulvar pruritus, and eosinophilia have occurred.

Blood: Neutropenia, leukopenia, thrombocythemia and positive direct and indirect Coombs tests have occurred.

Hepatic and Renal: Transient rise in SGOT, SGPT, BUN and alkaline phosphatase levels has been observed without clinical evidence of renal or hepatic impairment.

Gastrointestinal: Nausea, anorexia, vomiting, diarrhea, oral candidiasis (oral thrush) have been reported.

Other: Pain at site of injection after intramuscular administration has occurred, some with induration. Phlebitis at site of injection has been noted.

DOSAGE AND ADMINISTRATION

'Ancef' may be administered intramuscularly or intravenously after reconstitution.

Dosage

In adults, usual dosage for pneumococcal pneumonia is 500 mg. every 12 hours. In acute, uncomplicated urinary tract infections, usual dosage is 1 gram every 12 hours. In mild infections caused by susceptible Gram positive cocci, usual dosage is 250 to 500 mg. every 8 hours. In moderate to severe infections, usual dosage is 500 mg. to 1 gram every 6 to 8 hours. 'Ancef' has been administered in dosages of 6 grams per day in serious infections such as endocarditis.

'Ancef' may be used in patients with reduced renal function with the following dosage adjustments: Patients with a creatinine clearance of 55 ml./min. or greater or a serum creatinine of 1.5 mg. % or less can be given full doses. Patients with creatinine clearance rates of 35 to 54 ml./min. or serum creatinine of 1.6 to 3.0 mg. % can also be given full doses, but dosage should be restricted to at least 8-hour intervals. Patients with creatinine clearance rates of 11 to 34 ml./min. or serum creatinine of 3.1 to 4.5 mg. % should be given 1/2 the usual dose every 12 hours. Patients with creatinine clearance rates of 10 ml./min. or less or serum creatinine of 4.6 mg. % or greater should be given 1/2 the usual dose every 18 to 24 hours. All reduced dosage recommendations apply after an initial loading dose appropriate to the severity of the infection.

In children, a total daily dosage of 25 to 50 mg. per kg. (approximately 10 to 20 mg. per pound) of body weight, divided into three or four equal doses, is effective for most mild to moderately severe infections. Total daily dosage may be increased to 100 mg. per kg. (45 mg. per pound) of body weight for severe infections. Since safety for use in premature infants and in infants under one month has not been established, the use of 'Ancef' in these patients is not recommended.

For additional information on dosage and administration, see package literature or contact your SK&F Representative.

HOW SUPPLIED

Ancef (sterile cefazolin sodium, SK&F) – supplied in vials equivalent to 250 mg., 500 mg. or 1 gram of cefazolin; in Overfill ("piggyback") Vials for intravenous admixture equivalent to 1 gram of cefazolin; and in Pharmacy Bulk Vials equivalent to 5 grams or 10 grams of cefazolin.

Instructions to authors

Submission of contributions. Manuscripts should in general be sent to a particular Editor according to the following plan: If it is from the southeastern quadrant of the United States or from Canada, or if it has been presented before one of the official sponsoring societies, to Dr. Brewer; if from the northeastern quadrant (including Ohio), or if it is a Clinical Opinion or a Letter to the Editors, to Dr. Zuspan; if from the north central states, any of the United States west of the Mississippi, Hawaii, Alaska, or abroad, to Dr. Quilligan.

All articles published in this Journal must be contributed to it exclusively. Articles previously published in another language are not acceptable.

It is assumed by the Editors that articles emanating from a particular institution are submitted with the approval of the requisite authority, **including all matters pertaining to human studies.** Articles dealing with human experimentation cannot be accepted unless the experiment was approved by the author's local Human Experimentation Committee.

Statements and opinions expressed in the articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or publisher and the Editor(s) and publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the publisher guarantee, warrant, or endorse any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

Manuscripts. Manuscripts should be typewritten on one side of the paper only, with double spacing and liberal margins. The original and one copy of the manuscript are required. References should be placed at the end of the article and should conform to the style of the Cumulated Index Medicus, viz., name of author, article title, name of periodical, volume, page, and year. Authors are encouraged to limit references to *16, except* for Communications in Brief, limited to *2,* Current Investigation and Clinical Opinion, limited to *6,* and Current Developments for which there is *no* limit. Illustrations accompanying manuscripts should be numbered, provided with suitable legends, and marked lightly on the back with the author's name. Authors should indicate on the manuscript the approximate position of tables and text figures.

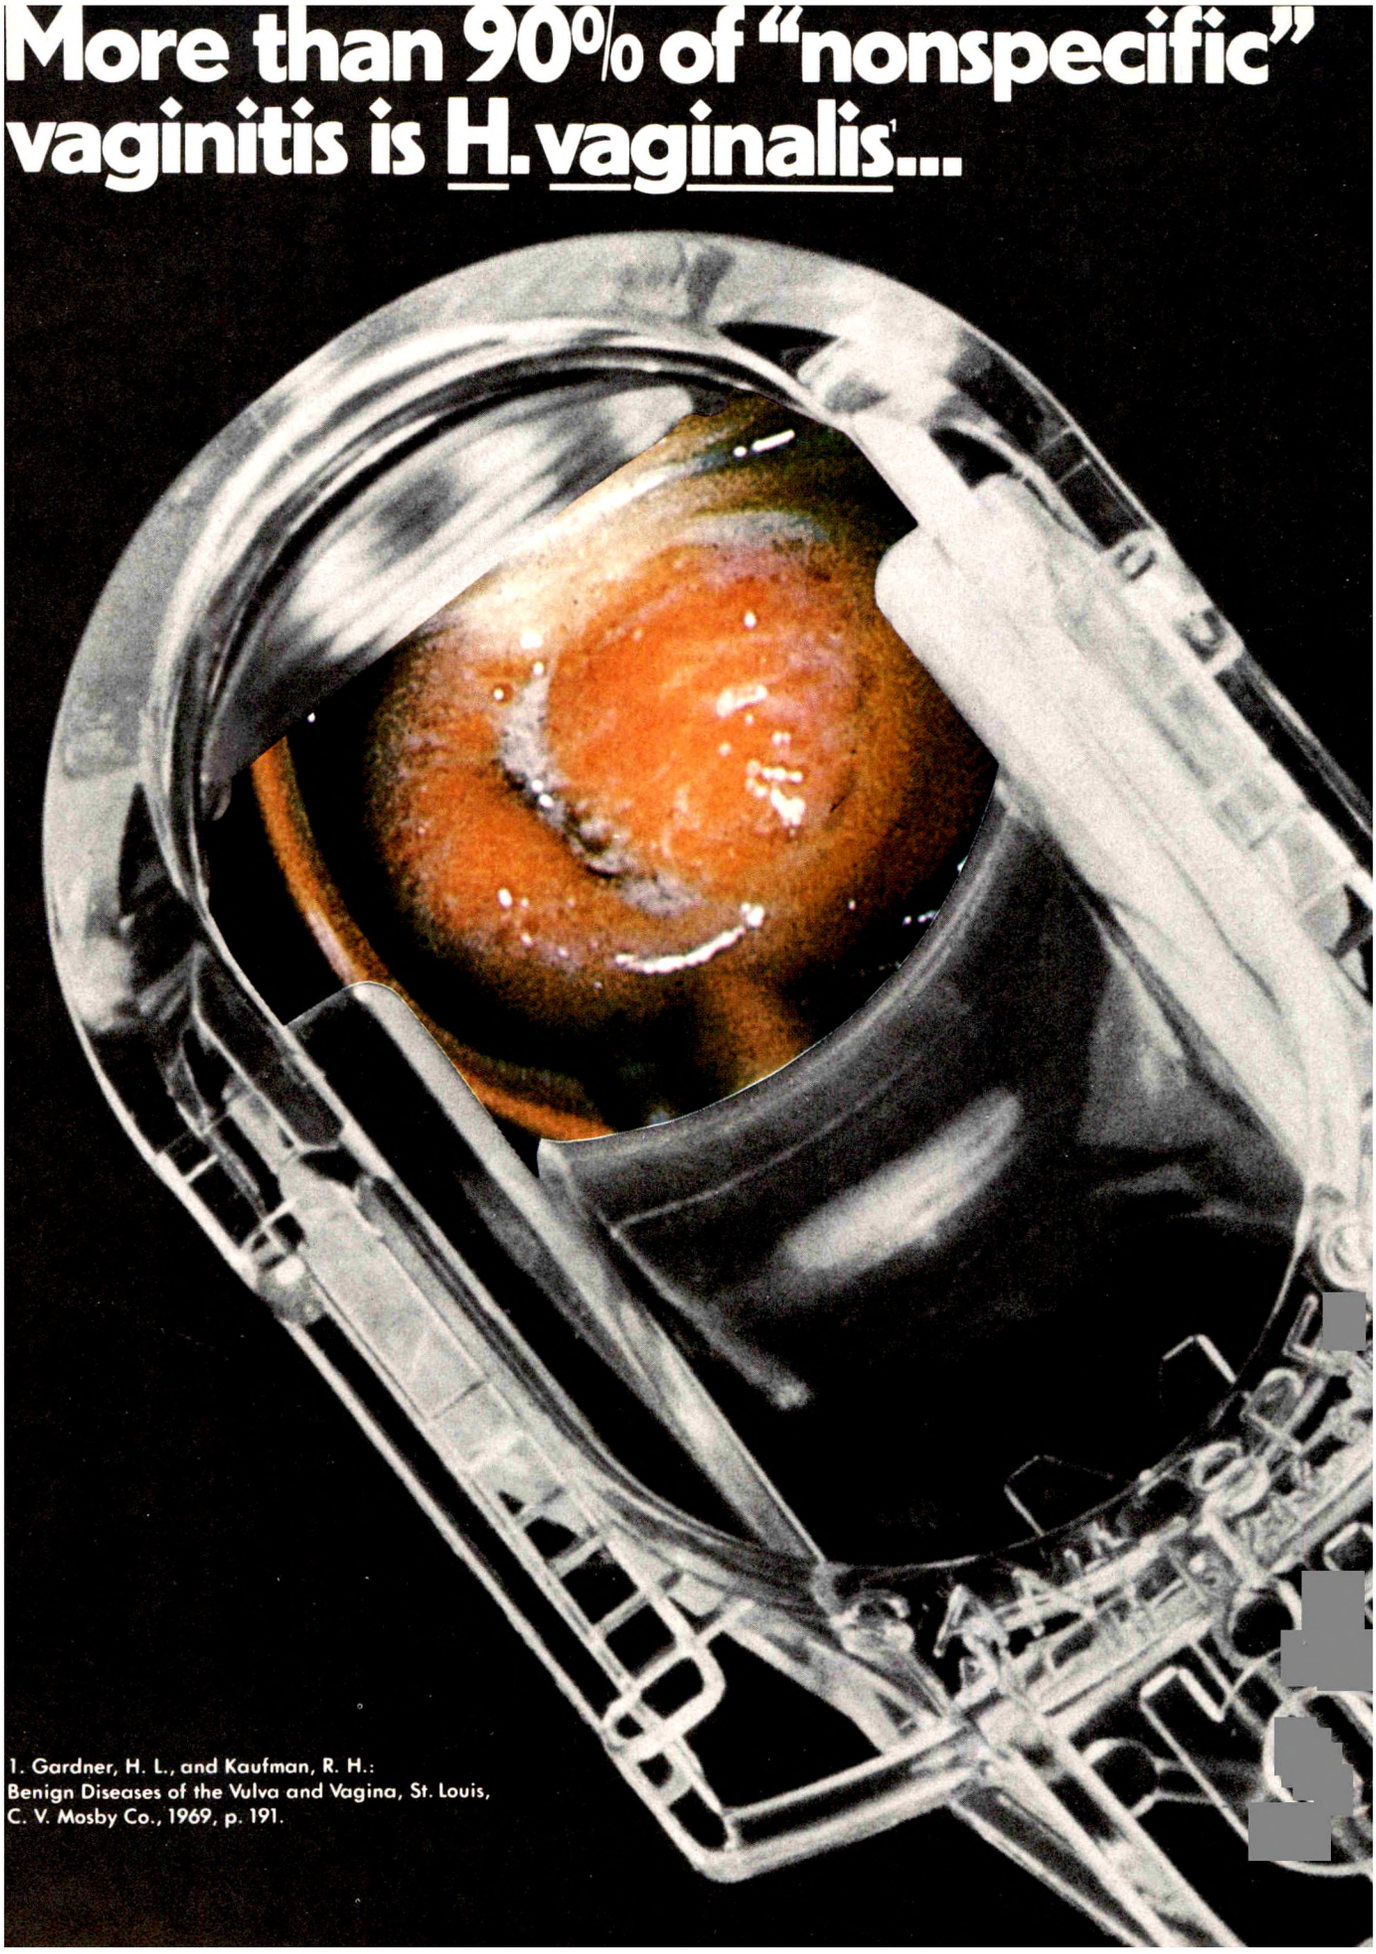
Tables should be typed on separate sheets of paper, not in the text, with one table to a page. They should be numbered in sequence and each must be referred to at an appropriate point in the text. Captions of the tables should be brief, yet indicate clearly the purpose or content of each table. Rows and columns in the table should precisely define the nature of the data in each. Abbreviations in tables should be used as little as possible and if abbreviations are used they should be explained in a footnote to the table.

An abstract of 50 to 150 words, to be published as an introduction, should accompany each manuscript and should be typed on a separate sheet of paper.

A footnote should be included which gives the name and complete mailing address of the person to whom reprint requests and correspondence should be sent.

A Guide to Writing for the American Journal of Obstetrics and Gynecology may be obtained from the Publisher on request.

Illustrations. A reasonable number of halftone illustrations will be reproduced free of cost to the author, but special arrangements must be made with the Editors for color plates, elaborate tables, or extra illustrations. Original drawings or graphs should be drawn with black India ink. Typewritten or freehand lettering is not acceptable. All lettering must be done professionally. Do not send original art work, x-ray films, or ECG tracings. Glossy print photographs are preferred, for good black and white contrast is essential.



Announcements. Announcements of meetings must be received by Dr. Brewer at least 2½ months prior to the time of the meeting. Such announcements should concern major meetings and other significant activities. Announcements of symposia or seminars for which fees are charged are not published in the scientific pages of the Journal but may be submitted for paid advertisements, if desired.

Letters to the Editors: A brief Letter to the Editors commenting upon some article which has appeared in the Journal will be considered for publication. The writer of the original article will have an opportunity to reply to unfavorable comments. A brief case presentation of special interest in the form of a Letter to the Editors will also be considered for publication. All such letters should be sent to Dr. Zuspan.

Books. Books received will be listed in the Journal. They should be sent to Dr. Gerbie.

Reprints. Reprints of articles must be ordered from the Publishers, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63141, who will send their schedule of prices. Individual reprints of an article must be obtained through the author.

More than 90% of "nonspecific" vaginitis is H. vaginalis[1]...

1. Gardner, H. L., and Kaufman, R. H.:
Benign Diseases of the Vulva and Vagina, St. Louis,
C. V. Mosby Co., 1969, p. 191.

...and specific for H. vaginalis is

Sultrin TRIPLE SULFA CREAM

TRADEMARK

Effective

Prompt symptomatic relief

Marked clinical response often within days

Effective in H.V. vaginitis occurring concomitantly with vaginal trichomoniasis and/or candidiasis

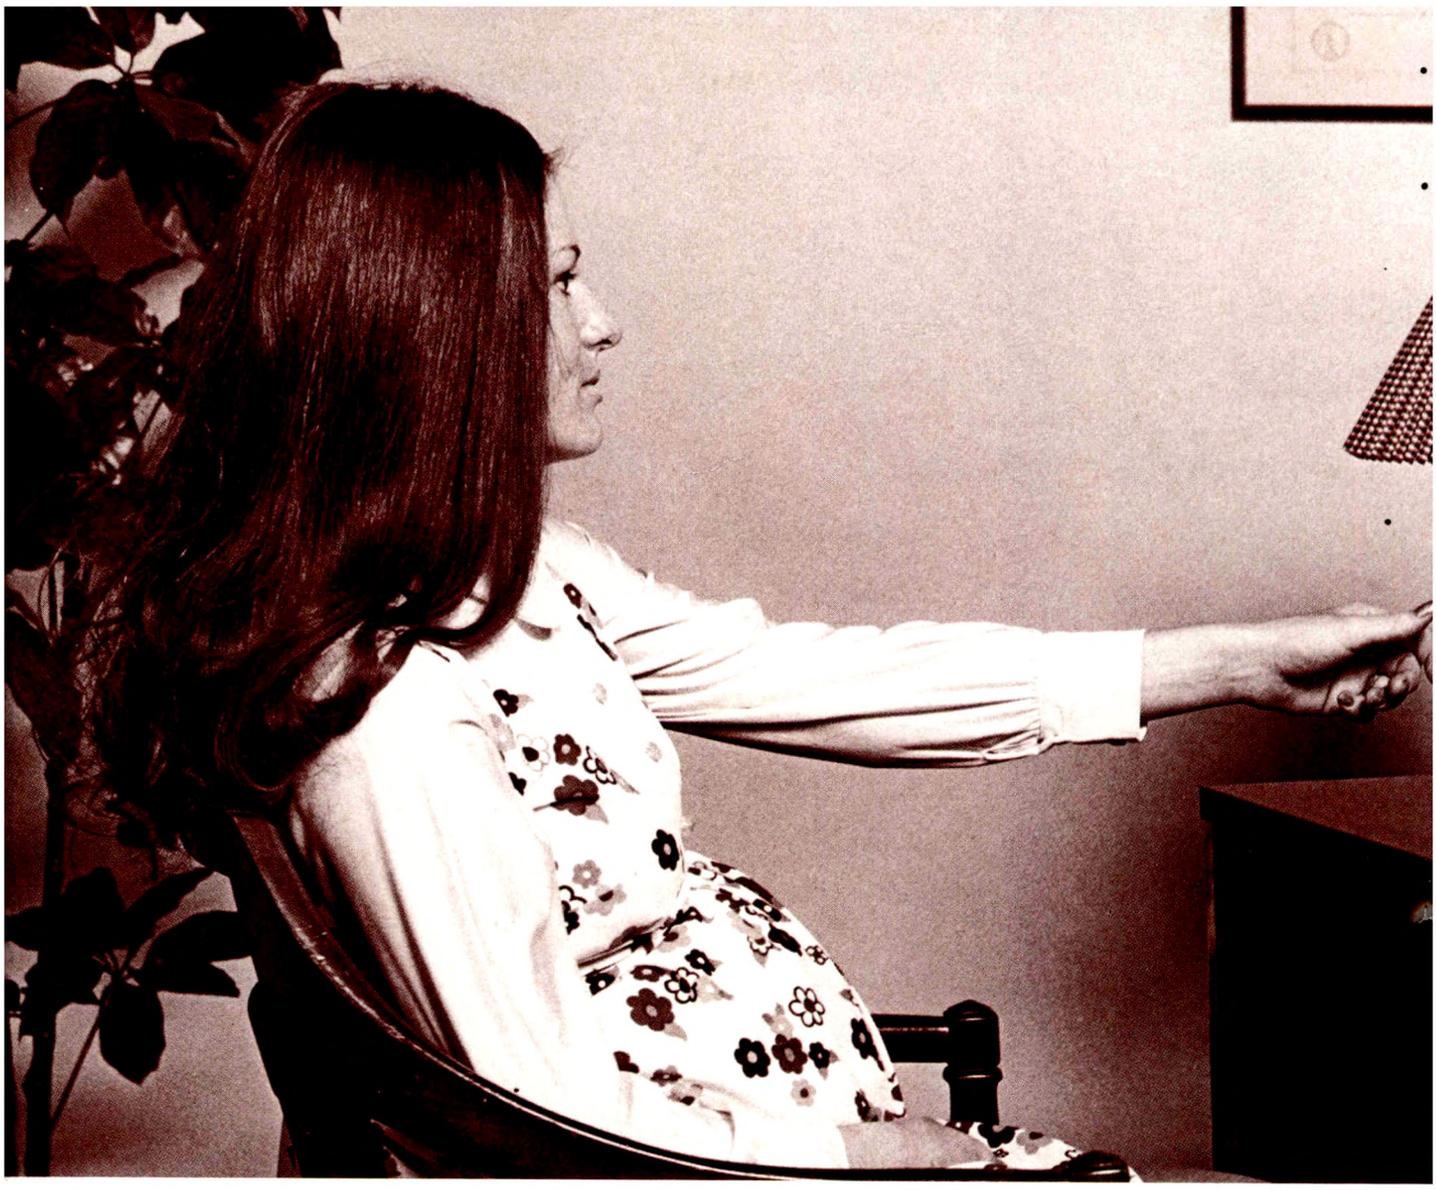
...also available in convenient vaginal tablets

Composition: SULTRIN Cream contains sulfathiazole 3.42%, sulfacetamide 2.86%, and sulfabenzamide 3.7%, and urea 0.64%. Each SULTRIN Tablet contains sulfathiazole 172.5 mg, sulfacetamide 143.75 mg, and sulfabenzamide 184.0 mg.

Indications: SULTRIN Cream and Tablets are indicated for treatment of *Haemophilus vaginalis* vaginitis. They may also be used as a deodorant for saprophytic infection following radiation therapy.

Contraindications: Sulfonamide sensitivity and kidney disease.

Dosages: SULTRIN Cream: One applicatorful intravaginally twice daily for 4 to 6 days. The dosage may then be reduced one-half to one-quarter. SULTRIN Tablets: One tablet intravaginally before retiring and again in the morning for ten days. This course may be repeated if necessary.



Supplied: SULTRIN Cream is available in 2.75 oz. (78 g) tubes with the ORTHO* Measured-Dose Applicator. SULTRIN Tablets are available in packages of 20 foil-wrapped tablets with vaginal applicator.

How these Abbott hematinics meet your pregnant patients' needs

- Each product contains the recommended*800 mcg. of Folic Acid for pregnancy.
- Each product contains 525 mg. of Ferrous Sulfate in controlled-release form to minimize gastric upset—an important consideration in pregnancy.
- Dosage for each product is once-a-day—helps to assure that the busy or forgetful patient complies with your regimen.

*Federal Register, 38:20737, Aug. 2, 1973.

Fero-Folic-500® ℞

Controlled-Release Iron

525 mg. of Ferrous Sulfate (equivalent to 105 mg. elemental iron)

Plus Enhanced Iron Absorption

500 mg. Ascorbic Acid (as sodium ascorbate)

Plus 800 mcg. of Folic Acid

Indications: For the treatment of iron deficiency and prevention of concomitant folic acid deficiency in non-pregnant adults. Also indicated in pregnancy for the prevention and treatment of iron deficiency and to supply a maintenance dosage of folic acid. **Contraindications:** Pernicious anemia. **Warnings:** Folic acid alone is improper therapy in the treatment of pernicious anemia and other megaloblastic anemias where vitamin B_{12} is deficient. **Precaution:** Where anemia exists, its nature should be established and underlying causes determined. Fero-Folic-500 contains 800 mcg. of folic acid per tablet. Folic acid especially in doses above 1.0 mg. daily may obscure pernicious anemia, in that hematologic remission may occur while neurological manifestations remain progressive. **Adverse Reactions:** The likelihood of gastric intolerance is remote. If such should occur the tablet may be taken after a meal. Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

Gradumet—Controlled-release dose form, Abbott. 503085

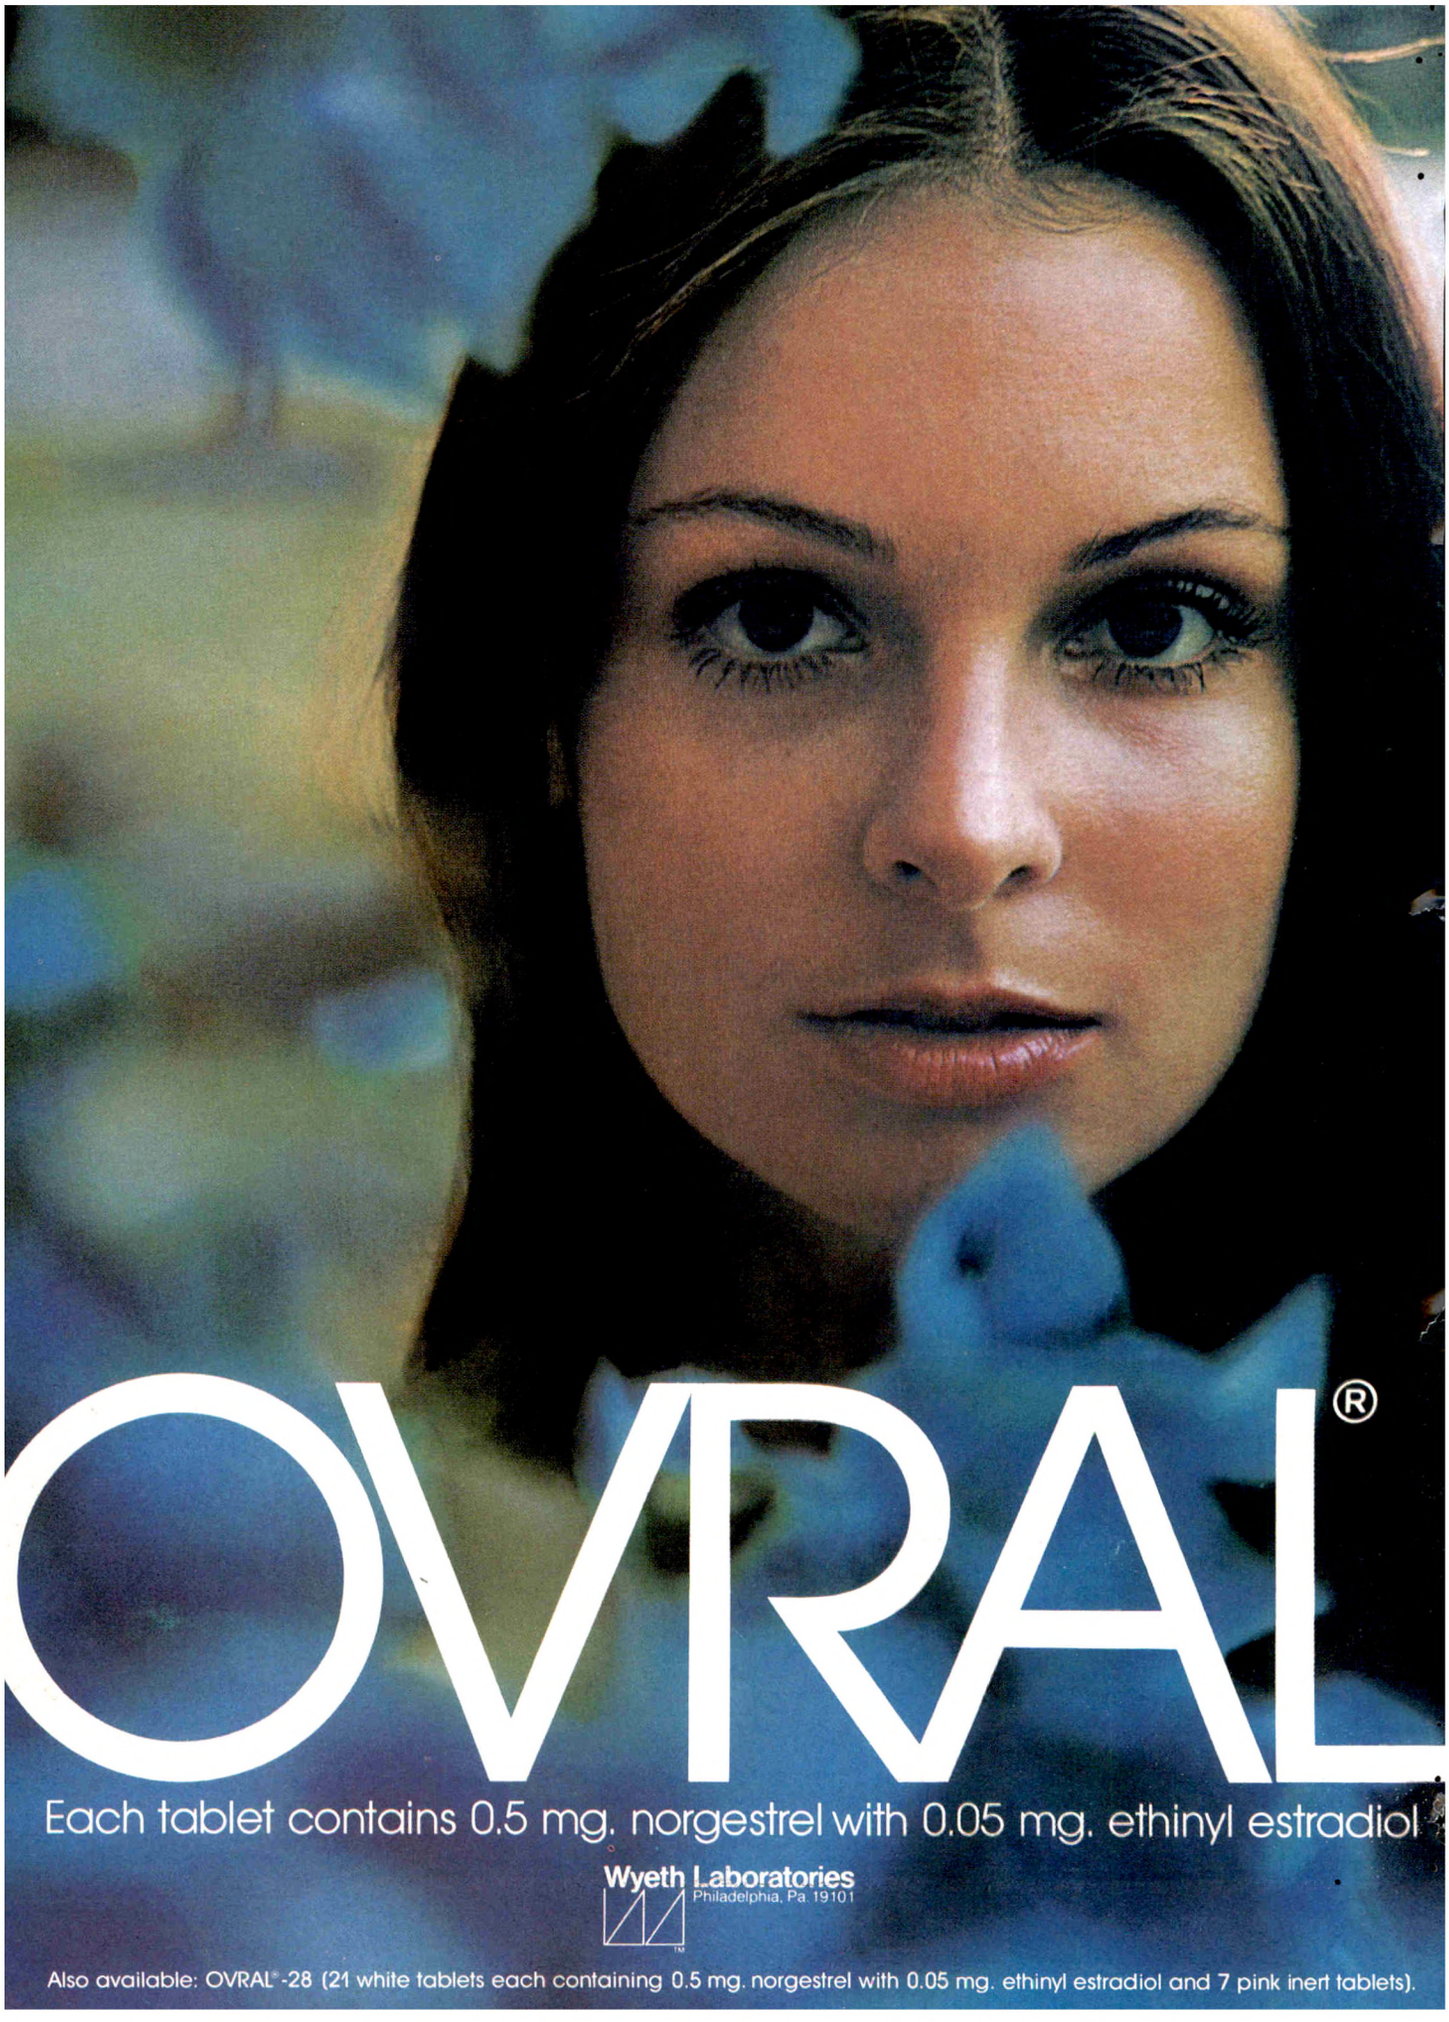
Iberet-Folic-500® ℞

Controlled-Release Iron

525 mg. of Ferrous Sulfate (equivalent to 105 mg. elemental iron)

Plus Enhanced Iron Absorption

500 mg. Ascorbic Acid (as sodium ascorbate)



Plus the B-Complex

Niacinamide	30 mg.
Calcium Pantothenate	10 mg.
Vitamin B_1 (Thiamine Mononitrate)	6 mg.
Vitamin B_2 (Riboflavin)	6 mg.
Vitamin B_6 (Pyridoxine Hydrochloride)	5 mg.
Vitamin B_{12} (Cyanocobalamin)	25 mcg.

Plus 800 mcg. Folic Acid

Indications: In non-pregnant adults, for the treatment of iron deficiency and prevention of concomitant folic acid deficiency where there is an associated deficient intake or increased need for the B-complex vitamins. Also indicated in pregnancy for the prevention and treatment of iron deficiency where there is a concomitant deficient intake or increased need for B-complex vitamins (including folic acid). **Contraindication:** Pernicious anemia. **Warnings:** Folic acid alone is improper therapy in the treatment of pernicious anemia and other megaloblastic anemias where vitamin B_{12} is deficient. **Precaution:** Where anemia exists, its nature should be established and underlying causes determined. Iberet-Folic-500 contains 800 mcg. of folic acid per tablet. Folic acid especially in doses above 1.0 mg. daily may obscure pernicious anemia, in that hematologic remission may occur while neurological manifestations remain progressive. **Adverse Reactions:** The likelihood of gastric intolerance is remote. If such should occur, the tablet may be taken after a meal. Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

ABBOTT

OVRAL®
Each tablet contains 0.5 mg. norgestrel with 0.05 mg. ethinyl estradiol
Wyeth Laboratories
Philadelphia, Pa. 19101
Also available: OVRAL®-28 (21 white tablets each containing 0.5 mg. norgestrel with 0.05 mg. ethinyl estradiol and 7 pink inert tablets).

CLINICAL OPINION

This section reports opinion on the handling of clinical situations, i.e., the clinical diagnosis and management of certain disease entities. Papers should range from eight to twenty typed pages, including illustrations, tables, and figures which clarify the author's management. References are limited to six citations. Mail to Frederick P. Zuspan, M.D., Editor.

Unresolved issues in the first five years of the rubella immunization program

MORRIS SIEGEL, M.D., M.P.H.

Brooklyn, New York

Despite extensive use of attenuated rubella vaccine during the past five years, the degree of fetal risk in susceptible women inoculated early in pregnancy is still an unresolved issue. Although there is considerable evidence of chronic vaccine virus infection of the products of gestation in aborted fetuses, congenital defects have not yet been reported in the newborn infants of susceptible vaccinated pregnant women. The normal findings in the newborn infant can be misleading with respect to the safety of the vaccines in early pregnancy, because they represent only a small selected group of reported cases. The immediate need is for more complete reporting of all relevant cases wherever they occur in order to determine without many more years of delay whether the fetal risk has public health significance or is so low as to be of negligible importance.

SOME OF THE problems encountered in the control of congenital rubella (German measles) during the first five years of the immunization program require review and analysis. During this period, more than 50 million doses of rubella vaccines were distributed in the United States alone.[1] Unlike that for other vaccination programs, the target population for large-scale immunization in the United States has not been those at risk, susceptible women of childbearing age, but the age group from one to twelve, those who will require protection a decade or two later.[2] This ambiguous approach to the prevention of congenital rubella has been controversial since the inception of the program.[3–5] It was deemed necessary because the vaccine, though attenuated, consists of live virus capable of infecting the products of gestation in susceptible

		No.	*%*	*No.*	*%*	*No.*	*%*	
Susceptible	51	3	5.9	25	49.0	23	45.1	0
Unknown	239	12	5.0	112	46.9	115*	48.1	0†

*Based on data collected by the CDC, Atlanta, Georgia.[26]

†Only about 15 per cent of the unknown immune group or 17 women were probably susceptible before inoculation, according to expectancy in the general population.[26, 41]

women. The validity of the present policy on mass immunization of the childhood population depends on two interrelated questions that remain to be resolved: (1) Of what value is immunizing the prepuberty population as a measure to control contact spread and rubella outbreaks? (2) What is the degree of fetal risk in susceptible adolescents and adults who have been inoculated early in pregnancy?

The large-scale inoculation of children from one to twelve years of age was said to be of value in preventing rubella for several reasons. Most children were susceptible and could be readily inoculated on a large scale without the need of testing for susceptibility. Also, they were the primary source of infection for susceptible household contacts of childbearing age. As the main disseminators of infection, their mass immunization was considered essential to the prevention of outbreaks, according to the concept of herd immunity. However, field experience soon showed that the mass inoculation of young children could not be relied upon to prevent rubella outbreaks and infection of susceptible contacts. Epidemics affecting all susceptible subjects were reported in military units, even though about 85 per cent of the exposed population were found to be immune in serologic surveys.[6, 7] In civilian populations, large-scale inoculation of prepuberty children several months before an outbreak only served to protect that age group but not older girls of childbearing age.[8] Similar experiences have been reported in college outbreaks of rubella affecting large numbers of female students.[9]

The lack of protection for those most in need of the vaccine at the time of an outbreak is an inevitable outcome of a mass vaccination program that at present is geared primarily to prepuberty youngsters. This anomalous situation in public health practice could be justified partly on the grounds that any large-scale inoculation program for children over age 12 would necessarily include many susceptible out-of-wedlock pregnant teen-agers. Their number has increased in recent years, and their pregnancies are generally concealed in the first trimester when the fetus is most vulnerable to rubella virus infection. However, the nature of the ill effect to be expected in any large-scale inoculation program for young teen-agers with attenuated virus strains has remained largely speculative, because the nature and extent of fetal damage in susceptible inoculated pregnant women have not been well defined.

Current concepts on the degree of fetal risk in inoculated pregnant women derive from the high incidence of congenital malformations following maternal rubella in the first trimester and the necessity of using live virus strains in order to induce an adequate

immune response.[10–12] The infectivity of the vaccine virus for the products of gestation and the nature of the pathologic reactions were readily demonstrable in studies on susceptible women scheduled for abortions and on aborted fetuses and stillborn infants following inadvertent inoculation during pregnancy.[13–19] The frequency of demonstrable vaccine virus infection of the placenta and decidua was found to be about 25 per cent in susceptible cases.[14] On the other hand, considerable difficulty has been encountered in isolating vaccine virus from fetal tissue in susceptible cases. As shown in Table I, virologic studies were either negative or positive in single cases only, according to results reported in preabortion inoculated women and in women who were inadvertently inoculated while pregnant by six groups of investigators. In their combined series of 62 cases (36 known susceptible subjects), there were 3 positive fetal cases (eye, kidney, bone marrow). Two additional positive cases (fetal eye and kidney) have been reported by the Center for Disease Control (CDC) out of an unspecified number of cases in its own series of fetal tissue examinations.[20] The low frequency of positive fetal tissue has been attributed speculatively to the very small amounts of viable vaccine virus in its tissues and to failure to process specimens promptly and properly.[21] Evidence of chronicity of fetal infection has been reported in isolation of vaccine-like virus from the bone marrow 94 days after inadvertent inoculation in one case and from the eye of a 13 week fetus following maternal inoculation seven weeks before conception (described below).[16, 22]

Because of the hazards of vaccine virus infection of the fetus, release of the vaccine for general public use was not in accord with governmental safety requirements. Nevertheless, licensure of the vaccine was justified on at least two counts. First, vaccine virus was recommended on a large scale for prepuberty children only and on an individual basis for susceptible women, providing they would not become pregnant for two or three months.[2] Second, the risk of transmitting vaccine virus from inoculated subjects to susceptible pregnant contacts by means of infected nasopharyngeal secretions was rare.[11, 23–25] Subsequent experience soon showed that the contraindications to use of the vaccine during pregnancy were either disregarded or overlooked. Women either were unaware of being pregnant at the time of inoculation or they became pregnant soon thereafter despite precautions. In either instance, inoculation shortly before or after conception often led to an induced abortion or to months of anxiety over the outcome for those who went to term.

Specific information on the outcome of gestation for those inoculated early in pregnancy has been collected on a nationwide basis by the CDC.[20, 26, 27] A recent rubella surveillance report by the CDC describes results obtained on 300* women who were "inadvertently" vaccinated from 8 weeks before to 16 weeks after conception during 1970 to 1974.[26] Their distribution by preimmune status in serologic tests was unknown in 239 cases; 51 were susceptible and 10 were immune. In the small immune group, fetal defects were not expected and none was observed. The outcome in the other two groups consisting of 290 cases is shown in Table II by number of fetal deaths and live births. Fetal deaths occurred in about half the cases in each group mainly by "therapeutic" abortion. Since about 85 per cent of women in the United States are probably immune to rubella, most of the many induced abortions in the unknown immune group were unnecessary and could have been avoided by serologic testing before inoculation.

In about 45 per cent of the reported cases, gestation was not interrupted before term, and data are now available on the condition of 138 newborn infants following maternal rubella vaccination in the United States (Table II). There was no evidence of congenital defects in any of the live-born infants and no serologic evidence of congenital infection in 37 infants tested.[26] Since only susceptible women are actually at risk, the negative findings properly apply only to the 23 cases in the known susceptible group and to an estimated expectancy of about 15 per cent or 17 additional presumably susceptible cases in the unknown immune group, for a total of 40 cases (Table II). These favorable results seem to indicate that the fetal risk may be less common or less serious than expected from the chronicity of vaccine virus infection of the fetus and the high degree of susceptibility of fetal tissue to rubella virus. On the other hand, the reported outcome in the newborn infant may be very misleading because the number of cases is so small and probably is not representative of the total population at risk because of underreporting.

The histopathologic findings observed in aborted cases represent direct evidence of fetal injury, the nature and outcome of which are difficult to ascertain, because the process is interrupted at an early stage by the induced abortion and the cause is usually not confirmed by virologic studies. The reported tissue changes consist mainly of cellular infiltrations in the decidua and placenta and of damage to the fetus in a single case which affected the eyes.[16–19]

The cellular lesions represent initial response to

*Excluded are 17 additional cases in which the outcome of pregnancy was unknown.

vaccine virus infection or to some other cause and are terminated before the nature of the final outcome can be determined. Consequently, the prospect that such changes can lead to major congenital malformations is only conjectural. In the report on pathologic changes in the fetal eye, evidence implicating vaccine virus is described which was "consistent with congenital infection."[16] The histologic abnormalities consisted of pyknotic nuclei and cytoplasmic vacuoles in the fiber cells of the lens nucleus and "degenerative changes with liquification" in the lens cortex. In addition, "particles resembling rubella virus were seen on electron microscopy," and an interfering agent was isolated from the eye with "in vitro growth characteristics similar to those of vaccine virus." The abnormal findings resembled the early changes noted in wild virus infection.[28] They were observed in a fetus from a 25-year-old patient inoculated about 7 weeks before conception and aborted after 13 weeks' gestation. Since the abortion interrupted the course of the pathologic process, there is no way of knowing for sure whether it would have progressed to the formation of a nuclear cataract characteristic of congenital rubella. Even in natural rubella infection, the development of congenital cataracts and other major malformations cannot be determined "with assurance" from histopathologic changes in the aborted fetus.[28] Consequently, in search for conclusive evidence on the frequency of significant fetal damage, reliance should be placed on the occurrence of vaccine virus–induced congenital defects in the newborn infants of susceptible mothers inoculated early in gestation.

Such bona fide cases have not yet been reported in the United States. The experience in other countries appears to be similar to that described for the United States, according to a review of the available literature and correspondence with various investigators and with the Ministries of Health in Europe, South America, Mexico, Canada, Australia, New Zealand and Israel. Until authenticated cases are described, there seems to be no reliable way of confirming the teratogenic effects of rubella vaccines. The normal newborn findings indicate that the fetus was either not infected, as substantiated by negative serologic tests, or was infected but suffered no demonstrable major defect at birth, as occasionally observed in maternal rubella.[29] Since the reported number of normal cases is small and the duration of follow-up is short, much more time will be needed to determine whether the fetal risk is serious enough to be of public health significance or is so low as to be of negligible importance.

Accurate determination of fetal risk is an elusive problem not only because of incomplete case reporting, short-term follow-up, and unknown preinoculation immune status of inoculated mothers but also because of ethical considerations forbidding studies on randomly allocated inoculated and uninoculated susceptible women shortly before or after conception. In the absence of well-designed prospective studies, the risk cannot be determined reliably because the study population or the number of susceptible inoculated women is unknown. Furthermore, because of incomplete notification, the reported number of newborn infants represents a highly selected group of only about 10 cases per year in the United States and a smaller number elsewhere.[30–32] At this rate, it would take almost a decade to accumulate about 100 cases. More complete reporting would not only increase the number of cases but also make them more representative of the total at risk. By intensifying the search for cases both here and abroad, one may be able to determine without too many more years of delay the frequency of major malformations caused by rubella vaccines.

Until such meaningful data on the newborn infant become available, much can be done to reduce the number of unnecessary abortions by stressing the importance of determining rubella susceptibility before inoculation and the necessity of avoiding pregnancy for at least two months after inoculation. For those who do become pregnant, despite its contraindication, and prefer to go to term, the probable outcome of pregnancy remains uncertain for the present. In these cases, cord blood should be routinely tested for serologic evidence of congenital infection. The number of susceptible subjects reaching the childbearing age can be reduced by developing acceptable programs for large-scale inoculation of premenarchial schoolgirls who were not immunized in early childhood.[33] In addition, the size of the susceptible adult population can be decreased with minimal risk by inoculating seronegative postpartum women within 48 hours after delivery when the likelihood of conception is quite low for at least a month, even without precautions.[34] Where feasible, premarital and prenatal tests for rubella antibodies should be routine, and serologic surveys should be undertaken in other postpubertal groups.[35] If vaccination is recommended, the use of suitable informed consent provisions would be helpful to patient and physician.

The ultimate solution to the problem of preventing abortions, malformations, and the anxieties associated with rubella depends on the continued search for safer specific vaccines and other effective prophylactic measures. Further attenuation of currently used vac-

cine strains by additional tissue culture passage would increase their safety but reduce their immunogenicity or effectiveness. An obvious approach is to search for less teratogenic wild strains. Such strains are said to be prevalent in Japan where the incidence of rubella embryopathy is reported to be very low despite widespread epidemics.[36] Their low teratogenicity, if confirmed, may be related to their capacity to induce high levels of interferon, according to comparative studies in placental cell cultures.[37] Preliminary field trials in Japan and the United Kingdom indicate that a vaccine prepared from a Japanese strain attenuated by tissue culture passage (To-336) is as antigenic as current vaccines, and is nontransmissible to susceptible contacts.[38, 39] Its effect on the fetus has not yet been investigated. This crucial point will probably take a long time to clarify, because ethical restrictions limit such determinations to women inadvertently inoculated shortly before or after conception. Other measures that might be used to prevent or treat rubella are either not effective (e.g., drugs), or of questionable value (e.g., gamma globulin).

Whether interferon or its inducing agents can be used to protect the fetus of exposed or vaccinated mothers is in an early stage of investigation.[40]

In summary, there is no quick and easy solution to the problems arising from the current need to use live vaccine virus in the control of rubella (German measles). Despite its attenuation, the virus is capable of causing a chronic infection of the products of gestation and cellular reaction resembling an early lesion of wild virus infection. Whether the attenuated vaccine virus can cause major malformations characteristic of natural rubella has not yet been substantiated in studies of the newborn infant. Although the normal newborn findings are based on a small number of reported cases, they raise hopes that the risk of a major defect may be less frequent and less serious than expected. Because of sampling variation and incomplete reporting, these hopes may prove to be false. Whether they are real or false can be reliably ascertained only by an evaluation of fetal risk based on the outcome in the newborn infant. For this purpose, intensified and coordinated efforts will have to be made by official agencies and medical groups at more complete reporting of relevant newborn cases wherever they occur in the United States and in other countries. The results obtained should establish whether the risk from current vaccines is minimal or whether safer vaccines are needed for large-scale use in women of childbearing age.

GYNECOLOGY

The effectiveness of two oral contraceptives in suppressing plasma androstenedione, testosterone, LH, and FSH, and in stimulating plasma testosterone-binding capacity in hirsute women

JAMES R. GIVENS
RICHARD N. ANDERSEN
WINFRED L. WISER
EDWARD S. UMSTOT
STEWART A. FISH
Memphis, Tennessee

The effectiveness of two oral contraceptives in suppressing plasma androstenedione (A), testosterone (T), LH, and FSH and in stimulating testosterone-estradiol–binding globulin (TeBG) was evaluated in 39 hirsute women. Twenty-seven hirsute women received norethindrone 2 mg.–mestranol 0.1 mg. (Group I) and 12 received norgestrel 0.5 mg.–ethinyl estradiol 0.05 mg. (Group II). Hormone assays were performed before treatment and at the end of 3 weeks of therapy. Ninety per cent of the women in both groups had an elevated plasma A and/or T. During treatment, plasma A, T, LH, and FSH were significantly reduced in both groups ($p < 0.01$). In Group I, 78 per cent of the women had a normal plasma A and T during treatment. In Group II, 83 per cent of the women had a normal A and T during treatment. There was a greater increase in TeBG in Group I ($p < 0.01$). It is concluded that these two oral contraceptives effectively suppressed the hyperandrogenism of most of the hirsute women.

From the Division of Reproductive Medicine, Department of Obstetrics and Gynecology, University of Tennessee Center For The Health Sciences, Memphis, Tennessee

This study was conducted in the University of Tennessee Clinical Research Center which is supported by grant RR-211 from the General Clinical Research Center Program of the National Institutes of Health.

This study was supported in part by United States Public Health Service grants ME-000-79, HL-09495, and LM-00-102.

Received for publication November 4, 1974.

Revised March 3, 1975.

Accepted March 10, 1975.

WE RECENTLY described the time-course of the suppression of plasma androstenedione (A), testosterone (T), LH, and FSH by a combination-type oral contraceptive containing norethindrone 2 mg. and mestranol 0.1 mg.* in seven hirsute women with

*Proved polycystic ovaries.

polycystic ovarian disease.[1] After a refractory period, mean plasma A and T decreased progressively throughout the first 3 weeks of drug administration. Mean plasma A and T were suppressed 58 per cent and 65 per cent, and all elevated levels were reduced to normal. Suppression of A and T correlated temporally with the decrease in plasma LH, suggesting LH-dependent hyperandrogenism. The purpose of this study was to determine the degree of suppression of plasma A and T and the degree of stimulation of plasma testosterone-estradiol–binding globulin (TeBG) by norethindrone 2 mg.–mestranol 0.1 mg. or norgestrel 0.5 mg.–ethinyl estradiol 0.05 mg.* in 39 unselected hirsute women.

Materials and methods

The 39 hirsute women who participated in the study represented consecutive cases of hirsutism seen in our clinic, except for a few women who had to be excluded because they did not return for hormone assays while on therapy. Twenty-seven of the hirsute women received norethindrone 2 mg.–mestranol 0.1 mg. and are termed Group I. Twelve hirsute women received norgestrel 0.5 mg.–ethinyl estradiol 0.05 mg. and are termed Group II. There was no *a priori* basis for assigning the women to one or the other of the two therapeutic groups.

The clinical data of the women in Group I are listed in Table I and those of the women in Group II are listed in Table II. The women in Group I ranged in age from 15 to 31 years (mean, 22). The women in Group II also ranged in age from 15 to 31 years (mean, 22). Most of the women in both groups had mild to moderate hirsutism. The degree of hirsutism was graded on a 1+ to 4+ scale. A 1+ rating was used when there was increased hair only on the upper lip; 2+ for excessive hair on the upper lip and sideburns; 3+ for excessive hair on the upper lip, sideburns, and chin; 4+ was used to indicate a male-type beard. Cases 17 and 22 in Group I were virilized and were 4+ hirsute. Twelve of the 27 women in Group I had enlarged ovaries and seven of these had documented polycystic ovaries by direct visualization. Four of the women in Group II had enlarged ovaries. The majority of the

women in both groups had oligomenorrhea or amenorrhea.

Blood was obtained from the antecubital vein between 10 A.M. and 4 P.M. prior to therapy and again at the same time of day during the last part of the third week of the first cycle of oral contraceptive administration.

Plasma T was measured by radioimmunoassay as described by Furuyama and associates,[2] including preassay chromatography on alumina columns. There was significant cross-reactivity between dihydrotestosterone (DHT) and the T antiserum, but DHT was separated from T by the preassay chromatography. The interassay coefficient of variation of the T assay was ±8.9 per cent at the level of 56 ng. per 100 ml.

Plasma A was measured by radioimmunoassay in a manner similar to T but with an earlier eluate from the alumina columns.[1] There was significant cross-reactivity of androsterone with the A antibody, but it was separated from A by preassay chromatography. The interassay coefficient of variation of the A assay was ±9.5 per cent at the level of 568 ng. per 100 ml.

Plasma FSH and LH were determined by a two-stage, double-antibody radioimmunoassay technique similar to that of Morgan.[1, 3] The LH (LER-960) and the FSH (LER-1366) used for radioactive labeling and the antisera (human chorionic gonadotropin antiserum and human pituitary FSH antiserum absorbed with hCG) were furnished by the courtesy of the Endocrine Study Section of NIH. The second international reference preparation of human urinary menopausal gonadotropin (2nd IRP-HMG) furnished by the World Health Organization and LER-907, a human pituitary gonadotropin reference preparation furnished by the Endocrine Study Section of NIH, were used as standards. Assay results are expressed in terms of the 2nd IRP-HMG standard. The interassay coefficient of variation at 12 mI.U. per milliliter was ± 11 per cent for the LH assay and ± 12 per cent for the FSH assay.

Urinary 17-ketosteroids (17-KS) and urinary 17-ketogenic steroids (17-KGS) were determined by the method of Sobel and associates.[4] Urinary pregnanetriol (P-3) was determined either at Endocrine Science Laboratories, Tarzana, California, or Bioscience Laboratories, Van Nuys, California.

Plasma TeBG binding capacity was determined by the method of Rosner.[5] The interassay coefficient of variation of the TeBG assay was ± 3.3 per cent at the level of 3 μg per 100 ml.

Two-factor analysis of variance with repeated measures was used for statistical analysis.

Results

The A, T, TeBG, LH, and FSH levels before and during treatment of the women in Group I are listed in Table I and the same data on the Group II women are listed in Table II. Fig. 1 illustrates the mean pretreatment and treatment levels of plasma A, T, TeBG, LH, and FSH of the two groups of hirsute women.

Pretreatment. Nineteen Group I women and nine Group II women had an elevated plasma A. Pretreatment plasma A of the women in Group I ranged from 208 to 535 ng. per 100 ml. (mean ± S.E., 351 ± 19) and in Group II ranged from 257 to 555 ng. per 100 ml. (mean, 372 ± 31). Plasma A between 10 A.M. and 4 P.M. of 10 normal menstruating females ranged from 93 to 300 ng. per 100 ml. (mean, 195).

Twenty-one Group I women and nine Group II women had an elevated plasma T. Pretreatment plasma T in Group I ranged from 22 to 134 ng. per

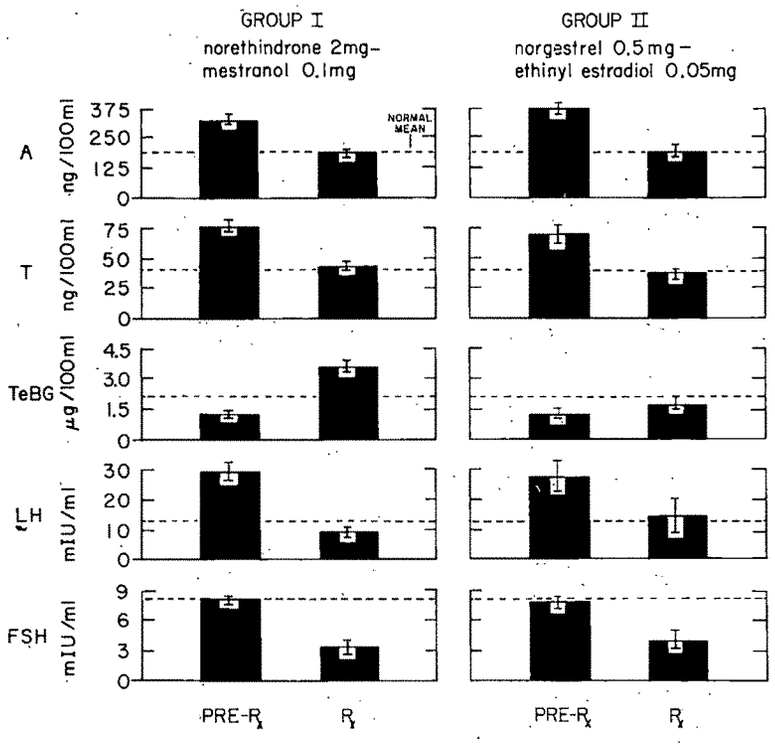

Fig. 1. Mean pretreatment (*pre-R_x*) and treatment (*R_x*) plasma levels of Δ^4-androstenedione (*A*), testosterone (*T*), testosterone-binding globulin (*TeBG*) capacity, *LH*, and *FSH* of the Group I and Group II hirsute women. Bars define the standard error of the means.

100 ml. (mean, 75 ± 5) and in Group II ranged from 36 to 118 ng. per 100 ml. (mean, 70 ± 8). Plasma T between 10 A.M. and 4 P.M. of 10 normal menstruating females ranged from 19 to 50 ng. per 100 ml. (mean, 39).

Plasma A and T were both elevated in 16 of the 27 Group I women. Plasma A and/or T were elevated in all but two of the Group I women. Plasma A and T were both elevated in seven of the 12 Group II women. Plasma A and/or T were elevated in all but one of the Group II women.

Fifteen Group I women and four Group II women had an abnormally low TeBG binding capacity. Pretreatment plasma TeBG binding capacity in Group I ranged from 0.1 to 3.9 µg per 100 ml. (mean, 1.2 ± 0.2) and in Group II ranged from 0.3 to 2.7 µg per 100 ml. (mean, 1.3 ± 0.2). Plasma TeBG binding capacity of 10 normal menstruating females ranged from 1.1 to 3.3 µg per 100 ml. (mean, 2.1).

Seventeen Group I women and five Group II women had an elevated LH level. Pretreatment plasma LH in Group I ranged from 5 to 76 mI.U. per milliliter (mean, 29 ± 3) and in Group II ranged from 8 to 70 mI.U. per milliliter (mean, 27 ± 5). Midfollicular plasma LH (day −7 from the ovulatory LH peak) of nine normal women ranged from 8 to 22 mI.U. per milliliter (mean, 13 ± 2).

Plasma FSH was within the normal range in all but one woman in each group. These two women had low levels of FSH. Pretreatment plasma FSH in Group I ranged from 3 to 12 mI.U. per milliliter (mean, 8 ± 0.3) and in Group II ranged from 4 to 11 mI.U. per milliliter (mean, 7 ± 0.6). Midfollicular plasma FSH (day −7 from the ovulatory LH peak) of nine menstruating women ranged from 5 to 12 mI.U. per milliliter (mean, 8 ± 1.4).

Eight women in Group I (Nos. 1, 3, 4, 5, 7, 8, 13, and 14) had elevated urinary 17-KS ranging from 1 to 4 mg. above the upper limit of the normal range. Seven women in Group I (Nos. 1, 3, 4, 7, 11, 13, and 16) had an increase in urinary P-3 of 1 mg. or less above the upper limit of the normal range. Four of the women who had elevated urinary 17-KS and/or elevated urinary P-3 had enlarged ovaries.

Treatment. There was a significant reduction of mean plasma A in both groups during treatment ($p < 0.01$). Treatment reduced mean plasma A of the women in Group I from 350 ± 19 to 175 ± 10 ng. per 100 ml. and reduced mean plasma A of the women in Group II from 372 ± 31 to 203 ± 22 ng. per 100 ml.

Plasma A was reduced in every individual of both groups and only one woman in Group I and two in Group II had a plasma A that remained elevated during treatment. The individual percentage decreases of plasma A in Group I ranged from 20 to 73 per cent (mean decrease, 48 ± 3) and in Group II ranged from 10 to 74 per cent (mean decrease, 45 ± 5).

There was a significant reduction in mean plasma T of both groups during treatment ($p < 0.01$). Treatment reduced mean plasma T of Group I from 75 ± 5 to 43 ± 3 ng. per 100 ml. and reduced mean plasma T of Group II from 70 ± 8 to 38 ± 3 ng. per 100 ml. Plasma T was reduced in every individual except one (No. 14, Group I), in whom the T level increased. Six Group I women and one Group II woman had an elevated plasma T during treatment. The individual percentage decreases of plasma T in Group I ranged from 11 to 77 per cent (mean decrease, 39 ± 4) and in Group II ranged from 17 to 77 per cent (mean decrease, 41 ± 6).

The degree of suppression of mean plasma A and T was not different in the two groups ($p > 0.05$). In Group I, 95 per cent of the elevated A levels and 71 per cent of the elevated T levels were reduced to within the normal range. In Group II, 78 per cent of the elevated A levels and 89 per cent of the elevated T levels were reduced to within the normal range. In Group I, 78 per cent of the women had a normal plasma A and T during treatment. In Group II, 83 per cent of the women had a normal A and T during treatment.

There was no significant difference in the degree of suppression of A and T between those who had normal urinary 17-KS and the others who had slightly elevated urinary 17-KS or between those who had a normal urinary P-3 and the others who had a minimally elevated urinary P-3 ($p > 0.05$).

Treatment significantly increased mean plasma TeBG binding capacity of the women in Group I from 1.2 ± 0.2 to 3.6 ± 0.3 μg per 100 ml. ($p < 0.01$). Mean TeBG of Group II was increased from 1.3 ± 0.2 to only 1.8 ± 0.2 μg per 100 ml. during treatment. There was a significantly greater increase in the TeBG binding capacity in the Group I women than the Group II women ($p < 0.01$). Plasma TeBG binding capacity was increased in 26 of the 27 women in Group I and in 10 of the 12 women in Group II. The maximum individual percentage increase in TeBG in Group I was 1,100 per cent (mean individual percentage increase, 323 ± 61) and in Group II the maximum percentage increase was 275 per cent (mean individual percentage increase, 82 ± 38).

There was significant reduction of mean plasma LH in both groups ($p < 0.01$). Treatment reduced mean plasma LH of Group I from 29 ± 3 to 9 ± 1 mI.U. per milliliter and reduced mean plasma LH of Group II from 27 ± 5 to 15 ± 6 mI.U. per milliliter. The maximum individual percentage decrease of plasma LH in Group I was 94 per cent (mean decrease, 65 ± 5) and in Group II was 94 per cent (mean individual percentage decrease, 47 ± 9).

There was a significant reduction of mean plasma FSH in both groups ($p < 0.01$). Treatment reduced mean plasma FSH of Group I from 8 ± 0.3 to 3.4 ± 0.4 mI.U. per milliliter and reduced mean plasma FSH of Group II from 7.3 ± 0.6 to 4.3 ± 0.9 mI.U. per milliliter. The maximum individual percentage decrease of FSH in group I was 88 per cent (mean, 58 ± 5) and in Group II was 86 per cent (mean, 44 ± 9).

Comment

Prior to the development of specific androgen assays, a large percentage of hirsute women were diagnosed as having constitutional hirsutism because they had normal urinary 17-KS. Following the development of specific A and T assays, most hirsute women were found to have elevated A and/or T plasma levels or production rates.[6-8] In the present study, plasma A and/or T were elevated in approximately 90 per cent of the hirsute women. In order to utilize A and T plasma levels to discriminate hyperandrogenic from normal women, several factors must be considered which are essential for properly defining the normal range. First, the assays must have specificity. If the A and T antisera are not entirely specific, preassay chromatography is necessary for reliable assays. Second, the time of day of the blood drawing must be considered in determining whether a plasma A value is normal or elevated, because of the diurnal rhythm of plasma A. Our studies indicate that in normal women there is a mean ± S.E. change of plasma A of 110 ± 11 ng. per 100 ml. throughout a 24 hour period which is synchronous with the change in cortisol, the major portion of the change occurring within 3 to 4 hours after the early morning peak.[9] Because the early morning peak of pituitary-adrenal activity occurs at different times in individuals, there is uncertainty whether a single blood specimen drawn in the early morning hours (6 A.M. to 9 A.M.) is at the time of the morning peak pituitary-adrenal activity or not. Therefore, a single plasma A value can be interpreted with greater confidence as to whether it is normal or high if it is drawn after 10 A.M. The time of the blood drawing is not as important a consideration in evaluating a

plasma T value, since the mean ± S.E. change of T throughout a 24 hour period is only 9 ± 3 ng. per 100 ml. in normal women.[9] However, the circulating TeBG binding capacity must be considered in utilizing plasma T levels to discriminate hyperandrogenic females from normal women. A normal total plasma T associated with an abnormally low TeBG binding capacity is presumptive evidence of hyperandrogenism, since circulating free T is likely increased in this circumstance.[10]

An important feature of the design of this study was that consecutive cases of hirsutism were studied. In this unselected group of hirsute women, the two oral contraceptives reduced plasma A and T to within the normal range in 78 and 83 per cent of the women. The data suggest that most of the women had a significant degree of LH-dependency of their hyperandrogenism, since the principal mechanism by which the contraceptive agents reduced plasma A and T was likely through suppression of LH. The fact that over one half (59 per cent) of the hirsute women in this study had an elevated pretreatment LH level also suggests LH-dependent hyperandrogenism.

Determination of A and T levels in ovarian and adrenal effluent blood indicates that the ovaries rather than the adrenals are more commonly the source of the increased A and T production in hirsute women.[11] The catheterization data are in keeping with the clinical observation that pituitary-ovarian suppression is generally more efficacious than pituitary-adrenal suppression in the treatment of hirsutism.[12] A pure adrenal source of hyperandrogenism is apparently uncommon in hirsute women.

Pituitary-ovarian suppression with a combination-type oral contraceptive should be performed in hirsute women with elevated A and/or T levels and normal or only minimally elevated 17-KS. Some of the earlier attempts to use oral contraceptives for the suppression of elevated A and T levels in hirsutism were disappointing, but this was likely due to the fact that the agents were not given long enough. The pituitary-ovarian axis is slower to suppress with sex steroids than the pituitary-adrenal axis is with glucocorticoids. The longer suppression time is due at least in part to the positive feedback effect of the estrogen content of the oral contraceptive on the secretion of LH. A study of the dynamics of the suppression of A and T in polycystic ovarian disease indicated that at least 3 weeks of norethindrone 2 mg.–mestranol 0.1 mg. therapy is required to suppress the pituitary-ovarian axis.[1] It is important to emphasize that maximal attainable suppression of LH, A, and T may not occur after 3 weeks of therapy in some hirsute women. The time required to evaluate the maximum degree of suppressibility of LH, A, and T by norethindrone 2 mg.–mestranol 0.1 mg. or norgestrel 0.5mg.–ethinyl estradiol 0.05 mg. in hirsute women has not been established. Consequently, hirsute women who have A and T levels that remain elevated after 3 weeks of therapy should have the levels determined again after two or three cycles of drug administration.

The choice of the suppressive agent may be critical. Estrogen alone is a poor suppressant of LH in hirsute women.[13] Plasma T is increased, not decreased, in hirsute women given norethindrone 1 mg.–mestranol 0.08 mg.[10] Further investigation is needed to evaluate the relative effectiveness of various progestin-estrogen combinations in suppressing LH, A, and T in hirsute women.

The reduction of plasma T in our patients during treatment is more impressive when the accompanying increase in TeBG binding capacity is also taken into consideration. The fact that T levels were decreased at a time when the TeBG binding capacities were increased indicates there was a reduction in T production, since T levels should rise when TeBG binding capacity increases if no change occurs in T production.

Norethindrone 2 mg.–mestranol 0.1 mg. induced a significantly greater increase in TeBG binding capacity than norgestrel 0.5 mg.–ethinyl estradiol 0.05 mg. The larger increase in TeBG binding capacity probably reflects the larger amount of estrogen in this agent. Furthermore, the antiestrogenic and/or androgenic activity of norgestrel may have partially counterbalanced the stimulatory effect of the ethinyl estradiol on TeBG synthesis.[14] Increasing TeBG binding capacity may be beneficial in and of itself in hirsute women because of the associated decrease in the amount of circulating free or biologically active T.[10] Although the degree of A and T suppression was comparable with the two contraceptive agents, the greater increase in TeBG by norethindrone 2 mg.–mestranol 0.1 mg. may make it a preferable agent in the treatment of hirsutism.

It is noteworthy that the degree of suppression of A and T was no less among those hirsute women who had a minimal elevation of urinary 17-KS and P-3 as compared to those who had normal 17-KS and P-3. These women may have a combined adrenal and ovarian source of their hyperandrogenism. It should not be assumed that the reduction of plasma A and T by these combination-type oral contraceptives is due exclusively to decreased ovarian secretion. The cortisol secretion rate is decreased by approximately 30 per cent in normal women receiving norethindrone 2 mg.–mestranol 0.1 mg.[15] The decrease in cortisol

production apparently results from the decreased metabolic clearance rate of cortisol secondary to an increase in the circulating level of cortisol-binding globulin. The reduced cortisol secretion rate is probably accomplished through decreased ACTH secretion, although this point has not been documented by the measurement of plasma ACTH. It is not known whether the decreased cortisol production is associated with decreased adrenal androgen production. If there is decreased ACTH secretion, then a portion of the decrease in the plasma A and T may be due to reduced adrenal as well as ovarian secretion of A and/or T.

The suppression of A and T concomitant with the suppression of LH by sex steroids does not rule out an ovarian or adrenal tumor, since tumors of these glands can be LH-dependent. A stromal luteoma of the ovary and two cases of T-secreting adrenal adenomas have been noted to be gonadotropin dependent or responsive.[16–18] When the A level is over 1,000 ng. per 100 ml, or the T level is over 300 ng. per 100 ml., the possibility of an adrenal or ovarian tumor must be considered.[19] The location of a tumor is likely best determined by differential catheterization of the adrenal and ovarian veins and measurement of A and T in the glandular effluent blood, rather than by suppression or stimulation studies.

Although an objective parameter was not used in this study to measure the effect of these contraceptive agents on hirsutism, approximately 60 per cent of the 20 hirsute women of this study who have received norethindrone 2 mg.–mestranol 0.1 mg. for more than 6 months subjectively reported a decrease in the rate of hair growth and/or a decrease in the amount of facial hair.

Appreciation is expressed to Ann McEachran of the Cardiovascular Computer Center for the statistical analyses.

Gonadotropin-releasing hormone radioimmunoassay and its measurement in normal human plasma, secondary amenorrhea, and postmenopausal syndrome

NORMAN G. ROSENBLUM*
SHELDON SCHLAFF, M.D.
Philadelphia, Pennsylvania

A sensitive and specific double antibody radioimmunoassay for gonadotropin-releasing hormone (GnRH) has been developed for measurement in ethanol extracts of human plasma. Iodinated hormone was prepared with the use of the chloramine-T method, and antibodies were developed in rabbits over a six-month period with a GnRH synthetic copolymer immunogen. A Scatchard plot revealed at least three species of antibody. The assay can measure conservatively at the 5 pg. per milliliter level and shows no cross-reactivity with other available hypothalamic and pituitary hormones. The releasing hormone was quantitatively recovered from human plasma with immunologic identity to native hormone. Unextracted plasma could not be used because of nonspecific displacement. The measurement of GnRH in individuals receiving 100 μg of intravenous bolus infusions of the synthetic decapeptide show extremely elevated values with two half-lives: one of two to four minutes and another of 35 to 40 minutes. In our experiments, we have found measurable GnRH in patients with secondary amenorrhea and at the midcycle in normal women. In the normal cycling woman during the follicular and luteal phases, GnRH was undetectable. In postmenopausal women with extreme hypoestrogenism and markedly elevated luteinizing hormone values, GnRH was also undetectable. No bursts of GnRH could be detected in normal men when sampled every ten minutes over a two-hour period and every two hours throughout the day.

THE STRUCTURAL IDENTIFICATION and synthesis of luteinizing hormone–follicle-stimulating hormone–releasing hormone (GnRH) from porcine hypothalamus[1] has allowed evaluation of the physiology and control of the secretions of pituitary gonadotropins. However, the elucidation of significant information depends to a major extent on a sensitive and specific assay for GnRH itself. Several groups have already reported an immunoassay for GnRH,[2–4] while Malacara and associates[5] have developed significant biological and clinical data with the use of a bioassay for evaluation of feedback control of this hormone. We would like to report a sensitive and specific radioimmunoassay for GnRH and measurement in normal human men and women as well as in clinical conditions such as postmenopausal syndrome and secondary amenorrhea and relate this to control of gonadotropin secretion.

Material and methods

Synthetic GnRH as well as a human luteinizing hormone (LH) immunoassay kit, human growth hormone, and a reference pituitary preparation of LH and follicle-stimulating hormone (FSH) (LER-907) were obtained from the National Institutes of Health, Hormone Distribution Section. Thyrotropin-releasing hormone (TRH) was obtained from Beckman Instrument Company and porcine adrenocorticotropic hormone (ACTH) from Calbiochem. Chromatographically pure human chorionic gonadotropin (HCG, 5,700 I.U. per milligram by Second International Reference Preparation for human menopausal gonadotropin) was

prepared in our laboratory from crude urine pregnancy preparations obtained from Organon (3,000 I.U. per milligram by Second Internation Reference Preparation for human menopausal gonadotropin).

A synthetic copolymer of glutamic acid, lysine, alanine, and tyrosine (GLAT) with a molecular weight of 30,000 in the molar proportion 0.36, 0.24, 0.35, and 0.05 was a kind gift of Jefferson Medical College, Department of Biochemistry. Sephadex media was obtained from Pharmacia Fine Chemicals, I^{125} from Amersham Searle, Freund's adjuvant from Difco, and egg albumin and rabbit gamma globulin from Pentex. Chloramine-T, sodium metabisulfite, benzidine, sodium azide, ethanol, and other salts and solvents were obtained from Fisher Scientific and were ACS grade or better. A Nuclear Chicago Model 1185 gamma counter was used to monitor radioactivity. Amino acid analysis was performed on a BioCal Model 200.

Coupling of GnRH to synthetic immunogen (GLAT). A synthetic copolymer was used for coupling rather than a biologically derived protein (albumin) to allow quantitation of bound GnRH. GnRH was covalently coupled to GLAT via bisdiazo reaction. GnRH (500 mg.) and GLAT (710 mg.) were dissolved in 2 ml. of sodium borate 0.3M, pH 9 (molar ratio GnRH:GLAT = 15:1). The diazobenzidine was prepared by addition of two 100λ aliquots five minutes apart from sodium nitrite, 400 mg. per milliliter in H_2O, to ice-cold benzidine, 30 mg. in 10 ml. of 0.05M HCl. Three 100λ aliquots of the reacted benzidine-HCl solution were then added to the GnRH mix, five minutes apart. After an additional 30 to 45 minutes in the cold the solution was applied to a G-25 fine column (2.0 × 30 cm.) and eluted with ammonium bicarbonate 0.05M, pH 7.8. The initial yellow protein peak at the void volume as per optical density 280 mμ was collected, lyophilized, and stored. Amino acid analysis revealed 6 moles of GnRH per mole of GLAT.

Immunization. New Zealand white rabbits, 2.5 kilograms, were given intramuscular injections of an emulsified mix of 0.5 ml. of Freund's complete adjuvant and 0.5 ml. of Krebs-Ringer buffer containing 100 μg of the GLAT-GnRH complex every three to four weeks for five months. Generation of workable antisera (titer > 1:1,000) was achieved between three to six months in several rabbits. Animals were bled every two to three weeks and plasma titered as described below.

Iodination. Iodination was carried out by the method of Hunter and Greenwood.[6] To 1 mc. of I^{125} was added 25 λ of 0.4M phosphate buffer, pH 7.5, followed by 2 to 5 λ of a 1 mg. per milliliter solution of GnRH (1 to 2.5 μg), followed by 5 λ of 3 mg. per milliliter chloramine-T solution and 60 seconds later by 250 λ of an 0.12 mg. per milliliter Sodium Metabisulfite solution. The GnRH, chloramine-T, and metabisulfite were all dissolved in 0.1M phosphate, pH 7.5. The iodinated material was then developed on a 0.9 × 75 cm. column of G-25 fine Sephadex and eluted with a 0.1M phosphate buffer, pH 7.5, containing 1 mg. per milliliter egg albumin and 0.1 per cent sodium azide. Approximately 200 tubes of 0.6 ml. fractions were collected, and 10 λ samples were aliquoted from each tube and radioactivity counted. Then 0.5 ml. of a 1/1,000 dilution of antibody was added to the same tubes, incubated at 20 degrees C. for 24 hours and precipitated with 0.5 ml. of saturated ammonium sulfate. Free GnRH I^{125} had less than eight per cent precipitation while bound GnRH or gamma globulin was quantitatively precipitated. Tubes were centrifuged after 30 minute incubation, supernatant removed, and the pellets resuspended in 1 ml. of 50 per cent ammonium sulfate. They were then recentrifuged for ten minutes, supernatant removed, and the pellets counted. Specific activity of immunologically active GnRH ranged from 60 to 500 μc per microgram or from 0.1 to 0.3 moles I^{125} per mole GnRH. This simple precipitation method could not be used in plasma because of nonspecific effects.

Standard curve. The displacement curve was generated in a total volume of 0.5 ml. by addition of GnRH I^{125}, 250 λ (approximately 5,000 counts per minute, 6 pg. of GnRH) in 0.1M phosphate buffer, pH 7.4, with 0.25 mg. per milliliter of carrier rabbit gamma globulin, ethylenediaminetetracetic acid (EDTA), 0.01M, and 0.1 per cent sodium azide). To this was added cold GnRH in a volume of 200 λ followed by 50 λ antibody in a 1 to 400 dilution (final running dilution of 1 to 4,000). Plasmas were worked up by extraction of 0.5 ml. with 1.5 ml. of ethanol followed by air drying of the supernatant ethanol extracts. This took approximately two hours, after which the residue was reconstituted in 200 λ of buffer to which GnRH I^{125} and antibody were added as above. The extraction of GnRH I^{125} by ethanol was routinely over 95 per cent, and thus no correction was made for extraction efficiency. After 24 hours incubation at room temperature, 100 λ of goat antirabbit gamma globulin was added to each tube and allowed to incubate overnight at four degrees C. The tubes were then centrifuged for 20 minutes at 3,000 r.p.m., supernatant removed by vacuum, and the pellets counted on the gamma counter. For the specificity studies, identical procedures were used with other hormones replacing unlabeled GnRH.

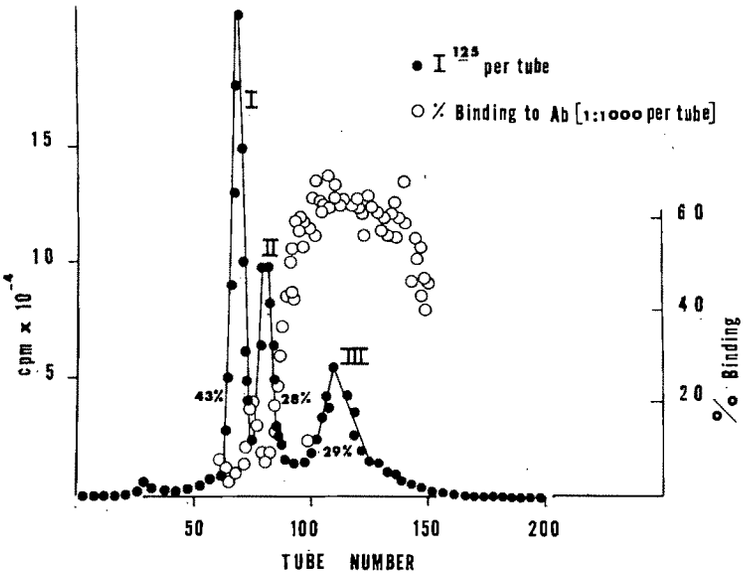

Fig. 1. Separation by Sephadex G-25 fine chromatography of GnRH iodination mix into I^{125} *(peak I)*, damaged GnRH *(Peak II)*, and immunologically active GnRH I^{125} *(peak III)*.

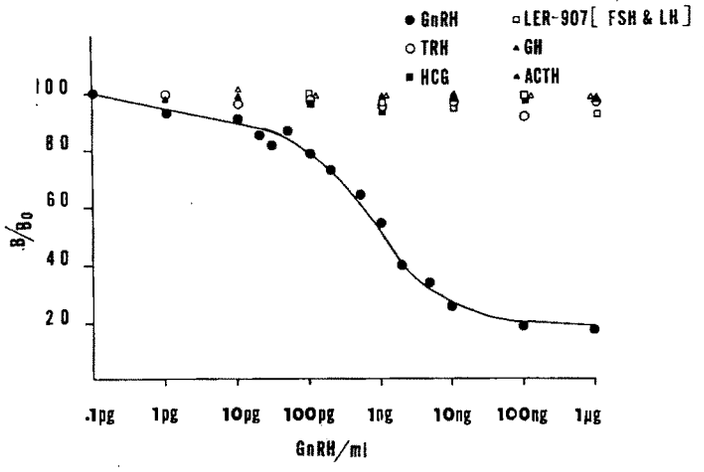

Fig. 2. Displacement of GnRH I^{125} from antibody with added GnRH or pituitary or hypothalamic hormones. Results are expressed as the ratio of amount bound at each point *(B)* to the initial point B_o (no added hormone).

LH immunoassay was performed by the double antibody method of Odell, Ross, and Rayford.[7]

Patient selection. Heparinized blood was collected randomly (10 A.M. to 3 P.M.), refrigerated within 15 minutes, spun down at 1,000g up to two hours later, and plasma stored at zero degrees C. until assay. Normal men (nine subjects) and women (eight subjects) were laboratory and medical school personnel (ages 22 to 38 and age 19 to 37, respectively). Normal female blood was drawn in both the follicular and luteal phases as well as midcycle as judged by basal body temperature and subsequently by LH rise in two patients. The patients with secondary amenorrhea (five subjects, age 20 to 28) had no history of drug use, weight loss, anorexia nervosa, significant psychologic disturbance or personality disorder, galactorrhea, diabetes, or hyperthyroidism. All were outpatients with amenorrhea of three to six months' duration with estrogen deficiency as judged by vaginal cytology. The postmenopausal women (eight subjects) were all nonhospitalized, ambulatory patients, ranging in age from 51 to 69. Half of the patients in this group complained of hot flashes. No patient was on any medication for up to two months prior to this study.

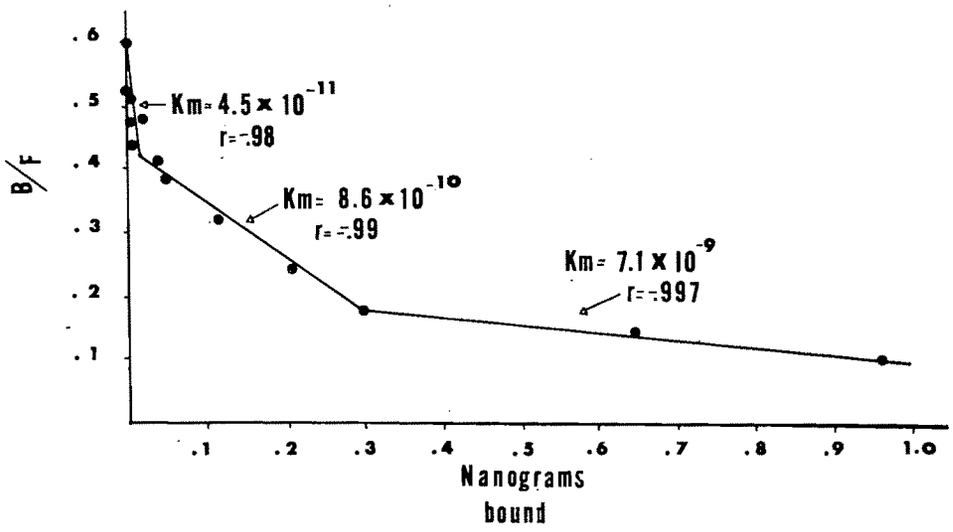

Fig. 3. Scatchard plot derived from Fig. 2. is expressed as ratio of antibody bound *(B)* and free *(F)* GnRH I^{125} versus nanograms bound per assay tube. *Km* is the dissociation constant between GnRH and antibody for each phase of displacement and *r* is the statistical correlation coefficient for the derived straight line. Three sets of antibody sites are presumed from this data.

Results

Iodination. Separation of the iodination mix on G-25 Sephadex fine gave three distinct peaks (Fig. 1). Peak 1 had identical chromatographic mobility as I^{125} on Whatman paper 3 MM with the use of a 0.1M phosphate buffer in a simple wick chromatography system.[8] Peaks 2 and 3 had identical mobility on wick chromatography, but only Peak 3 bound to antibody. Peak 1 was assigned to I^{125}, Peak 2 to damaged GnRH, and Peak 3 to GnRH I^{125} tracer with binding activity. Other investigators[9] have reported heterogeneity of iodinated GnRH and formation of "damaged" polymers. It should be stressed that our material has constant specific activity across the binding peak; that is, the counts bound per total mass of I^{125} per tube are identical. This is a major criterion of chemical purity, buttressing the fact that Peak 3 is immunochemically pure across all of its tubes without further purification necessary. This differs from the results of Arimura and associates[4] in which several ion-exchange purification methods were necessary to obtain more active material.

In some runs the efficiency of iodination was so good that the initial free iodide peak was absent, and only damaged and active GnRH was present. Slightly higher specific activity could be obtained if the column was developed at four degrees C. as opposed to room temperature (20 degrees C.), Approximately 20 tubes from Peak 3 were frozen at zero degrees C., thawed individually on the day of assay, and the remainder discarded. Iodinations were carried out at least once per month to maintain high specific activity. The efficiency of iodination (production of immunologically active material) ranged from 20 to 50 per cent of total iodide added.

Standard curve. Antibody from one animal at a titer of 1:4,000 (final dilution) bound 35 to 40 per cent of tracer with significant displacement with the use of unlabeled GnRH (Fig. 2). No displacement could be achieved with the use of TRH, HCG, LER-907 (a standard gonadotropin reference preparation containing LH and FSH) and human growth hormone, and ACTH.

The antibody thus had a significant degree of specificity. Cogeners of GnRH were not available for testing which could have provided significant further information on the sequence specificity of the antibody.* However, neither TRH nor other pituitary hormones cross-reacted. It can also be seen from the Scatchard plot in Fig. 3 that three distinct series of lines are generated with the use of the data in Fig. 2. This indicates that the antisera contain at least three distinct species of antibody which recognize GnRH over a 150-fold range in affinity. The sensitivity of the assay varied between less than 1 to 5 pg. per milliliter and the curves were easily reproducible.

Recovery. While these results indicated that our

*A total of eleven derivatives supplied by Parke, Davis & Co. and Abbott Laboratories have subsequently shown specificity to the C-terminal tripeptide amide (-Arginine-Proline-Glycine amide).

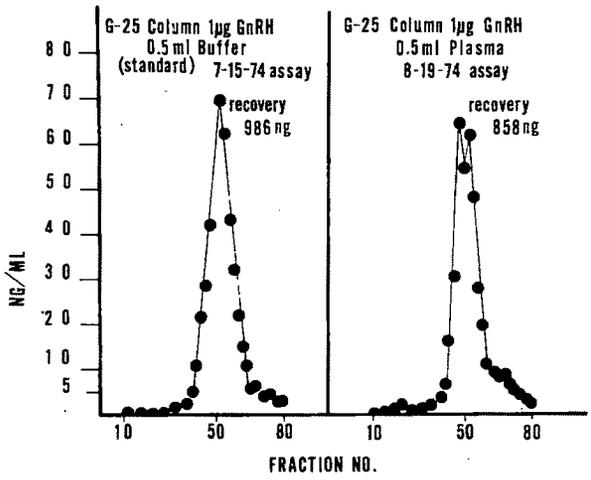

Fig. 4. G-25 fine chromatography of GnRH added to buffer or plasma to evaluate presence of binding proteins and recovery of added material.

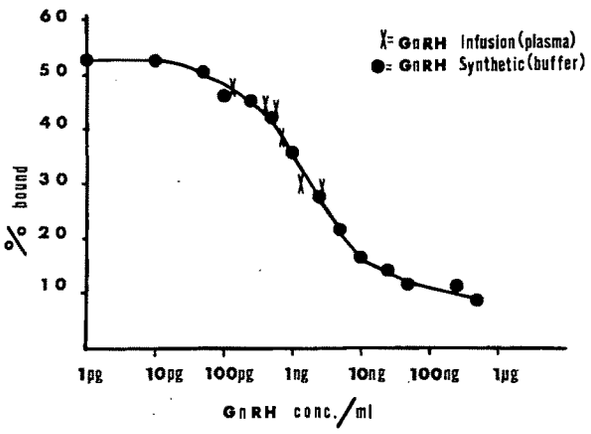

Fig. 5. Standard displacement curve with dilutions of plasma derived from a GnRH infusion to illustrate immunochemical identity.

system had immunologic specifity, two recovery experiments were performed to show identity between GnRH in plasma and buffer.

GnRH measured in unextracted dialyzed plasma still gave significantly high blank values in the nanogram range. Thus, it was important to establish that measured immunochemical GnRH had a chemical identity to synthetic GnRH to rule out measurement of several different cross-reacting species. A purposely large 1 µg load was added to plasma to saturate any carrier proteins and show any binding to higher molecular weight material. Sephadex G-25 chromatography was performed in the identical calibrated 0.9 × 60 cm. column to calculate not only recovery but evaluation of other immunologically active material from the elution position. As seen in Fig. 4, the plasma and buffer GnRH were quantitatively recovered from the column in identical positions without any evidence of binding to higher molecular weight components. The absence of multiple components in the chromatography experiments points to a species of immunologically measured GnRH in plasma with a molecular weight similar, if not identical, to synthetic GnRH.

In addition, immunologic identity of plasma hormones to unlabeled hormone in buffer was evident with the use of plasma from a GnRH infusion study containing 8 ng. per milliliter (Fig. 5). These diluted identically to the standard buffer curve. Thus, GnRH recovery and immunologic identity of plasma GnRH, as well as specificity, seems inherent to our system.

GnRH infusion. The measurement of GnRH in individuals receiving a 100 µg intravenous bolus infusion is shown in Fig. 6. The disappearance rate of GnRH is usually rapid with half-lives of approximately two to four minutes for one phase and 37 minutes for the second phase. These disappearance rates are so rapid, in fact, that considerable difficulty would be encountered in measuring small hypothalamic secretions. The 30 minute phase occurs after over 90 per cent of the material has been removed from plasma.

Patient data.

Plasma levels of GnRH in both normal men and women (follicular and luteal phases) were less than 5 pg. per milliliter (Fig. 7). In addition, no periodic secretion could be detected in normal men in samples drawn every two hours from 9:00 A.M. to 11:00 P.M. or every ten minutes over a two-hour period. Levels in postmenopausal women were undetectable. In contrast to this four of five individuals with secondary amenorrhea but normal LH had very significant measurable levels ranging from 6 to 26 pg. per milliliter. Two individuals on the day of ovulation as judged by basal body temperatures and LH rise also had elevated values.

Comment

GnRH can be measured conservatively in either buffer or plasma at the 5 pg. per milliliter level with this assay. Recovery of unlabeled material added to plasma was essentially quantitative and plasma GnRH diluted identically to the buffer curve. The immunologic identity, as well as recovery and specificity, define a workable assay. It should be stressed that GnRH cannot be measured in this system on unextracted plasma since significant nonspecific cross-reaction (that is, displacement) occurs which is dose related to the amount of plasma utilized. The normal of less than 5 pg. per milliliter becomes "1,000 t

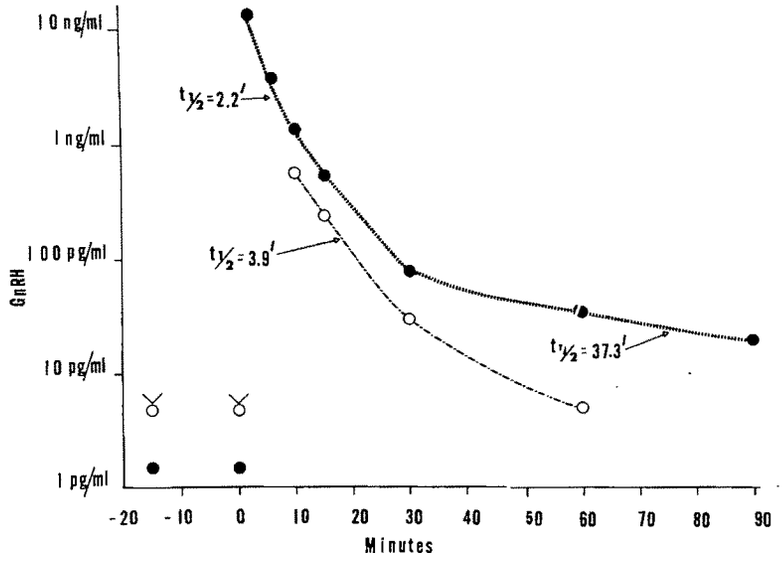

Fig. 6. GnRH infusion in two patients illustrating 1,000-fold rise from basal levels with rapid decrement. $t_{\frac{1}{2}}$ = half-life.

2,000" pg. even in GnRH free dialyzed plasma. Unlike TRH, however, which undergoes a time-dependent destruction in plasma,[10] GnRH is remarkably stable in plasma or serum at 20° to 25° C. for at least 48 hours and at 4° C. for 96 hours as judged by recovery of added unlabeled GnRH to plasma or serum.

GnRH is easily measured during bolus infusion studies with a two-component disappearance curve: one $T_{\frac{1}{2}}$ two to four minutes and the other 35 to 40 minutes. Because of the extremely rapid disappearance of the bulk of the material it would be extremely difficult to measure random samples even in acute GnRH bursts. Indeed, even with a massive 100 μg bolus infusion the return to normal levels is virtually complete at approximately 60 to 90 minutes.

Good evidence exists for a physiologic role for GnRH. Its rise is consistent with the midcycle LH surge as shown by us and others[11, 12] and the testicular atrophy shown in male rabbits immunized to GnRH.[4] Also, it has been shown that ovulation can be blocked in rats with the use of GnRH antiserum.[13] In our assay normal levels of GnRH are undetectable (less than 5 pg. per milliliter) in normal men and cycling women, except during the midcycle. These results are in agreement with those of Jeffcoate and co-workers[2] (less than 20 pg. per milliliter) and Arimura and associates[4] (less than 10 pg.) but differ from the initial preliminary values of Keye and colleagues[14] (50 to 80 pg/ml). However, the latter investigators used unextracted plasma and some nonspecificity may have resulted in a higher value.

What is surprising is our inability to detect circulating levels in postmenopausal women in the face of elevation in patients with secondary amenorrhea and midcycle peaks. Similarly, bioassayable GnRH could be detected by Seyler and Reichlin[15] in only seven of 36 samples from postmenopausal women; yet, elevated levels were found by the same investigator in women in midcycle, estrogen-treated men, and long-term castrated patients[16] with the same assay.* Since pituitary gonadotropins are secreted episodically with a periodicity of one and one-half to two hours.[17] peak to peak, presumably the result of GnRH bursts,[18] it is possible that random samples would not detect elevated values of the releasing hormone because of the rapid disappearance rate. It is to be stressed that GnRH with a $T_{\frac{1}{2}}$ of two to five minutes can cause secretion of LH and FSH with significant prolonged disappearance rates ($T_{\frac{1}{2}}$ of at least 30 and 90 minutes[19]) so that the effect of small amounts of GnRH can be amplified many times at the pituitary level. Thus, the periodicity of GnRH may be significantly less than the one and one-half to two hours of gonadotropin secretion. Indeed, the initial data of Seyler and Reichlin[20] indicate that with sequential testing during one day, bioassayable GnRH is not necessarily associated with peak LH bursts. We could not detect differences in normal individuals sampled every two hours from 9:00 A.M. to 11:00 P.M. or every ten minutes for a two-hour period.

*Subsequent to submission of our paper, Bolton (J. Endocrinol. 63: 255, 1974) detected no difference in urinary excretion of GnRH between normal men, postmenopausal women, and patients with Klinefelter's syndrome, which further substantiates our results.

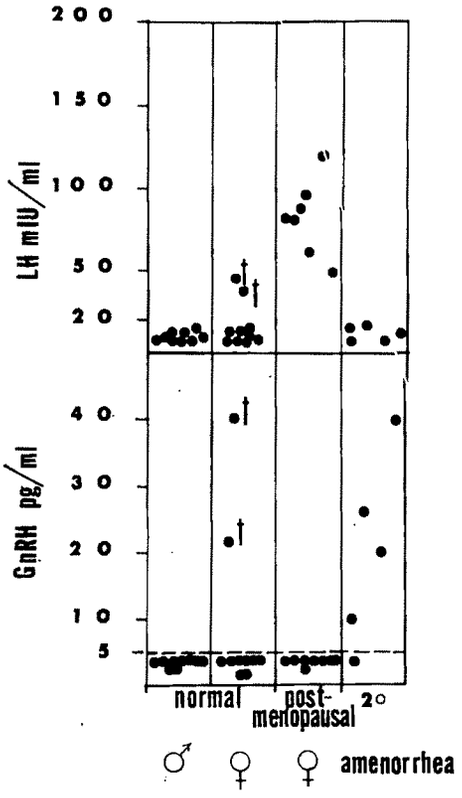

Fig. 7. GnRH and LH values in normal men, women during the follicular, luteal, and midcycle (†), postmenopausal women, and patients with secondary amenorrhea. The dotted line at 5 pg. per milliliter represents the limit of detectability.

The presence of significant random elevations of GnRH in four of five consecutive patients with secondary amenorrhea unassociated with previous medication, weight loss, anorexia nervosa, thyrotoxicosis, or diabetes mellitus stands in significant contrast to the low unmeasurable levels of post-menopausal women. It is clear that if one assumes a purely random oscillation or intermittent periodic bursts of GnRH it would be at best equally unlikely to measure elevated hormone levels in those individuals with secondary amenorrhea. Since the elevations were, indeed, noted on random blood specimens in each case, we feel that our patient data are not explainable simply by the vagaries of random measurement.

It is well known that low-dose estrogen can sensitize the pituitary to exogenous GnRH.[21] The absence of measurable GnRH in postmenopausal patients in the face of markedly elevated gonadotropins would point to pituitary sensitivity as a significant modulating if not controlling factor to the secretion of gonadotropins. However, our estrogen-deficient patients with secondary amenorrhea had elevated GnRH with associated normal LH levels: (normal mean 12.6, range 8.1 to 16.0; secondary amenorrhea mean 14.1, range 10.5 to 19.0, no significant difference). Individuals with secondary amenorrhea and low LH have been reported to have a hypothalamic defect[22] since exogenous GnRH stimulation gives significant pituitary stimulation in the face of low basal and absent episodic secretion of LH. However, our patients did not fall into those clinical states usually associated with hypothalamic amenorrhea such as, psychogenic amenorrhea, acute weight loss, postpill amenorrhea, or anorexia nervosa, nor did they have low basal gonadotropins. Further studies defining the hypothalamic-pituitary axis such as pituitary response and feedback control of GnRH in these patients must be done to define the possible cause of elevated GnRH. These data on normal men and cycling women and patients with secondary amenorrhea provide a point for further evaluation of the hypothalamic pituitary axis in man and with more extensive studies can result in important biological information on the control of secretion of gonadotropins in health and disease.

Incidence of cervical cancer in perimenopausal and postmenopausal women detected by Papanicolaou smears

RALPH M. NEIGHBOR, M.D.
ROBERT L. NEWMAN, M.D.
Kansas City, Missouri

This paper concerns itself with the prevalence of abnormal Papanicolaou smears in women 40 years of age or older. They are considered in two groups, i.e., perimenopausal (40 through 49) and postmenopausal (50 or more). In the perimenopausal group, the incidence of abnormal smears was higher than in a central population of women of all age groups. Abnormal smears were less than half as common in the postmenopausal group. Invasive cancer was four times greater in the perimenopausal group and two times greater in the postmenopausal group.

IT IS THE PURPOSE of this paper to present statistical data concerning abnormal cervical cytologic findings in two limited samples of individuals in the perimenopausal and postmenopausal age groups.

The Papanicolaou smear of the uterine cervix is the modern woman's first defense against death from cancer of this organ. Before its advent, deaths in the United States from cancer of the breast and cervical malignancy were virtually equal. At this time, death from cervical cancer has been reduced to two fifths the rate of death from breast cancer, because of the widespread use and acceptance of the Papanicolaou smear. Procope[1] points out that of 1,085 postmenopausal women who presented with postmenopausal bleeding, 28 per cent were of malignant etiology, one half of these being due to cervical cancer.

Material and methods

In September, 1966, an ongoing cervical cancer detection program was initiated by the St. Luke's Foundation at St. Luke's Hospital of Kansas City. The specimens are obtained through obstetric and gynecology clinics associated with the residency training program at St. Luke's Hospital and the Kansas City, Missouri, Family Planning Agency. The data collection form is portrayed in Fig. 1 and is designed to supply not only pertinent information believed to be important concerning etiologic theories of carcinoma of the cervix but also adequate personal data to allow the social work staff to seek out patients with abnormal smears for appropriate follow-up.

Single slides are prepared for each patient from samples of the squamocolumnar junction taken with a wooden spatula. These are preserved with a fixative spray. All smears are screened by cytotechnologists, with abnormal smears being categorized by a pathologist. All abnormal smears are reviewed by the Department of Obstetrics and Gynecology, and appropriate further diagnostic procedures are decided upon. The staining of the smears is by the standard Papanicolaou technique.

The smears are classified in any one of three categories, according to the absence or presence of abnormal cells. These categories are: (1) negative, meaning no abnormal cells were seen; (2) positive, meaning abnormal cells were seen; and (3) suspicious, meaning no frankly abnormal cells were seen, but all cells were not perfectly normal.

The two patient populations of particular interest in this paper are: (1) the perimenopausal group, which are defined as those women 40 through 49 years old;

Positive smears per 1,000	6.8	(21)	4.5	(6)	5.0	(339)

and (2) the postmenopausal group, which are defined as those women 50 years of age and older.

Results

In order to assess the adequacy of the samplings, a distinction has been made between initial smears and subsequent smears from the same individual. The subsequent smears have been designated as "repeat" and should reflect newly developing lesions as well as those that escaped detection on the initial examination. Table I reflects these results as suspicious and positive smears per thousand examinations in the age groups outlined above, also contrasts the initial and repeat examinations, and gives a summation of all smears obtained.

Table II shows the tissue diagnoses obtained on further evaluation of those individuals with suspicious and positive smears. The designation "no follow-up required" deserves some explanation. This category pertains to those smears in which the presence of parabasilar cells precluded their designation as negative smears. This situation is compatible with inadequately estrogenized epithelium, and these 49 smears "cleared" after exogenous estrogen administration. Those individuals whose smears were "cleared" in this manner were not subjected to further diagnostic procedures.

Table III reveals the incidence of cervical neoplasia in the various age groups per thousand smears.

Table II. Tissue diagnoses of abnormal smears

	Age group	
	40-49	*50 and over*
Suspicious		
Invasive	1	1
Carcinoma in situ	4	1
Dysplasia	12	1
Nonmalignant	5	0
NFR*	37	12
Pending	5	1
Total smears	65	16
Positive		
Invasive	1	4
Carcinoma in situ	16	2
Dysplasia	2	0
Nonmalignant	2	0
Total smears	21	6

*Follow-up required (see text for explanation).

Table III. Incidence of cervical neoplasia (expressed as cases per thousand smears)

	Invasive carcinoma	*Carcinoma in situ*	*Dysplasia*
Through 39 years	0.077 (5)	4.9 (321)	4.9 (301)
40 through 49 years	0.65 (2)	6.5 (20)	4.5 (14)
50 years and over	3.7 (5)	2.2 (3)	0.74 (1)
All smears	0.18 (12)	5.0 (344)	4.6 (316)

Comment

The results indicate that the perimenopausal age group demonstrates a slightly higher incidence of abnormal smears than the total population, whether they are suspicious or positive. The postmenopausal age group displays an incidence of positive smears about equal to that in the total population; however, the incidence of suspicious smears appears to be reduced. The apparent reduction of incidence in all cases when the initial and repeat screenings are compared may indicate to some degree the efficacy of the technique employed.

Of note in Table II is the wide variety of tissue diagnoses in the suspicious group, while the positive group consists mainly of carcinoma in situ and invasive carcinoma.

An attempt is made in Table III to determine the incidence of the various stages of neoplasia on the basis of the smears performed. Invasive carcinoma was seen in the postmenopausal group 21 times as often as in the total population, while the perimenopausal group demonstrated invasive carcinoma four times as often as the total population. Carcinoma in situ in the perimenopausal group was similar to that in the total population; however, this manifestation was present

less than half as often in the postmenopausal group. The occurence of dysplasia was again similar in the perimenopausal group and the total population, with the postmenopausal group showing dysplasia one sixth as often.

In a computerized study of 137,877 smears, von Hamm and Nikolewski[2] accumulated 18,064 smears from women in the perimenopausal age group. Of these, 60 were suspicious (0.37 per cent) and seven were positive (0.04 per cent). In the postmenopausal age group, 5,193 smears were accumulated with thirteen suspicious smears (0.25 per cent) and seven positive smears (0.13 per cent). Their entire study yielded 306 suspicious smears (0.27 per cent) and 27 positive smears (0.02 per cent). The frequency of abnormal smears in their study is of a much lower magnitude than that presented here. The descrepancy is probably due to the fact that their study population consists of spouses of armed services personnal, while ours is an indigent population. Indigent populations are commonly thought to be at greater risk to develop cervical neoplasia.

Conclusions

The data presented appear to justify the following statements when comparisons are made with the total population: (1) The perimenopausal years hold a slightly greater risk for development of an abnormal smear; (2) the perimenopausal years hold a distinctly greater risk of invasive carcinoma (fourfold); (3) the postmenopausal years hold less risk for development of an abnormal smear; (4) the postmenopausal years hold a decreased chance of carcinoma in situ and a much reduced incidence of dysplasia; (5) the postmenopausal years hold a much greater risk of invasive carcinoma (twenty-one–fold).

The interpretation and significance of the fractional postcoital test

DONALD R. TREDWAY, M.D., PH.D.*

Los Angeles, California

This investigation was designed to objectively determine the clinical usefulness of the fractional postcoital test. Forty-three normal subjects had midcycle cervical mucus collection at various times after insemination. There was a significant correlation between the number of motile sperm at the internal os level and the total sperm count within the cervical mucus. The median internal os count was 15 motile sperm per high-power field with a lower 95 per cent confidence limit of five motile sperm per high-power field. Therefore, the fractional postcoital test is useful clinically as it is a physiologic indication of sperm transport in cervical mucus.

THE CLINICAL postcoital evaluation of midcycle cervical mucus of infertile couples is widely practiced. Reasons for the frequent use of this test are: (1) the cervical mucus is the only readily obtainable secretion from the female genital tract; (2) it is only by examining the cervical mucus for spermatozoa that any direct information about the adequacy of insemination can be obtained; and (3) this examination provides information as to how the sperm are interacting with the female secretions.

Sobrero and MacLeod[1] have demonstrated the rapidity of sperm transport to the cervix. In their subjects spermatozoa were found to be present in the cervical mucus as soon as the observer could make his first examination (90 seconds) following normal coitus. It has also been shown that, providing large numbers of actively motile sperm are found in the cervical mucus, the semen analysis of the husband usually is normal.[2] This highly positive degree of correlation between the sperm quality in the cervical mucus and in the ejaculated semen makes it possible to utilize the postcoital test (PCT) as an adequate screening method of sperm penetration in the diagnostic survey of infertile couples. When no sperm or only spermatozoa of poor quality are present in the cervical mucus, however, no definite conclusions can be drawn as to the quality of semen.

The interpretation of what constitutes a positive PCT varies among different investigators. The range of a normal test in reference to the number of sperm varies from one motile sperm per high-power field to 20 or more.[3–5] Davajan and Kunitake[6] emphasized the importance of finding motile sperm in cervical mucus removed from the level of the internal cervical os. They concluded that the number of sperm at the level of the internal os is a more rational test than the number of sperm at the external os as originally described by Sims[7] and Huhner.[8] Davajan and colleagues[9] have attempted to standardize this evaluation by means of a fractional PCT. By comparing fertile and infertile women they noted that in the former the number of sperm per high-power field in cervical mucus ranges from 7 to 15 at the internal os level (2.5 cm.). These investigators have stated that the presence of five or more highly active sperm per high-power field at the internal os level constitutes a normal PCT.

Since the fractional PCT represents a very practical method for evaluating one possible etiology of infertility, a study was undertaken to further characterize and quantitate the fractional PCT. This report represents an extension of preliminary data concerning sperm transport in the human female reproductive tract at

midcycle[10] which has been presented in detail in a doctoral dissertation.[11] A study regarding the optional time for performing the postcoital test has been previously reported.[12]

Materials and methods

The study group consisted of 43 women, with a history of regular menstrual cycles, whose ages ranged from 21 to 42 years. The investigation took place at midcycle and the cervical mucus spinnbarkeit was greater than 8 cm. in all subjects at the time of insemination. All 43 subjects were examined prior to insemination to ensure the absence of extraneous sperm in the cervical mucus.[10, 11] Each of the study cycles was presumed to be ovulatory on the basis of spontaneous menses after an appropriate luteal phase and/or elevated luteal serum progesterone.

Insemination with fresh semen was performed in a group of 38 subjects. The technique of vaginally inseminating via a syringe has been described in detail previously.[10–12] The five patients who were not inseminated were seen at varying times after natural coitus.

From 5 minutes to 48.8 hours after insemination or coitus, the cervical mucus column was removed by the technique of Davajan and Kunitake.[6] The portio vagina of the cervix was carefully cleansed with a cotton swab. Then a sterile polyethylene catheter, 3 mm. in diameter (standard intravenous connecting tubing), was inserted in the endocervical canal without contamination from the vaginal contents. Advancement of the catheter to the level of the internal os was done while gentle suction was applied to the tubing by a syringe. The ratched clamp used to advance the tube was closed, the tubing was removed from the endocervical canal, and any remaining mucus at the tip of the tubing was cut. In this fashion, cervical mucus present at the tip of the tubing represented that at the level of the internal cervical os and that closer to the syringe represented mucus at the level of the external os. The number of sperm and the per cent motility at the level of the internal os was determined by direct microscopic observation of the mucus in the distal 2 mm. of tubing at 400× magnification. The cervical mucus remaining in the tubing was then dissolved in a mucolytic solution.[11]

The assumptions of the analysis of variance could not be satisfied in this investigation since the sperm count at the internal cervical os level was determined on the ordinal scale. Consequently nonparametric (ranking) and graphic data analysis were done.[13, 14] The data presented were analyzed nonparametrically by Kendall rank correlations and graphically by rankit methods.

†Internal cervical os level.

Results

The sperm count of the internal cervical os level (distal 2 mm. of the polyethylene tubing) and the total number of cervical mucus sperm remaining in the polyethylene tubing at various times after insemination are presented in Table I. The ranking scale of each sperm count is also listed in Table I. Note that on an ordinal scale of measurement, > 30 sperm per high-power field has a higher rank than > 10 sperm per high-power field.[13] It has been reported previously that the cervical mucus sperm count of the subjects

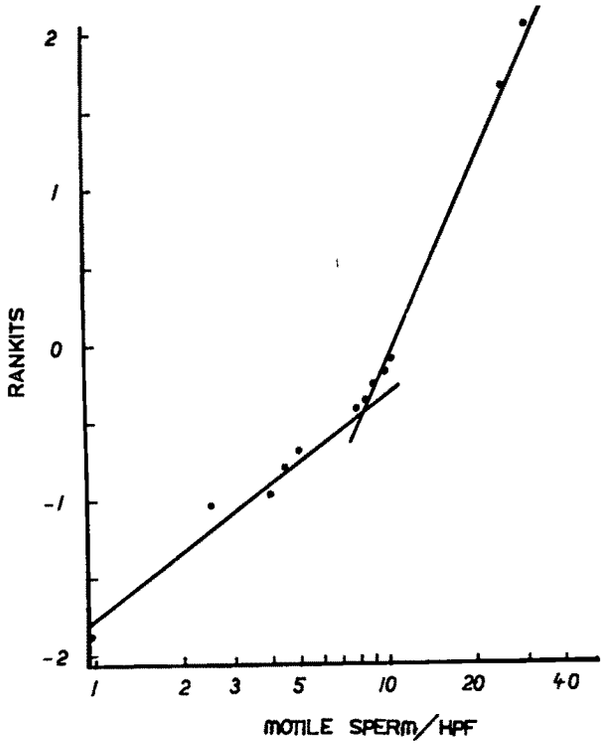

Fig. 1. Number of motile sperm per high-power field at the internal cervical os. Linear transform method (rankits) reveals two different populations. The first group is characterized by a median collection time of 1,440 minutes after insemination; the second group is 60 minutes (N = 43).

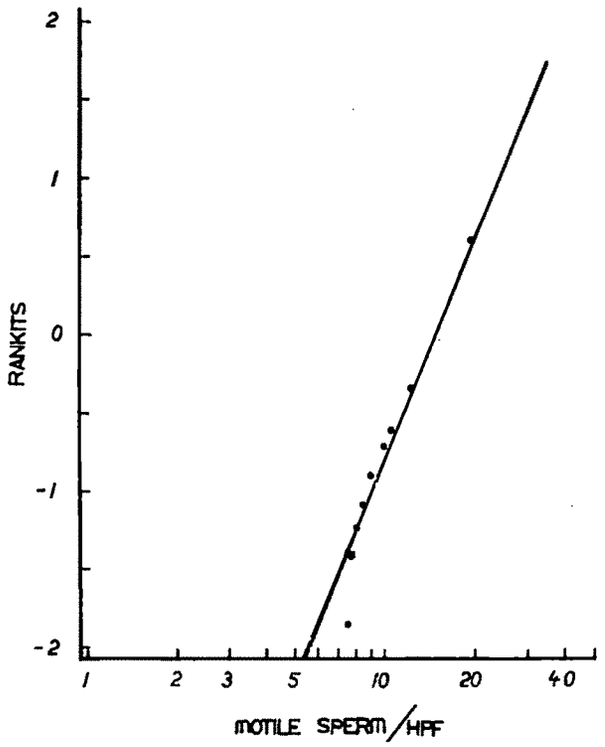

Fig. 2. Number of motile sperm per high-power field at the internal cervical os in group 2 (N = 32).

after natural coitus corresponds to that of those inseminated via the syringe.[12]

With a nonparametric measure of correlation,[13] there is a significant correlation between the internal cervical os sperm count and the total cervical mucus count. The Kendall rank correlation (τ) coefficient is 0.420, which yields a z value of 3.97 ($p < 0.001$). As is evident from Table I, however, three variables are present: internal cervical os sperm count, cervical mucus sperm count, and time. Therefore, the data were further analyzed by the Kendall partial rank correlation ($\tau xy.z$). This partial correlation determined whether a correlation existed between the internal cervical os sperm count and the cervical mucus count with the third variable, time, kept constant. When this condition was satisfied, the correlation was still significant. The Kendall partial rank correlation ($\tau xy.z$) is 0.406 instead of 0.420, which still generates a significant z value of 3.83 ($p < 0.001$).

The internal cervical os sperm counts were then graphically analyzed by a linear transform method. Rankit analysis revealed two different populations for the sperm counts at the internal os (Fig. 1). The two populations differed in the time of collection after insemination. The median collection time after insemination in the first group (11 of the 43 samples) was 1,440 minutes while the second group was 60 minutes. The second group is further characterized by the graphic analysis depicted in Fig. 2. Rankit analysis reveals that the median sperm count at the internal os level is 15 motile sperm per high-power field. The lower 95 per cent confidence limits (2 S.D.) is five to six motile sperm per high-power field. Comparable graphic analysis of the total cervical mucus sperm counts revealed similar populations and a median value of 7.8×10^4 sperm.

Comment

The present investigation was designed to measure sperm and cervical mucus interaction in order to further characterize and quantitate the fractional PCT. Davajan and co-workers[6, 9] demonstrated a difference between the internal cervical os sperm count obtained from fertile and infertile patients with no previously determined etiologic factor. If their statement is true that the number of sperm at the level of the internal cervical os is a reflection of the cervical factors in infertility, then the sperm count at the level of the internal cervical os should correlate with the total sperm count of cervical mucus in normal subjects

irrespective of the time of collection after insemination or coitus. The results of this study reveal a definite correlation between the motile sperm count at the internal cervical os and the total cervical mucus count ($p < 0.001$). This positive correlation confirms the clinical findings of Davajan that the fractional method of testing postcoital cervical mucus is a true reflection of sperm transport in cervical mucus. Consequently, it can be used as an accurate and practical means to diagnose the cervical cause of infertility.

In regard to what constitutes a normal PCT, Davajan originally stated that five or more highly active sperm per high-power field at the internal os level of cervical mucus was normal. Recently, however, he[15] stated that two or more motile sperm per high-power field at the internal os could be normal, since some of his infertility patients have become pregnant with that count. As noted in Fig. 2, the median sperm count at the internal os level is 15 motile sperm per high-power field; however, the 95 per cent lower confidence limit is five motile sperm per high-power field. Therefore, statistically, the lower limit of a normal fractional PCT is five motile sperm per high-power field with 95 per cent confidence. Occasionally fewer than five motile sperm per high-power field will be found in the cycle of conception, but this finding should occur less than 5 per cent of the time.

It has been previously reported that the postcoital examination should be optimally performed within 2½ hours after coitus.[12] This is evident since there is a significant statistical increase in the ratio number of motile inseminated sperm to the number of sperm within the cervical mucus after 150 minutes. Therefore the fractional postcoital test performed within 150 minutes after coitus is useful clinically as it is a physiologic indication of sperm transport in cervical mucus. Provided more than five motile sperm per high-power field are found at the internal os level, the couple has normal sperm transport in the cervical canal. If fewer than 5 motile sperm per high-power field are seen, then the test is abnormal and may account for the infertility. Thus the fractional PCT provides a more precise and easily defined method of determining sperm transport in cervical mucus than the original test described by Sims and modified by Huhner.

The author wishes to acknowledge the assistance of Daniel R. Mishell, Jr., M. D., and Robert M. Nakamura, Ph. D., in the preparation of this manuscript.

Periovulatory changes in ovarian temperature in ewes

HENRY J. BENOIT, M.S.E.E.
RUDI BORTH, D.Sc.
ALLEN R. ELLICOTT, PH.D.*
C. ALLAN WOOLEVER, M.D.
Toronto, Ontario, Canada

Thermistors were implanted in intact ewes, and ovarian and aorta temperatures were recorded for 72 hours following the removal of a progesterone implant intended to induce estrus. Serum levels of luteinizing hormone (LH) were measured hourly over a 10 hour period beginning at the onset of estrus. Ovaries were examined by laparotomy at the end of each experiment. Estrus behavior, LH surge, and a fresh corpus luteum were all found to be present in four, and absent in two, of a total of six experiments. To remove variations in basal body temperature, ovarian temperatures were measured relative to aorta temperature at all times. In the nonovulating ewes, both mean ovarian temperatures varied at random, whereas in the ovulating ewes they decreased by approximately 0.15° C. to reach a minimum 1 hour before the time of maximum rate of increase in LH. The ovulating ovaries differed from the contralateral ovaries (where ovulation did not occur) in two respects: the mean temperature in the ovulating ovaries was lower by 0.02 to 0.10° C. at all times, and its preovulatory decrease began several hours earlier. When taken in conjunction with published data on secretion and on the local and systemic effect of estradiol, these findings are consistent with the hypothesis that ovarian estradiol induces an increase in ovarian blood flow. A heat-sink effect of the uterine mass due to its proximity to the ovaries may also be involved.

HORMONE-DEPENDENT temperature changes known to occur during the ovarian cycle in mammals are of two types which differ in cause, effect, and mechanism. Through central metabolic action, progesterone from the corpus luteum induces the familiar postovulatory rise in basal body temperature which has been extensively studied and widely used for the retrospective detection of ovulation in women.[1] When secreted by the growing follicle at an increasing rate, peaking in sheep 0 to 8 hours before the onset of estrus,[2] estradiol increases blood flow in the reproductive tract, and this change in blood flow, through the mechanism of perfusion and heat removal, induces local temperature changes in the tissues involved.[3-5]

Local ovarian hyperemia is a well-known early effect of gonadotropins on the rodent ovary, and has been used as an end-point in the bioassay of these hormones,[6] but the local temperature change likely to accompany the increase in blood flow—whether induced by the administration of gonadotropins, or physiologically at certain phases of the ovarian cycle—does not seem to have been established. When ovarian temperature was telemetered intermittently over several months in rhesus monkeys, the readings fluctuated by as much as 1.7° C. in any 24 hour period, there was some parallelism with rectal temperature changes, and the investigators concluded that continuous circadian temperature rhythms would be needed before further interpretation.[7]

Reproductive tract temperatures in sheep exceed aorta or basal body temperature by no more than 0.2 to 0.4° C.,[3] and basal body temperature in rhesus monkeys may vary throughout a day by as much as 2° C.[8] Although these data refer to different species, they do

indicate an order of magnitude of the variation to be expected in any one animal. Attempts to detect thermal shifts due to cyclic ovarian function are likely to fail unless the variation in basal body temperature is taken into account.

The design of the present investigation was based on these data and considerations. Its objective was to record ovary temperature bilaterally along with aorta temperature in ewes around the time of ovulation, in order to ascertain whether a cycle-dependent feature in ovarian temperature could be detected when the temperature component dependent on basal metabolism was removed. The significance of such studies lies in the possibility that they may lead to the development of electronic devices for the detection or prediction of ovulation.

Material and methods

Aorta and ovarian tissue temperatures were measured in ewes by means of implanted glass bead thermistors (diameter, 1 to 2 mm.) with hard-wire connections to bridge amplifier circuits, and continuous recording on a strip chart. The system was calibrated with a water-bath over the interval of 34 to

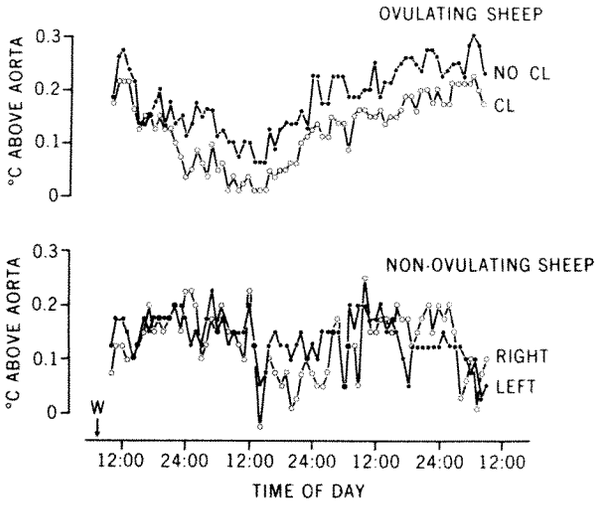

Fig. 2. Ovarian temperature in ewes measured relative to basal body temperature (aorta) after withdrawal of progesterone *(W)* to induce estrus. Plotted points are averages over ovulating ovaries (*CL*, fresh corpus luteum found at laparotomy) and over the quiescent contralateral ovaries *(NO CL)* in four experiments with occurrence of ovulation and over right and left ovaries in two anovulatory experiments.

42° C. Drifts over 15 days of individual bridge amplifier outputs were between 0.005 and 0.080° C.

Five Dorset ewes, 2 to 5 years old and with regular behavioral estrus patterns, were used in six experiments, i.e., one animal (Ewe No. 39C) was used twice (Exps. 2 and 3). The animals were kept at 22° C in individual pens 3 M. square, with lighting adjusted weekly to match the duration of actual daylight.

For the control of estrus, a silicone rubber implant impregnated with progesterone was placed subcutaneously.[9] One week later, surgery was carried out to insert one thermistor probe into the medulla of each ovary, after a pathway was prepared with a 16 gauge hypodermic needle; thermistor leads were sutured to the ovary capsule (Fig. 1, *a* and *b*). A third thermistor was sewn to the exterior ventral wall of the aorta near the uterine-artery branching. Leads were taken through the skin at the flank, and connection to sensor bridges was made through coiled cables permitting complete freedom of movement within the pen.

One week after surgery, the progesterone implant was withdrawn at 9:00 A.M. to induce estrus and recording of three temperature variables (aorta, left ovary, and difference left-right ovary) was begun and continued for 72 hours. Estrus behavior was tested with two rams (one vasectomized, the other intact) at 1 hour intervals beginning 24 hours after progesterone withdrawal and ending either at the onset of estrus or 48 hours after progesterone withdrawal. Jugular blood specimens for assay of luteinizing hormone (LH) were drawn at 1 hour intervals over a 10 hour period beginning at the onset of estrus.

Finally, both ovaries were photographed and examined for the presence of fresh corpora lutea, at a laparotomy carried out either 36 to 60 hours after the onset of estrus or—in ewes not coming into estrus—72 hours after progesterone withdrawal.

For numerical evaluation, average values over successive 1 hour intervals were read from the continuous temperature tracings, and the measurements were expressed for each ovary and hour as degrees Celsius above the corresponding aorta temperature.

The concentration of LH was determined in 200 μl samples of serum according to a double-antibody radioimmunoassay method.[10] The tracer was a purified preparation of ovine LH (Reichert's LER-1056-C2) iodinated with iodine-125. Rabbit antiserum to ovine LH (Niswender's No. 573) was used at a final dilution of 1:800000. The second antibody (antiserum to rabbit γ-globulin) was prepared in our laboratory. A preparation of ovine LH (NIH-S-15) was used as standard, and results were reported as weight equivalents of this standard. Under the conditions used, the detection limit of the assay was 0.5 ng. per milliliter.

Results

Three indicators of imminent or recent ovulation—namely, estrus behavior, LH surge, and a single fresh corpus luteum in one ovary—were all found to be present in four and absent in the other two of the six experiments. Some ovarian adhesions were usually found at laparotomy but there was never any ambiguity in corpus luteum identification (Fig. 1, *c* and *d*). Ovaries which did not contain a fresh corpus luteum were invariably small and unstimulated in appearance, much like those seen outside the estrus season. It is noteworthy that, in this series, no ewe had fresh corpora lutea in both ovaries at the same time. One ewe, which we used twice (Fig. 1) and had scheduled for a third experiment, was found to have become pregnant during the second experiment and had a normal lamb 149 days after estrus.

Temperature tracings showed random variations of ±0.1° C. or less within most 1 hour intervals. Aorta temperature varied between 37.8 and 39.8° C. with a circadian rhythm.

In all ewes, both ovary temperatures were greater than aorta temperature at all times.

Average ovarian temperatures above aorta were calculated in several ways. For the purpose of compar-

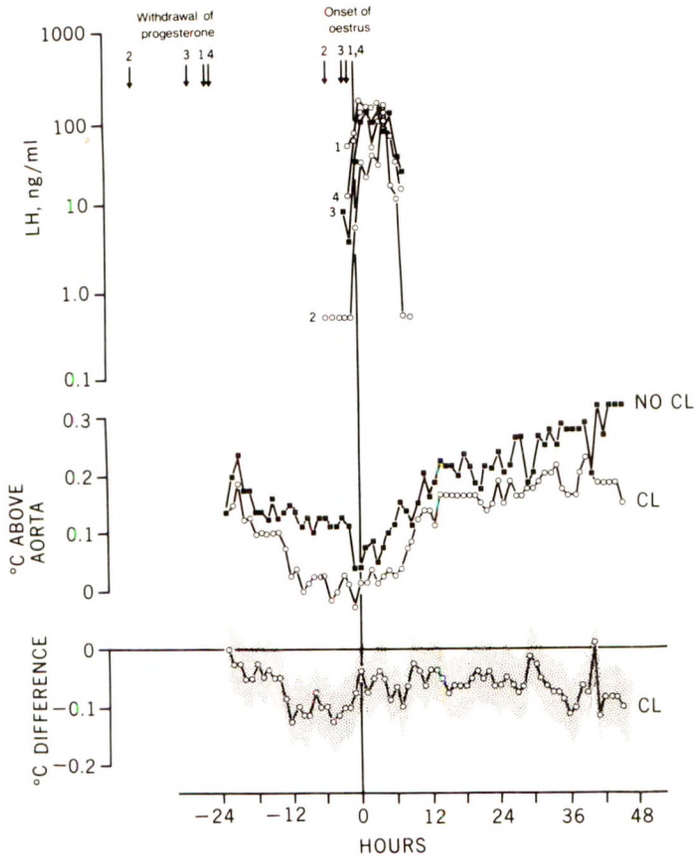

Fig. 3. Ovarian temperature and serum LH level in ovulating sheep (same experiments as in Fig. 2). LH levels, time of onset of estrus, and time of progesterone withdrawal are shown individually for each of the four experiments (1 to 4). The time scale is in hours before and after the time of maximum rate of LH increase indicated by the vertical line at time 0, and the plotted temperature averages over ovulating *(CL)* and quiescent *(NO CL)* ovaries were calculated with respect to this time scale. The bottom curve represents the mean temperature of ovulating ovaries relative to that of the contralateral quiescent ovary put equal to zero; the shaded area extends to 1 S.E. above and below the mean of these differences (*CL* minus *NO CL*).

ing the ovulating sheep (four experiments) with the nonovulating sheep (two experiments), the curves were aligned with respect to the time of progesterone withdrawal. The resulting hourly mean values over the ovulating and the nonovulating ovaries in the ovulating ewes, and over the right and the left ovaries in the anovulatory animals, are shown in Fig. 2. In the nonovulating ewes, the two ovarian temperatures varied independently and at random around a mean near 0.14° C. above aorta. In the ovulating ewes, both ovarian temperatures began to decrease shortly after progesterone withdrawal and continued to approach aorta temperature until reaching a minimum about 30 hours after progesterone withdrawal. They then rose again at a similar rate to the preovulatory level. From about 12 hours after progesterone withdrawal until the end of the recording 60 hours later, the mean temperature of the ovulating ovaries (i.e., those where the one fresh corpus luteum was found at laparotomy) was lower at all times than that of the contralateral ovaries.

For the purpose of examining further this difference between ovulating and nonovulating ovaries in the same animal, the hourly mean temperature values plotted in Fig. 3 were calculated after alignment of the individual curves with respect to the maximum rate of LH increase. The mean temperature in the ovulating ovaries was again consistently lower than in those not ovulating. The lowest mean temperature occurred 1 hour before the reference point in both ovaries, but the anovulatory ovaries lagged about 12 hours behind the ovulating ovaries in the beginning of the decrease.

When we examined alignment of the temperature curves with respect to the time of progesterone

withdrawal (as for Fig. 2), onset of estrus, or LH peak, none of these reference points revealed different or more clearly defined correlations. The relation between the four reference points in time is shown in Fig. 3 for each of the four experiments.

Comment

Estrus, LH surge, ovulation, and corpus luteum formation all occurred in five out of seven experiments (including a seventh experiment without temperature recording, not otherwise referred to in this report), and conception followed by birth of a normal lamb occurred in one of these; this attests the innocuous nature of the sensor implants which, on this evidence, did not interfere with normal reproductive processes.

The experiments generated their own controls in two respects which, though necessarily unplanned, contributed significantly to the interpretation of the findings. First, removal of the progesterone implant failed to induce an estrus cycle in two animals; this permitted comparison between estrous and anestrous ewes. Second, it so happened that, in all four ovulatory cycles, ovulation occurred in only one ovary; this permitted comparison between ovulating and nonovulating ovaries within the same animal.

Without the differential design which eliminated the variation in basal body temperature, it would not have been possible to demonstrate the suspected hormone-related variation in ovarian temperature, since this was of the same magnitude as the individual hourly variations.

According to current concepts, basal gonadotropin secretion is involved in initiating follicle growth and estradiol secretion after withdrawal of the progesterone block. Our findings suggest, in addition, the hypothesis that ovarian estradiol induces an increase in blood flow not only in uterus and vagina but also in the ovary itself. If the observed decrease in ovarian temperature is attributed to convection, i.e., to heat removal through increased blood flow, both the smaller magnitude and the later onset of the temperature decrease in the anovulatory (as compared with the ovulating) ovaries could well be explained by the difference in estradiol concentration between the secreting and the contralateral quiescent ovary. In fact, published data show that in the ewe estradiol is secreted mainly from the ovary destined to have follicles which mature and rupture,[11] and that response to estradiol in contralateral tissue is diminished by circulatory dilution.[12, 13]

Heat conduction through physical contact of the ovaries with the uterus may also be a factor contributing to the ovarian temperature changes, since uterine blood flow and temperature are known to vary with estrogen levels,[3] and the proximity of the uterine mass to the ovaries may well produce a heat-sink effect.

Pregnancy with bilateral ruptured benign cystic teratomas

USHA MEHRA, M.D.
TIMOTHY O'CONNOR, M.B., B.Ch.
FRANK OSTAPOWICZ, M.D., F.A.C.O.G.
DENIS CAVANAGH, M.D., F.A.C.O.G.
St. Louis, Missouri

A case of intra-abdominal rupture of bilateral cystic teratomas in the first trimester of pregnancy is reported. Review of the literature revealed 22 cases of intraperitoneal rupture of benign cystic teratoma (1908 to 1971). In all of these cases, only one ovary was involved, and the period of gestation was after the first trimester.

A CASE OF intra-abdominal rupture of bilateral cystic teratomas in the first trimester of pregnancy is reported.

Case report

An 18-year-old, unmarried, black nulligravida was admitted to the Gynecology Service on February 1, 1974, with a history of left lower quadrant pain, vaginal discharge, six weeks of amenorrhea, and a temperature of 100.2° F. The patient's last menstrual period was on December 12, 1973. Pregnancy test was positive, and ectopic pregnancy was suspected. Culdocentesis was performed, and a small amount of purulent material was obtained. The patient was treated for pelvic inflammatory disease with antibiotics. She was discharged on February 8, 1974, with a diagnosis of pelvic inflammatory disease and possible intrauterine pregnancy.

The patient was seen in the Prenatal Clinic on February 14 and 28, 1974. She had no specific complaints. A pelvic examination on February 28, 1974, revealed a soft, retroverted uterus at eight to ten weeks' gestation.

The patient was admitted to the St. Louis City Hospital through the Emergency Room on March 12, 1974, with a chief complaint of acute lower abdominal pain of two days' duration. Two days prior to this second admission, the patient had developed acute lower abdominal pain, nausea, and vomiting, and a foul-smelling vaginal discharge was noted. She was examined in the Emergency Room and was sent home after being given antibiotics and vaginal suppositories.

On admission, the patient had a temperature of 100.6° F.; pulse, 160 beats per minute; respirations, 36 per minute; blood pressure, 130/80 mm. Hg. The patient seemed to be in acute distress. On auscultation, there was marked tachycardia, and diminished air entry was noted at the lung bases. The abdomen was distended. Rigidity and guarding were present over the entire abdomen. There was marked direct and rebound tenderness, and bowel sounds were absent.

On pelvic examination, there was a foul-smelling discharge in the vagina. The cervix was soft, blue, and closed. Movement of the cervix was very painful for the patient. The uterus was anteverted, soft, and 12 weeks' gestation in size. The posterior cul-de-sac was bulging, and there was marked tenderness. A diagnosis of intrauterine pregnancy with ruptured tuboovarian abscess was considered. Culdocentesis was performed and yielded 7 to 8 c.c. of yellowish green foul-smelling purulent material. Hemoglobin was 13 Gm. per cent, and hematocrit was 40 per cent. White blood count was 20,800 per cubic millimeter with 74 per cent segmented cells, 15 per cent stab cells, 1 per cent juvenile cells, and 10 per cent lymphocytes.

The patient was treated with cephalothin intravenously, 2 Gm. every four hours, and kanamycin, 0.5 Gm. every 12 hours intramuscularly, and prepared for exploratory laparotomy.

4/1/74	8.5	27	12,000						

Hgb. = Hemoglobin; Hct. = hematocrit; WBC = white blood cell count; BUN = blood urea nitrogen.

The patient's abdomen was explored through a low midline incision. The abdominal cavity was full of foul-smelling, seropurulent fluid. About 500 to 600 c.c. of fluid was aspirated. The omentum was adherent to the uterus. The uterus was anteverted, 12 weeks' gestation in size, and covered with a film of seropurulent material. Posterior to the uterus, there were two large cystic masses, each about 8 cm. in diameter. As the bowel was being packed, sebaceous material and hair were found floating in the abdomen. A diagnosis of bilateral ruptured infected benign cystic teratomas was made. The right side was explored first, and a ruptured "dermoid cyst" 8 cm. in diameter was removed. Purulent material, hair, and fatty material were pouring out through the ruptured cyst wall. Right salpingo-oophorectomy was performed. The left side was then explored, and hair and fatty material were also seen leaking from the left ovarian cyst. The left adnexal mass was then freed of adhesions and "delivered" out of the cul-de-sac of Douglas. A left salpingo-oophorectomy was performed. The intrauterine pregnancy remained undisturbed although the uterus was irritated. Intramuscular progesterone was given during operation. Two hemovac drains were placed in the cul-de-sac, and the abdomen was closed. The pathologic diagnosis was "bilateral benign cystic teratomas with tuboovarian abscesses."

Over the following three days, the patient continued to have tachycardia of 160 beats per minute, and the temperature ranged from 102 to 103° F., with 30 respirations per minute. A chest x-ray showed bilateral pneumonitis before operation and it became worse afterward.

On the fourth postoperative day, the patient started coughing up large amounts of frothy sputum. She had rales at both bases. Medical consultation was obtained, and a diagnosis of congestive heart failure was made. Digitalis was administered, and 40 mg. of furosemide was given intravenously.

The patient showed some improvement over the next two days. The left lung base continued radiographically to show opacity but the right lung cleared rapidly. On the ninth postoperative day, a mass in the left upper quadrant was detected. A diagnosis of subphrenic abscess was confirmed by the surgical consultant. On March 21, 1974, a left subphrenic abscess was drained. On March 26, 1974, the abdominal wound was opened, and 500 c.c. of pus was drained. The abdominal wound was thereafter irrigated daily with hydrogen peroxide.

The subphrenic abscess continued to drain with low Gomco suction. On April 7, 1974, the drain was removed. The abdominal incision was granulating well. The patient was discharged in good condition on April 9, 1974.

All of the patient's pertinent laboratory data are given in Table I.

Comment

Benign cystic teratomas account for 22 to 48.5 per cent of ovarian neoplasms complicating pregnancy.[1, 2] The frequency of complications is said to be more common during pregnancy. Peterson and associates[1] found a complication rate of 24 per cent during pregnancy as opposed to 19 per cent in the nonpregnant state. The overall incidence of rupture of cystic teratomas is 1.2 per cent, but in pregnancy it has been quoted to be as high as 15.8 per cent.[3]

We have reviewed 21 cases of intraperitoneal

Cultures	Blood gases			
	pH	*O_2 (mm. Hg)*	*CO_2 (mm. Hg)*	*HCO_3 (mEq./Kg.)*
Blood—no growth Peritoneal fluid—no growth Cervix—100% alpha strep.	7.46	36	36.5	23.8
Urine—no growth	7.43	76.5	36.8	23.9
sputum—growth of normal flora	7.47	42.2	40.2	28.7

rupture of cystic teratomas in association with pregnancy and added the present case. The 22 cases are summarized in Table II. These cases were analyzed with regard to the etiology, presenting symptoms, and the maternal and fetal outcome.

The causes of rupture of cystic ovarian masses included torsion (2), infection (4), and trauma (7). In nine of the reported cases, the cause was unknown.

In the majority of cases, torsion of ovarian cysts occurs in the second trimester.[1] On the other hand, rupture appears to be rare at this time with only two cases being reported.[4, 5] Only one of these was due to torsion, the other case of torsion with rupture being in the third trimester. An analysis of the seven cases in which trauma was the precipitating factor revealed that the cysts rupture spontaneously during labor in three patients.[6, 7] Cysts were aspirated during labor and then ruptured in two patients.[6, 8] The cyst ruptured while amniocentesis was being performed in one patient,[9] and coitus was the precipitating cause of the acute episode in one patient.[10]

We could find no reported case of malignant degeneration precipitating rupture during pregnancy.

In the remaining eight cases, no cause was apparent, but, as most of these were diagnosed during the puerperium, trauma during labor may have been the precipitating factor.

After a review of the literature, it is apparent that patients have presented with two different clinical aspects of intraperitoneal rupture.[1, 11, 12] One group of patients presented with the clinical picture of an acute episode of sudden onset, and the diagnosis of ruptured cystic teratoma was made after celiotomy. The other group was of the "chronic," slow, leaking type. The patients were generally seen after the acute episode had passed and presented with vague abdominal pain, distention, and a pelvic mass. They were operated upon weeks or even months after the cysts had ruptured. In general, the acute presentation is the more rare; Kistner[11] found 5 of 22 acute cases, and Peterson and associates[1] reported only 5 of 13. However, of the 22 cases associated with pregnancy, 17 patients presented with the acute abdominal picture and required celiotomy during the acute episode. Celiotomy was delayed for periods of seven weeks to eight months in four patients, and one patient died after fat embolism.

The treatment of choice is surgical removal of the ruptured cyst and investigation of the other ovary by "bivalving" it. Thorough peritoneal lavage should be performed.

Kistner[11] was the first to advocate the regimen of abdominal drainage, intravenous fluids, nasogastric suction, and prophylactic antibiotics. Most authors agree with this management.

Three maternal deaths have been reported. One patient died 13 months following treatment; she had a cerebral vascular accident.[13] Another patient died after refusing surgical treatment; she was "dead on arrival" on the third postpartum day.[6] The third patient died after generalized fat embolism three hours following delivery.[14]

Maternal morbidity is difficult to assess as many authors fail to allude to it. Hospital stay varied from five days to three months in the 22 cases reported. Six cases were complicated by chemical peritonitis and paralytic ileus. Two patients developed a subphrenic abscess and wound infection. It is of some interest that in both of these cases the ruptured cysts were infected. (The two patients of Peterson and associates in whom there was infection were stated to have had a "stormy postoperative course").

Fetal outcome has been almost uniformly good. Thirteen patients had already been delivered before rupture or were delivered shortly after the rupture. Six patients were in the third trimester at the time of rupture. In three of these, the infant was delivered by cesarean section at the time of celiotomy.[9, 10, 15] In two cases, pregnancy was allowed to continue after operation. One patient went into premature labor 24 hours after operation and had a normal delivery.[19] The other patient carried the pregnancy to term. One patient was operated upon eight months after delivery.[16]

Two patients were in the second trimester. One

Cyst aspirated during labor. refused laparotomy later. Vague symptoms and pelvic mass	Multiple adhesions and granulomas	LSO, cornual resection, adhesionlysis	No complications	Live
"Acute abdomen"	Perforated L. dermoid	L. oophorectomy	Premature labor, 24 hr. postop.	Live
Rigor, hemoptysis, and coma at full dilatation	None	Autopsy, fat embolus from ruptured L. dermoid	Died 3 hr. post partum	Live
Severe dyspareunia, "acute abdomen"	Bilateral dermoid. R. ruptured	LSCS, RSO, L. ovarian cystectomy	No complications	Live
"Acute abdomen" following amniocentesis. Diagnosis: abruptio placentae	L. dermoid ruptured	Cesarean section, TAH and LSO	Chemical peritonitis	Live
"Acute abdomen"	Twisted ruptured L. dermoid	L. oophorectomy	No complications	Live
"Acute abdomen" in early puerperium, 2° arrest of dilation	Ruptured R. dermoid	R. oophorectomy	No complications	Live
"Acute abdomen"	Infected ruptured R. dermoid	Classical cesarean section, RSO, L. salp., Transverse colostomy, perforated sigmoid	1. Subphrenic abscess 2. Wound infection	Live
"Acute abdomen"	Bilateral ruptured dermoid, infected	BSO	1. Subphrenic abscess 2. Wound infection	Abortion

pregnancy progressed normally.[4] There was threatened abortion in the second case, but eventually pregnancy was terminated at term.[5]

Our case is apparently the first reported where bilateral cystic teratomas ruptured in the first trimester. Despite exogenous progesterone, a combination of severe generalized peritonitis and manipulation during operation probably caused abortion.

The dawn of a new age

Genisis—The Reason for Change

Discovery, isolation, identification, synthesis—the classical pattern for creating drugs which once were available from natural sources only. Antibiotics, vitamins, and sex hormones come to mind as examples of drugs which have been developed and perfected in this manner. Obvious advantages of this evolution include: economy, standardization, reproducibility, and purity.

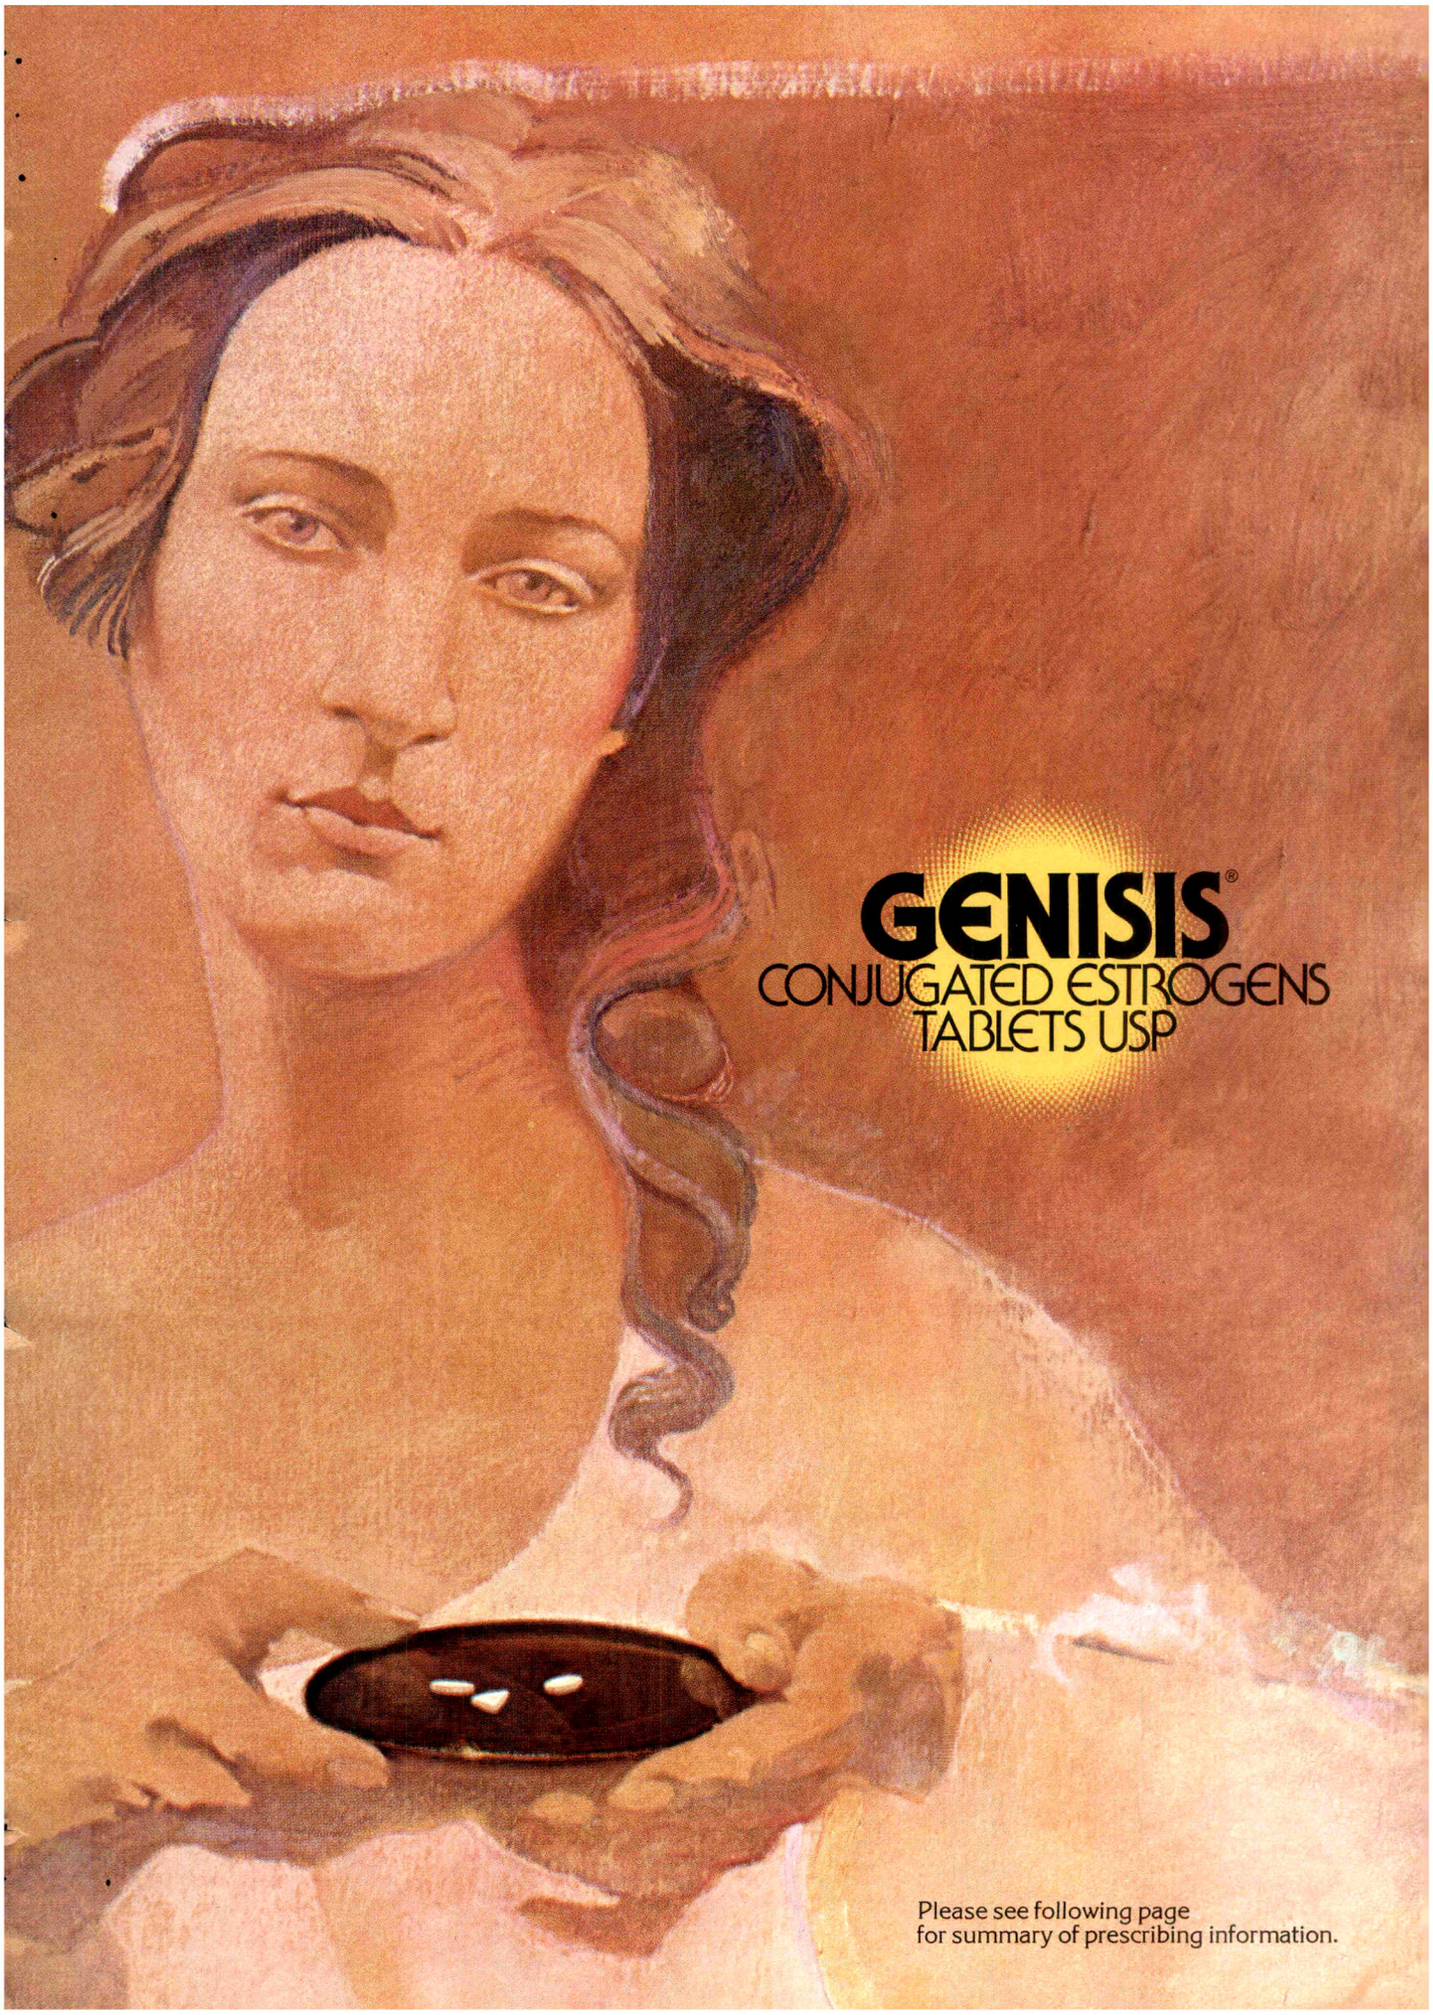
Natural Estrogens—A Mystique

There are those who would have us believe that conjugated estrogens, U.S.P. derived from the urine of pregnant mares is endowed with a certain mystique. What, precisely, is conjugated estrogens "natural"?

A study of the excretion pattern of pregnant-mare estrogens reveals that estrone and equilin are the major components and 17 alpha-dihydroequilin a minor one. Estrone predominates in early pregnancy but as this progresses equilin levels increase and may equal or surpass those of estrone in late pregnancy. This is believed to reflect continuing changes in the placental metabolism of estrogen.[1]

The urine of pregnant mares is pooled to compensate for these variations and provide a raw material of more or less average composition. This practice, however, has the disadvantage of providing a urine pool which contains all of the excreted estrogenic and related hormones whether active or not. For example, an assay study of the estrogenic content of a "large mixture" of mares' urine reveals the following proportions: 51% sodium estrone sulfate, 22% sodium equilin sulfate, 16% sodium 17 alpha-dihydroequilin, and smaller amounts of the sodium sulfates of equilenin, 17 alpha-dihydroequilenin and 17 alpha-estradiol. Related "non-estrogenic" steroids were also present.[2]

Despite these variations, conjugated estrogens, U.S.P. is defined as containing 50 to 65% sodium estrone sulfate and 20 to 35% sodium equilin sulfate.[3]



Genisis—A Beginning

With Genisis, the beginning of a new age of conjugated estrogens, U.S.P. preparations is here. It is free of extraneous natural residues such as "non-estrogenic" steroids. It is prepared synthetically and specifically formulated so that each tablet contains the following approximate proportions of active substances:

Sodium estrone sulfate—60%
Sodium equilin sulfate—30%
17 alpha-dihydroequilin sodium sulfate—10%

Genisis is indicated for those standard indications requiring conjugated estrogens.

Genisis is supplied in snow-white pure uncoated tablets in the usual potencies of: 0.625 mg/1.25 mg/2.50 mg.

GENISIS®
CONJUGATED ESTROGENS
TABLETS USP
Please see following page
for summary of prescribing information.

GENISIS®
CONJUGATED ESTROGENS TABLETS USP

BRIEF SUMMARY
Please consult full package circular before prescribing

Indications
Genisis is indicated for replacement therapy of estrogen deficiency associated with menopausal syndrome, female hypogonadism (hypogenitalism), amenorrhea, female castration or primary ovarian failure.

Important Notes on the Use of Estrogens
In view of the positive relationship between thromboembolic disease and the use of oral contraceptives containing estrogens and progestins, it would seem prudent and in keeping with basic therapeutic principles to utilize, whenever feasible, the smallest effective dose of estrogens in treating patients.

The possible carcinogenicity of estrogens cannot be confirmed or refuted at this time. Close clinical surveillance of all women taking estrogens must be continued.

Contraindications
Patients with, or with history, of:
markedly impaired liver function;
known or suspected carcinoma of breast (except progressing disease not amenable to surgery or irradiation in women at least 5 years postmenopausal, or in men in whom castration is not possible);
known or suspected estrogen-dependent neoplasia, such as carcinoma of the endometrium;
undiagnosed genital bleeding;
thrombophlebitis, thromboembolic disorders, cerebral apoplexy.

Warnings
Discontinue medication at the earliest sign of thrombotic disorders (thrombophlebitis, cerebrovascular disorders, pulmonary embolism, retinal thrombosis), or in the presence of papilledema, retinal vascular lesions or such untoward effects as progression of cancer or hypercalcemia. Discontinue pending examination if there is sudden onset of proptosis, diplopia or migraine.

A statistically significant association has been reported between maternal ingestion of diethylstilbestrol during pregnancy and the occurrence of vaginal carcinoma years later in the offspring. Whether such an association is applicable to all estrogens is not known at this time. In any event, estrogens are not indicated for use during pregnancy.

Estrogens excreted in mother's milk may affect the nursing infant.

Precautions
Certain patients may be unusually responsive and may respond with undesirable manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, edema, etc. Because of possible salt and water retention, estrogens should be used with caution in patients with epilepsy, migraine, asthma, cardiac or renal disease. Estrogens influence the metabolism of calcium and phosphorus. They should be used with caution in patients with certain metabolic bone diseases that are associated with hypercalcemia or in patients with renal insufficiency. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Diabetic patients should be followed closely because of possible decrease in glucose tolerance.

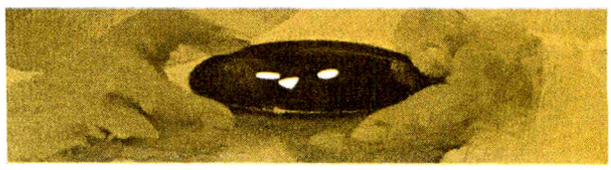
In the event of unexplained or excessive vaginal bleeding during estrogen therapy, nonfunctional causes should be borne in mind. The drug should be discontinued and a thorough investigation made as to the cause, being certain to rule out the possibility of malignancy. Pre-existing uterine fibromyomata may increase in size when estrogens are used. Therefore, patients should be examined at regular intervals throughout therapy. Women with a strong family history of cancer, recurrent chronic mastitis, or abnormal mammograms should be administered estrogens with caution. A pre-treatment physical examination should include special reference to breast and pelvic organs as well as a Papanicolaou smear since estrogens have been known to produce tumors, some of them malignant, in five species of animals.

Continuous use of estrogens will result in prolonged stimulation of the endometrium and breast. In order to avoid this, oral estrogens should be administered cyclically in the menopausal or hypogonadal patient.

The pathologist should be advised of estrogen therapy when relevant specimens are submitted. Certain endocrine and liver function tests may be affected by treatment with estrogens. If such tests are abnormal in a patient taking these drugs it is recommended that they be repeated after the drug has been withdrawn for two months. Any possible influence of prolonged estrogen therapy on pituitary, ovarian, adrenal, hepatic or uterine function awaits further study.

When large doses of estrogens are used, urinary stress incontinence may occur in nonpregnant females.

Adverse Reactions
A statistically significant association has been demonstrated between use of estrogen-progestin oral contraceptives and the following serious reactions: thrombophlebitis, cerebral thrombosis, pulmonary embolism.



Although available evidence is suggestive of an association, such a relationship has been neither confirmed nor refuted for the following serious reactions: coronary thrombosis, neuro-ocular lesions (e.g. retinal thrombosis and optic neuritis).

The following adverse reactions are known to occur in patients receiving estrogens: nausea, vomiting, anorexia, gastrointestinal symptoms (such as abdominal cramps or bloating), edema, breakthrough bleeding, spotting or withdrawal bleeding, breast tenderness and enlargement, change in body weight (increase or decrease), headache, increased cervical mucus, allergic rash, loss of libido and gynecomastia in the male, reactivation of endometriosis, aggravation of migraine headaches, hepatic cutaneous porphyria becoming manifest, cholestatic jaundice, rise in blood pressure in susceptible individuals, mental depression, cystitis-like syndrome, loss of scalp hair, erythema nodosum, hemorrhagic eruption, premenstrual-like syndrome, changes in libido, changes in appetite, nervousness, dizziness, fatigue, backache, erythema multiforme, itching, possible diminution in lactation when given immediately post-partum, irritability, malaise.

Dosage and Administration
Dosage requirements will vary with the severity of menopausal symptoms. Initially, doses ranging from 1.25 mg to 3.75 mg daily may be required to bring symptoms under control. When this has been accomplished dosage should then be gradually decreased until the minimal effective maintenance dose is established. This will usually be 0.625 mg or 1.25 mg daily or possibly less.

Caution
Federal law prohibits dispensing without a prescription.

How Supplied—0.625 mg tablets—bottles of 100 and 500
1.25 mg tablets—bottles of 100 and 500
2.5 mg tablets—bottles of 100

THE DEPARTMENTS OF OBSTETRICS AND GYNECOLOGY OF THE FACULTIES OF MEDICINE OF THE UNIVERSITIES OF THE PROVINCE OF QUEBEC

ANNOUNCE:

A SYMPOSIUM ON FETAL MONITORING

The Symposium will be held at the Château Frontenac in Quebec City, Canada, from Wednesday, April 21st to Saturday, April 24th 1976. The three days will be devoted to the study of recent advances in monitoring the fetal heart and uterine contraction. Internationally known experts in these fields will be giving presentations. Lectures and workshops have been organised for physicians and nurses interested in the subjects.

Official languages will be English and French with simultaneous translation available.

Registration will be closed April 1st 1976. The regular fee will be: physicians, one hundred and fifty canadian dollars ($150.00); nurses, fifty dollars ($50.00), including three breakfasts and two lunches at the Château Frontenac. For registration after April 1st, the fee will be: physicians, two hundred dollars ($200.00); nurses, seventy-five dollars ($75.00). Cheques should be made payable to: Symposium de monitorage foetal, Département d'Obstétrique-Gynécologie, Faculté de Médecine, Cité Universitaire, Québec, Canada, G1K 7P4.

For further information write to: Adrien Bastide M.D., Hôpital Saint-Francois d'Assise, 10 de l'Espinay, Québec, Canada, G1L 2H1 or call (418) 688-8710.

PERSONALIZED LIBRARY CASES

Keep your personal copies of AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY in these specially designed library file cases. Two files hold an entire year's issues. Designed to keep your journal copies near at hand in your office, library, or home.

Your case is heavy bookbinder's board in a rich red Kivar cover. Files are scuff-resistant and washable.

Lettering is stamped in gold leaf and the cases make a fit companion for the most costly binding.

Files are reasonably priced—only $4.25 each, postpaid (3 for $12., 6 for $22.). Add $1.00 postage per case for orders outside U. S. Satisfaction unconditionally guaranteed or your money back! Use the coupon for prompt shipment.

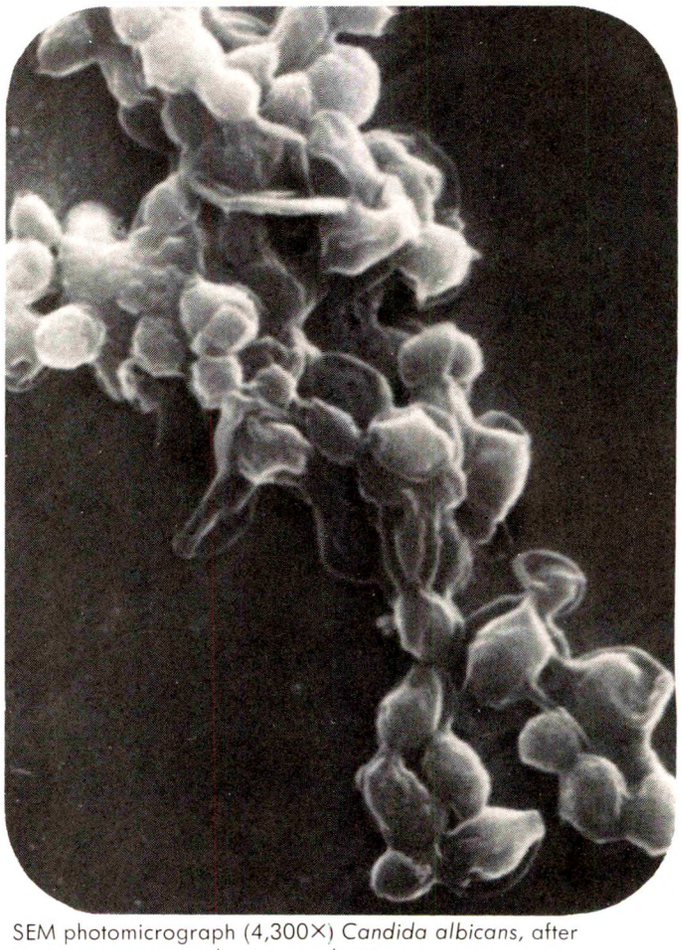
SEM photomicrograph (5,300×) *Candida albicans, in vitro* control



the first new agent for vaginal moniliasis in over 10 years...

effective when used once daily, h.s., for 14 days†

NOTE: Clinical studies have shown the efficacy of MONISTAT Cream in humans. The above Scanning Electron Microscope photographs represent *in vitro* research. No clinical significance should be drawn from this study concerning the effectiveness of miconazole nitrate, as it is not possible to extrapolate *in vitro* data to humans.

†Recommended dosage is once daily, h.s. for 14 days.

SEM photomicrograph (4,300×) *Candida albicans*, after *in vitro* treatment with miconazole nitrate

significantly high cures after one course of therapy

In a controlled study,[1] a total of 418 patients met the *rigid* criteria for inclusion. A cure was defined as complete relief of vulvar pruritus, burning and irritation plus negative KOH smear and negative NICKERSON'S* Medium Culture 30 days or more after completion of therapy.

Results show effectiveness in a wide range of patients

In clinical studies, new MONISTAT Cream produced outstanding cures in:

1. Pregnant†† and non-pregnant patients.
2. Patients on antibiotics or hormonal therapy and
3. Patients previously treated, one or more times with other antifungal drugs.

Monistat Cream is a soothing, non-staining, water-miscible cream

In addition to high cure rate, patients readily accept MONISTAT because...

Symptomatic relief for majority of patients by third application

that permits rapid contact with infected tissues and may be used on the vulva.

Convenient, once-a-day bedtime dosage

does not interfere with daytime activities.

Full 14-day course of therapy in one tube.

For the majority of patients this is sufficient to eliminate the infection.

[1]Clinical Compendium December 1973, Ortho Pharmaceutical Corporation, Raritan, New Jersey.

††MONISTAT Cream may be used in the second and third trimester. However, in the first trimester, it should be used only when the physician considers it essential to the patient's welfare. See precautions in prescribing information.

MONISTAT Cream

TRADEMARK

(MICONAZOLE NITRATE 2%)

Prescribing Information

Description MONISTAT (miconazole nitrate 2%) is a water miscible, white cream containing as the active ingredient, 2% miconazole nitrate, 1-[2,4-Dichloro-β-(2,4-dichlorobenzyloxy) phenethyl] imidazole nitrate.

Actions MONISTAT Cream exhibits fungicidal activity *in vitro* against species of the genus *Candida*. The pharmacologic mode of action is unknown.

Indications MONISTAT Cream is indicated for the local treatment of vulvovaginal candidiasis (moniliasis).

As MONISTAT Cream is effective only for candidal vulvovaginitis, the diagnosis should be confirmed by KOH smears and/or cultures. Other pathogens commonly associated with vulvovaginitis (Trichomonas and *Haemophilus vaginalis*) should be ruled out by appropriate laboratory methods.

MONISTAT is effective in both pregnant and non-pregnant women, as well as in women taking oral contraceptives. (See Precautions.)

Contraindication Patients known to be hypersensitive to this drug.

Precautions *General:* Discontinue drug if sensitization or irritation is reported during use. *Laboratory Tests:* If there is a lack of response to MONISTAT, appropriate microbiological studies should be repeated to confirm the diagnosis and rule out other pathogens.

Pregnancy: MONISTAT Cream was used in 209 pregnant patients. Follow-up reports now available in 117 of these patients reveal no adverse effects or complications attributable to MONISTAT therapy in infants born to these women.

Since MONISTAT Cream is absorbed in small amounts from the human vagina, it should be used in the first trimester of pregnancy only when the physician considers it essential to the welfare of the patient.

Adverse Reactions Thirty-nine (7.4%) of the 528 patients treated with MONISTAT reported complaints during therapy that were possibly drug-related. Most complaints were reported during the first week of therapy. Vulvovaginal burning, itching or irritation occurred in 6.6%, while other complaints such as vaginal burning, pelvic cramps, hives, skin rash and headache occurred rarely (each less than 0.2% patient incidence). The therapy-related drop-out rate was 0.9%.

Dosage and Administration One applicatorful is administered intravaginally once daily at bedtime for 14 days. Course of therapy may be repeated after other pathogens have been ruled out by appropriate smears and cultures.

Supplied MONISTAT Cream is available in 3 oz. (85 g) tubes with Ortho* Measured Dose Applicator.

MONISTAT (miconazole nitrate 2%) is a development of Ortho Research Foundation and Janssen Pharmaceutica, Belgium.

Abnormal uterine bleeding: progesterone replacement... to oppose unopposed estrogen

Estrogen replacement therapy... a frequent cause of abnormal uterine bleeding

Administration of estrogen for the relief of menopausal symptoms is a frequent cause of irregular bleeding or spotting during the menopause, and the most common cause of uterine bleeding after the menopause. Bleeding may occur when long-term administration of estrogen causes overstimulation of the endometrium.

It cannot be assumed, however, that uterine bleeding in a woman on estrogen replacement therapy is due solely to the exogenous estrogen. The existence of a pathologic condition—benign or malignant—should always be considered, thoroughly explored, and ruled out. It is generally agreed that any woman taking estrogen who complains of abnormal uterine bleeding should undergo a careful physical examination including a Pap test, followed by curettage of the uterine cavity.

A close look at the influence of estrogen and progesterone on the endometrium

In the normal proliferative endometrium (left), the epithelium contains rather flat, nonciliated cells with small microvilli, and scattered, uniform ciliated cells. Regrowth of the surface epithelial cells proceeds vigorously throughout the proliferative phase of the cycle. (X2250)

Under the continued and unopposed influence of estrogen (center), there is a striking increase in the number of ciliated cells and in the abundance and size of the microvillous processes on the nonciliated cells. (X1600)

During the normal secretory phase (right), the presence of progesterone causes the secretory cells to become more complex, and the microvilli to increase in number. Scattered droplets are visible on the surface of some of the nonciliated cells and are attached to the tips of some microvilli. (X2500)

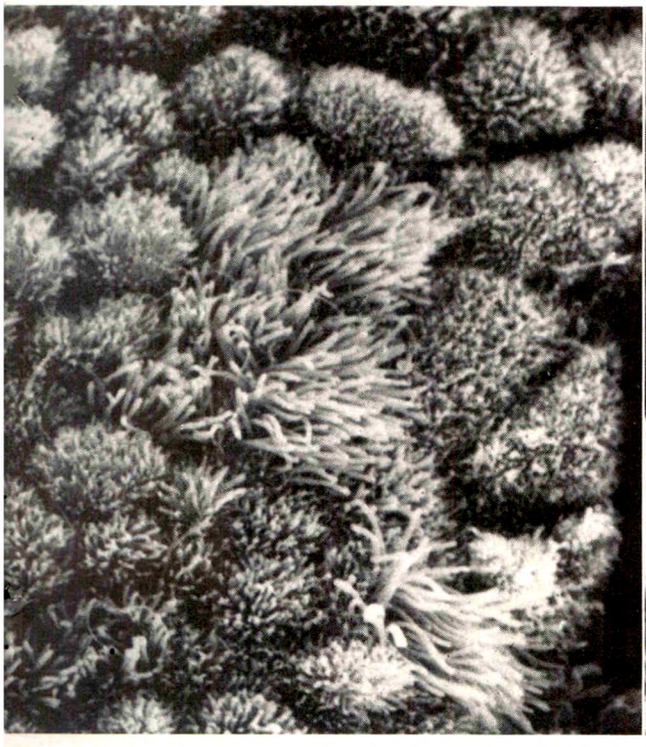
dometrium occur following cessation of
ogestin therapy.

recautions and
ontraindications

overa appears to be devoid of significant
trogenic activity; however, andro-
nic effects have been noted with the drug.
uring progesterone therapy, thrombophlebitis
d pulmonary embolism have been reported.
r this reason, such therapy is contra-
dicated in women with a history of these
cidents. Progesterone therapy is also
contraindicated in the presence of liver dysfunction or disease, known or suspected malignancy of breast or genital organs, undiagnosed vaginal bleeding, and missed abortion. Because a decrease in glucose tolerance may occur during Provera therapy, diabetic patients should be followed closely. Patients with a history of psychic depression should be carefully observed and if serious depression occurs, Provera should be discontinued.

To control abnormal uterine bleeding in the absence of organic pathology



Provera® 10 mg Medroxyprogesterone Acetate Tablets, U.S.P., Upjohn

To control abnormal uterine bleeding in the absence of organic pathology

Provera® 10 mg Medroxyprogesterone Acetate Tablets, U.S.P., Upjohn

Description and actions: Medroxyprogesterone acetate is a derivative of progesterone. Administered orally or parenterally to women with adequate endogenous estrogen it transforms proliferative endometrium into secretory endometrium.

Indications: Provera Tablets are indicated in secondary amenorrhea and abnormal uterine bleeding due to hormonal imbalance in the absence of organic pathology such as fibroids or uterine cancer.

Contraindications: Thrombophlebitis, thromboembolic disorders, cerebral apoplexy or patients with a past history of these conditions. Liver dysfunction or disease. Known or suspected malignancy of breast or genital organs. Undiagnosed vaginal bleeding. Missed abortion. Known sensitivity to medroxyprogesterone acetate.

Warnings: 1. Immediately discontinue administration should any of the following thrombotic disorders occur or be suspected: thrombophlebitis, cerebrovascular disorders, pulmonary embolism, retinal thrombosis. **2.** Beagle dogs treated with medroxyprogesterone acetate developed mammary nodules, some of which were malignant. Although nodules occasionally appeared in control animals, they were intermittent in nature, whereas the nodules in the drug treated animals were larger, more numerous, persistent, and there were some breast malignancies with metastases. Their significance with respect to humans has not been established. **3.** Discontinue medication pending examination if there is sudden partial or complete loss of vision, or if there is a sudden onset of proptosis, diplopia or migraine. If examination reveals papilledema or retinal vascular lesions, medication should be withdrawn. **4.** Detectable amounts of progestin have been identified in the milk of mothers receiving the drug. The effect of this on the nursing infant has not been determined. **5.** Usage in pregnancy is not recommended because of data indicating a possible association between administration of progestins early in pregnancy and congenital heart defects in the offspring. **6.** Three major studies in Great Britain and one in this country have shown a statistically significant association between thrombophlebitis, pulmonary embolism, cerebral thrombosis and embolism and the use of oral contraceptives. It has been estimated that users are several times as likely to undergo thromboembolic disease without evident cause as nonusers. The American study indicated that the risk did not persist after discontinuation and it was not enhanced by long continued administration.

Precautions: A pretreatment physical exam should include special reference to breast and pelvic organs and a Papanicolaou smear. This drug may cause some degree of fluid retention; therefore, observe carefully patients with conditions influenced by fluid retention such as epilepsy, migraine, asthma, and cardiac or renal dysfunction. In breakthrough bleeding, and other irregular bleeding per vaginum bear in mind nonfunctional causes. Perform adequate diagnostic measures in cases of undiagnosed vaginal bleeding. Advise pathologist of therapy when submitting relevant specimens. Carefully observe patients with history of psychic depression and discontinue drug if serious degree of depression recurs. Any possible influence of prolonged therapy on pituitary, ovarian, adrenal, hepatic, or uterine function awaits further study. Decreased glucose tolerance has been observed in a small percentage of patients on estrogen progestin combinations, therefore, carefully observe diabetic patients receiving progestin therapy. Age constitutes no absolute limiting factor, although onset of climacteric may be masked. Because of the occasional occurrence of thrombotic disorders (thrombophlebitis, pulmonary embolism, retinal thrombosis, and cerebrovascular disorders) in patients taking estrogen-progestin combinations and since the mechanism is obscure, the physician should be alert to the earliest manifestation of these disorders.

Adverse reactions: The following have been reported: breast tenderness or galactorrhea in a few instances; an inferential association between the administration of progestins early in pregnancy and the occurrence of congenital malformations (see also Warnings); occasional sensitivity reactions including pruritus, urticaria, edema and generalized rash; acne, alopecia and hirsutism in a few patients; thromboembolic phenomena including thrombophlebitis and pulmonary embolism.

The following adverse reactions have been observed in women taking progestins including medroxyprogesterone acetate: breakthrough bleeding; spotting, change in menstrual flow; amenorrhea; edema, increase or decrease in weight; changes in cervical erosion and secretions; cholestatic jaundice, rash (allergic) with and without pruritus, and mental depression.

A statistically significant association has been demonstrated between use of estrogen-progestin combination drugs and the serious adverse reactions of thrombophlebitis, pulmonary embolism and cerebral thrombosis and embolism. Therefore, patients on progestin therapy should be carefully observed.

Although available evidence is suggestive, a relationship has been neither confirmed nor refuted for the association of the serious adverse reaction of neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been observed *in* patients receiving estrogen-progestin combination drugs: rise in blood pressure in susceptible individuals; premenstrual-like syndrome, changes in libido; changes in appetite, cystitis-like syndrome, headache; nervousness; dizziness; fatigue; backache, hirsutism; loss of scalp hair; erythema multiforme; erythema nodosum; hemorrhagic eruption; and itching. Therefore, observe patients on progestin therapy carefully.

The following laboratory results may be altered by the use of estrogen-progestin combination drugs: increased sulfobromophthalein and other hepatic function tests; coagulation tests (increase in prothrombin factors VII, VIII, IX and X), metyrapone test; pregnanediol determination; thyroid function tests (increase in PBI, and butanol extractable protein bound iodine and decrease in T^3 uptake values).

How supplied: *2.5 mg* in bottles of 25. *10 mg* in bottles of 25 and 100.

Caution: Federal law prohibits dispensing without prescription

OBSTETRICS

Effects of progesterone, prostaglandin $F_{2\alpha}$ and its analogue ICI 81008 on the excitability and threshold of the uterus

A. I. CSAPO*

St. Louis, Missouri

Forty-eight uterine strips were excised from 24 New Zealand white rabbits and studied in vitro. Sixteen strips were examined when eight animals were 25 days pregnant, 24 strips when 12 animals were about 12 hours postpartum, and eight strips about 12 hours after four animals received a single dose of 5 mg. progesterone (P) at spontaneous delivery. When after repeated exposures to electric fields (60 cycles per second, alternating current, of optimum strength, four seconds' duration, at intervals of 30 seconds) the ~ 0.5 Gm. strips developed ~ 40-50g wall tension (WT) in steady state, the field strength was reduced in graded steps from 12 v per 5 cm. to 10, 8, 6, 4 and 3 v per 5 cm. and WT recorded. By measuring the effect on WT of "decreasing electric field stimulation" (DEFS), myometrial excitability and threshold were characterized and quantitated. The technique is based on the relationship between the fraction of myometrial cells activated in the total cell population and WT. As the stimulus is decreased in graded steps from optimal to increasingly suboptimal, DEFS activates fewer and fewer cells reflected by the decrease in WT. Threshold is defined by the strength of the minimum electric field which provokes WT and subthreshold by the field strength which fails to excite. Thus fractional WT averages the excitability of cells in the tissue and thus DEFS characterizes this important parameter of uterine function and quantitates threshold under a variety of regulatory conditions. The comparative study of excised uteri in three different endocrine states showed that the regulatory conditions of normal pregnancy (P levels 9 ng. per milliliter) suppressed excitability and increased threshold (to 6 v per 5 cm.). Post partum (P levels 1 ng. per milliliter) excitability increased and threshold decreased (to 4 v per 5 cm.), unless P treatment prevented this characteristic change by suppressing excitability and increasing threshold (to 6 v per 5 cm.). Both regulatory agents, prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) and its analogue ICI 81008, increased excitability and decreased threshold significantly in picogram per milliliter concentrations. However, this effect was observed only when the P levels were low. These compounds had little effect, even in nanogram per milliliter concentrations, when the P levels were high. The studies also revealed a close relationship between threshold and spontaneous uterine activity. Low threshold promoted while high threshold suppressed spontaneous activity. In similar concentrations the oxytocic actions of $PGF_{2\alpha}$ and ICI 81008 were similar but the effect of ICI 81008 was prolonged through strong binding at myometrial sites.

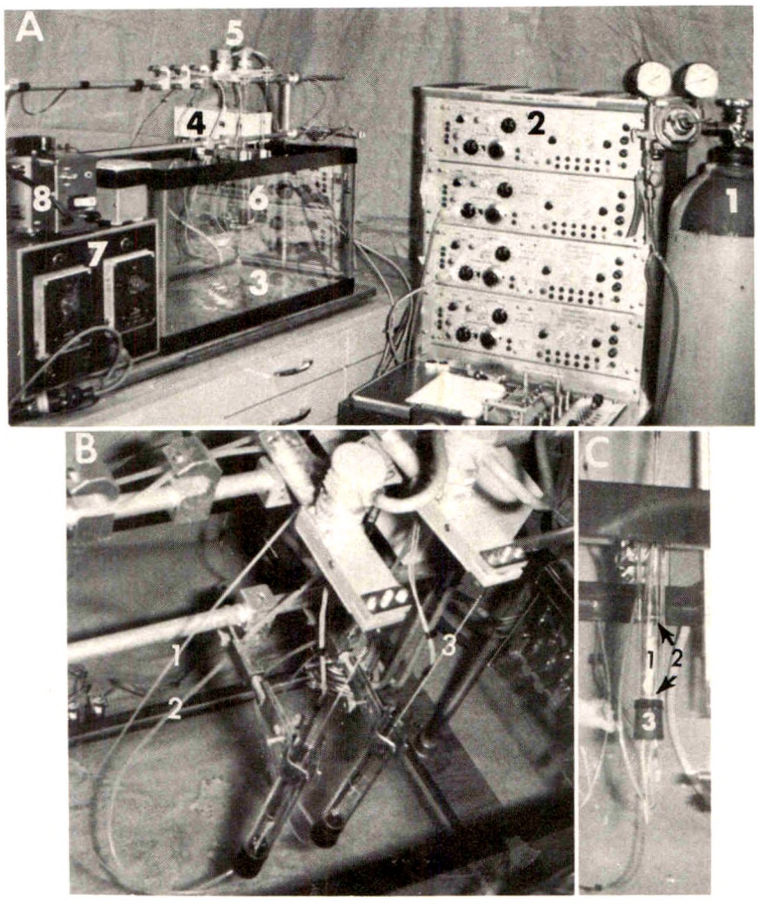
Intrauterine pressure (IUP) tracings, obtained during the pioneering trials with prostaglandins (PG's), showed explicitly[1] that these compounds trigger in the uterus normal oxytocic responses (for example, advanced cyclic IUP) only when gestation approaches term, while during pregnancy they provoke unphysiologic contractures. On these contracture responses advanced cyclic IUP (approximating the maximum working capacity of the uterus, described by LaPlace: IUP = 2WT/R*) was superimposed only after several hours' delay. These findings had been complemented by the additional demonstrations[2] that: (1) before a normal oxytocic response can be triggered by PG's (or other stimulants), the pregnant uterus must be "converted" (endogenously or exogenously) from a refractory to a reactive organ; (2) this characteristic and time-dependent regulatory change ("conversion") can be provoked by progesterone withdrawal (Pw); (3) conversion does occur regardless of how Pw is provoked, for example, by the endogenous mechanism,[3-5] by luteectomy,[6] by hypertonic saline,[7, 8] or by PG's.[9-16]

Despite this multiple evidence demonstrating that the abortifacient efficacy of PG's is dependent more on their potency to provoke conversion than oxytocic response, in some centers PG's were given in prolonged infusions or repeated small doses in an attempt to achieve sustained uterine stimulation. PG therapy by these delivery systems yielded unsatisfactory clinical results (*see* Csapo[2]). Other centers adopted the therapeutic principle: "PG impact" (PGI, a massive intrauterine PG dose) which did provoke uterine conversion, presumably by suppressing uterine microcirculation and fetoplacental endocrine function, resulting in Pw.[20-22] In provoking Pw, the PGI improved abortifacient therapy,[9-16] since the regulatory imbalance induced promoted the evolution of spontaneous uterine activity and clinical progress in cervical dilatation and abortion.

However, several questions remained to be answered. It had to be explained how Pw (a decrease in a suppressor) can increase the "sensitivity" of the uterus to stimulants, indeed bring about spontaneous activity. The studies[2, 17-19] revealed that: (1) the intrinsic myometrial stimulant is PG, present in the uterus at all times even under in vitro conditions; (2) when PG synthesis is blocked PG can, while oxytocin cannot, stimulate the uterus; (3) even PG's fail in provoking advanced cyclic IUP during pregnancy when normal P levels sustain high threshold; (4) PG-synthesis in the uterus is stretch dependent. Thus the activation of the pregnant uterus by Pw had been explained by a "shift" in regulatory balance[20] induced through an endogenously or therapeutically provoked dominance of PG over P in the control of threshold.



This re-examination of the regulatory mechanism[2-18] exposed the significance of threshold control in reproductive medicine. Once exposed, techniques had to be developed for studying it—specifically the effects of PG's and P on threshold and the relationship between threshold and spontaneous uterine activity and reactivity. Furthermore, it had to be determined whether the increased efficacy of PG analogues (exceeding those of the natural compounds) is due to their increased oxytocic potency or their binding at target sites, complemented with reduced metabolism. The present study is an attempt in answering some of these and related questions.

Material and methods

Technical considerations. Excised strips from pregnant uteri contain thousands of spindle-shaped myometrial cells, each of them approximately 100μ long and about 5 to 10μ wide. Extensive studies with intracellular microelectrodes revealed[23, 24, 27] considerable variations in the membrane and action potentials of these cells (regardless of their regulatory condition), indicating variations in the threshold of individual cells and in the pacemaker and conduction characteristics of different uterine regions. To reduce uncertainties, a method had to be developed which could characterize excitability and quantitate threshold by "averaging" the properties of all cells of the excised myometrium and relate the excitability and threshold to the spontaneous activity of the uterus in a variety of regulatory conditions. The technique of "decreasing electric field stimulation" (DEFS), used in earlier studies,[2, 17] promised a reliable method. The present experiments explored the potential of this technique for characterizing the regulatory and functional conditions of the uterus by defining threshold through the minimum electric field which provoked a tension response and excitability through a series of tension responses induced by a standard set of suboptimal electric stimuli.

The preparation of uterine strips and their transfer to in vitro conditions. The rabbits were killed by a blow on the head and opening of the carotid artery. One uterine horn was quickly transferred to oxygenated (95 per cent O_2 + five per cent CO_2) mammalian Krebs' solution. From this horn a 3 cm. long strip was removed with intact longitudinal fiber bundles and slit into twin portions, each approximately 30 mm. long,

*Where IUP = intrauterine pressure, WT = wall tension, and R = uterine radius.[23]

LIBRARY

Fig. 1. The experimental arrangement for the study of maximum tension, the effect on tension of decreasing electric field stimulation (DEFS), and the action of drugs on excitability and threshold. Photographs of the experimental arrangement: *A—1*, O_2 Tank; *2*, Grass polygraph; *3*, constant-temperature water bath; *4*, temperature control; *5*, force-displacement transducer; *6*, muscle chamber; *7*, Tandem automatic stimulator; *8*, rheostat. *B—1*, O_2 inlet; *2*, Krebs' inlet; *3*, silver chain, connecting muscle with transducer; *C—1, the uterine strip; 2*, pair of platinum ring stimulating electrodes; *3*, rubber stopper.

about 4 mm wide, and of natural thickness. Both strips were suspended isometrically in oxygenated Krebs' solution at 37° C. and pH 7.4 and stretched until they sustained ~ 2g resting tension ("optimum length"[23]). Since these strips were removed from different portions of the uterus in between the ovarian and cervical regions they represented the properties of the uterus as a whole. However, during pregnancy the placental implantation sites were avoided. The uterine wall thickness (W) of six 25 days' pregnant and six postpartum strips (measured at three different points in histologic cross-sections) were: 1.6 ± 0.1 and 1.7 ± 0.2 mm., respectively (of which the myometrial thickness was 0.9 ± 0.1 and 1.1 ± 0.1 mm.), $p > 0.05$).

The experimental arrangement, electric stimulation, maximum tension and threshold. Fig. 1 describes the experimental arrangement used. It consisted of: a pyrex tube closed at its lower end with a rubber stopper; two polyethylene tubes for the delivery of Krebs' solution and O_2 through the rubber stopper; a pair of platinum ring electrodes (5 cm.apart) for periodic stimulation of the uterus inside the Krebs' solution; two platinum hooks and a silver chain for isometric mounting of the uterus; an automatic (Tandem) timer for the delivery of four seconds' long electric stimuli in every 30 seconds; a rheostat for altering the strength of the electric field; and a Grass force-displacement transducer (Model FT03C) and polygraph (Model 5C) for the recording of tension. When twin strips were studied simultaneously, two muscle chambers were used.

Fig. 2 illustrates that at the beginning of the study the postpartum uterus developed stepwise increasing tension when stimulated repeatedly with an "optimum"

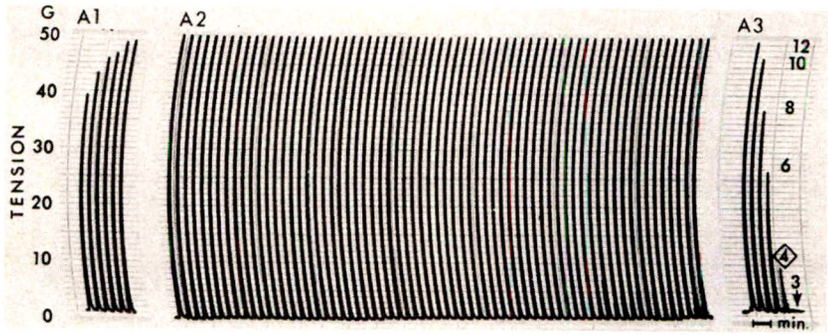


Fig. 2. Study of the effects of DEFS. Uterus: approximately 12 hours' postpartum. *A1*, The build up of uterine wall tension (WT) with 12 v. per 5 cm. field. *A2*, Maximum WT in a steady state. *A3*, The effect of stepwise "decreasing electric field stimulation" (DEFS) and the assessment of "threshold" (in this instance 4 v. per 5 cm.). For further description see text.

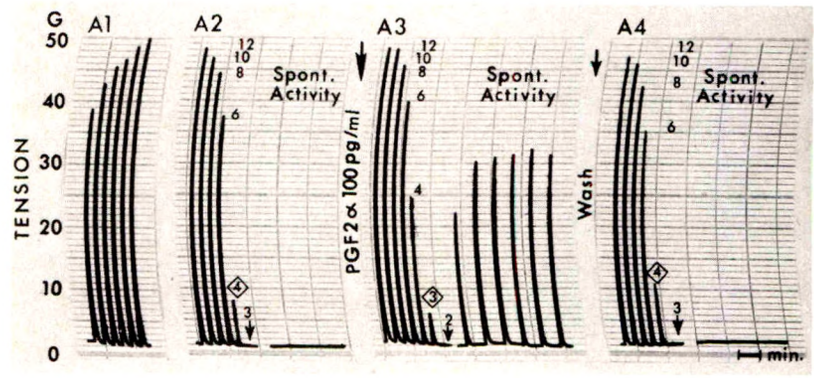

Fig. 3. The effect of $PGF_{2\alpha}$ on threshold and spontaneous activity. Uterus: approximately 12 hours' postpartum. *A1*, The build up of WT with 12 v. per 5 cm. field. *A2*, The effect of DEFS, the assessment of threshold (4 v. per 5 cm.), and spontaneous activity (none). *A3*, The lowering of threshold with 100 pg. per milliliter $PGF_{2\alpha}$ (to 3 v. per 5 cm.) and the initiation of spontaneous activity. *A4*, Removal of $PGF_{2\alpha}$ by washing, increase of threshold (to 4 v. per 5 cm.), and suspension of spontaneous activity.

field of 12 v. per 5 cm. (60 cycles per second, alternate current, during four seconds in every 30 seconds). Maximum tension was reached within three to five minutes (*A1*). Subsequently tension remained steady and maximal at ~ 50g (*A2*), although the weight of the strip was only about 0.5 Gm.

Having determined maximum tension and recorded it in a steady state, the effect of stepwise "decreasing electric field stimulation" (DEFS) was examined with the use of:12, 10, 8, 6, 4 and 3 v. per 5 cm. fields (*A3*). The decreasing field activated fewer and fewer cells of the total cell population resulting in stepwise decrease in WT. The subthreshold stimulus (3 v. per 5 cm.) failed to provoke WT altogether. The minimum field (4 v. per 5 cm.) which still triggered WT was called the threshold stimulus (*A3*), and thus by definition the threshold of this uterus was 4 v. per 5 cm.

The effect of $PGF_{2\alpha}$ on threshold and spontaneous activity of the uterus. Fig. 3 illustrates that after maximum tension had been built up with a series of 12 v. per 5 cm. stimuli (*A1*), DEFS was applied to characterize excitability and threshold of this approximately 12 hours postpartum uterus. Within the range of 12 to 6 v. per 5 cm. WT decreased only slightly, indicating high excitability. Threshold was low at 4 v. per 5 cm. and the subthreshold stimulus (which failed to excite) 3 v. per 5 cm. However, when stimulation was discontinued, no spontaneous activity appeared during ~ 5 minutes indicating that under the present experimental conditions the intrinsic stimulatory mechanism could not break through threshold (*A2*). Only when the same strip was exposed to 100 pg. per milliliter of $PGF_{2\alpha}$, which decreased its threshold to 3 v. per 5 cm., did spontaneous activity appear promptly on the discontinuation of electric stimulation (*A3*). Apparently $PGF_{2\alpha}$ lowers threshold, increases excitability, and in so doing promotes spontaneous uterine activity. Washing the strip with Krebs' solution removed $PGF_{2\alpha}$,

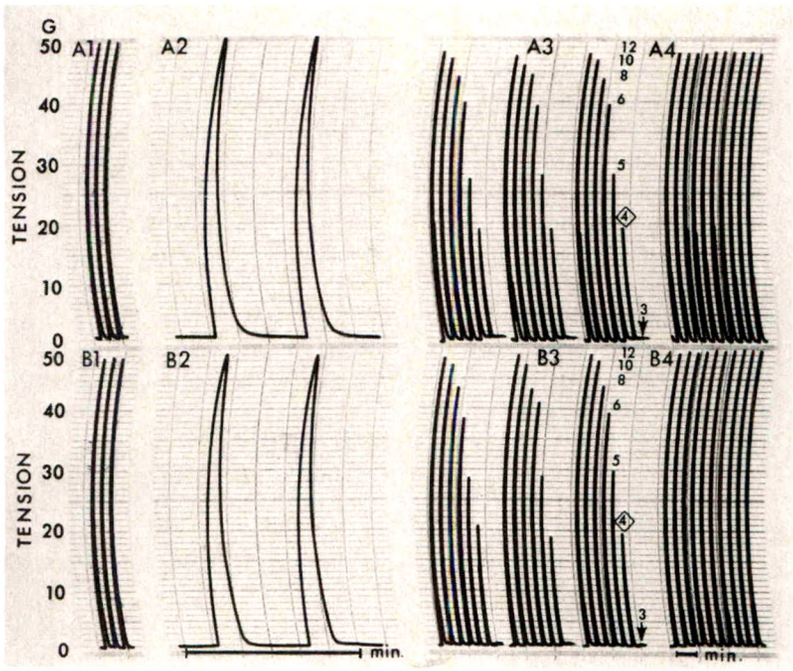

Fig. 4. The stability of excitability and threshold in twin strips. Uterus: approximately 12 hours postpartum. A simultaneous study of twin strips under identical experimental conditions. *A1* and *B1*, Maximum WT induced by 12 v. per 5 cm. field. *A2* and *B2*, The shape of the contraction cycles. *A3* and *B3*, The stability of excitability and threshold during three subsequent studies. *A4* and *B4*, Maximum WT in steady state at the end of the experiment.

increased threshold to the pretreatment value (4 v. per 5 cm.), and suspended spontaneous activity (*A4*).

The reliability of the method. Using twin (rather than single) strips of the same uterus the reliability of the method had been determined in preparation to comparative studies of excitability and threshold under a variety of regulatory conditions. Fig. 4 illustrates that when geometrically similar* twin strips (of the same uterus) were stimulated at optimum field strength (12 v. per 5 cm.) WT was maximal and steady (*A1* and *B1*) and the shape of the contraction-relaxation cycles comparable (*A2* and *B2*). Furthermore, the response of the strips to a series of DEFS was similar and threshold constant (4 v. per 5 cm.) during three subsequent studies (A3 and B3). In addition, 12 v. per 5 cm. triggered maximum WT in a steady state at the end of the experiment (*A4* and *B4*), further illustrating the stability of the uterine strips and the reliability of the technique.

Apparently a method (DEFS) had been developed which, in uterine strips of different regulatory background, can: (1) characterize excitability by the rate of decline in WT on DEFS; (2) quantitate threshold by the minimum field which provokes WT; (3) determine the regulatory action of various agents through their effect on excitability and threshold; (4) relate changes in threshold to the control of spontaneous uterine activity. The obvious advantage of the method is that, rather than characterizing excitability of a single cell or of several cells by repeated measurements during several hours, it describes the functional state of the entire uterine tissue by a series of rapid measurements. Also, it quantitates threshold after the uterus developed a series of responses provoked by a constant set of decreasing stimuli which stabilizes the organ prior to this critical measurement. The accuracy of the test is increased by repeating it (Fig. 4).

The design of the present studies. Having completed a series of pilot experiments, 48 uterine strips of 24 New Zeland white rabbits were studied systematically. At the twenty-fifth day of pregnancy (P = 9.1 ± 1.2 ng. per milliliter [18]), eight animals were killed and 16 uterine strips examined. Within 12 hours postpartum (P = 0.7 ± 0.2 ng. per milliliter[18]) 12 animals were put to death and 24 uterine strips studied. Postpartum (rather than term pregnant or parturient) uteri were used for studying the condition of high excitability and low threshold because term pregnancy varies with litter

*The significance of differences in W is explained in Comment.

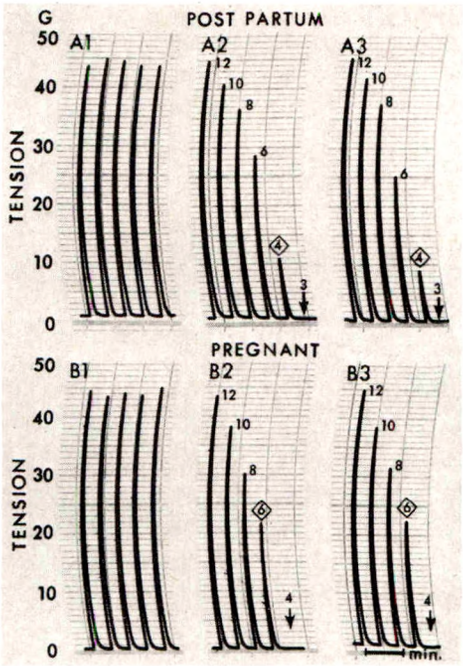

Fig. 5. The effects of pregnancy and parturition on excitability and threshold. Uterus: *A*, approximately 12 hours' postpartum; *B*, 25 days' pregnant. *A1* and *B1*, Maximum WT in steady state (stimulus 12 v per 5 cm.). *A2* and *B2*, The effect of stepwise DEFS. Note that the threshold of postpartum uterus was 4 v. per 5 cm. while that of the pregnant uterus 6 v per 5 cm. Note also that on DEFS WT decreased more rapidly in the pregnant than in the postpartum uterus, indicating suppressed excitability during pregnancy. *A3* and *B3*, The stability of excitability and threshold is illustrated by the similarity in WT responses on the repetition of the experiment.

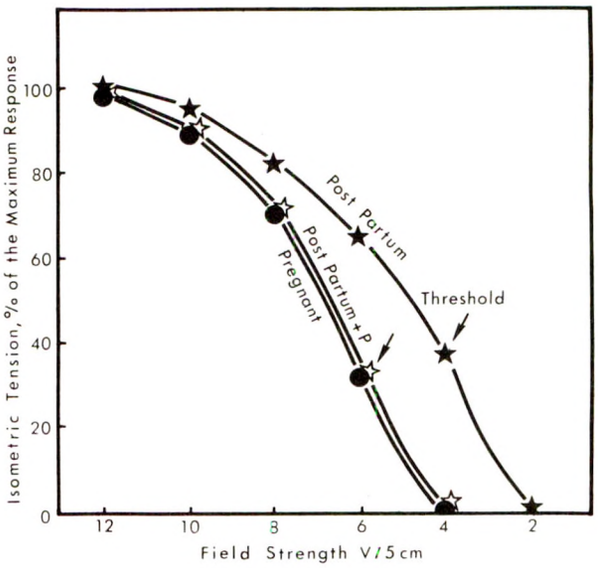

Fig. 6. The effects of pregnancy, parturition, and progesterone treatment on excitability and threshold. A summary of the results obtained in 24 uterine strips approximately 12 hours postpartum, 16 strips 25 days' pregnant, and eight strips postpartum pretreated with P. Note the steeper decrease in WT of the pregnant and postpartum P pretreated than of the postpartum uterine strips during exposure to DEFS. Note also that threshold was higher (6 v. per 5 cm.) in the pregnant and postpartum P pretreated than in the postpartum uteri (4 v. per 5 cm.).

size and parturition usually occurs overnight. The two regulatory conditions, 25 days' pregnant and postpartum, were selected for study to characterize by comparison the effect of progesterone withdrawal (Pw) on uterine excitability and threshold. The premise, that it is Pw (rather than some coincidental change) which lowers threshold and increases excitability, had been examined about 12 hours postpartum in eight uterine strips of four rabbits which received 5 mg. of progesterone (intramuscularly in oil) immediately after delivery.

Results

Excitability and threshold during pregnancy and after birth. Fig. 5 illustrates differences in excitability and threshold between pregnant and postpartum uteri. One uterine strip (*A1*) had been excised approximately 12 hours postpartum (P = 0.7 ± 0.1 ng. per milliliter), while the other (*B1*) was excised on the twenty-fifth day of pregnancy (P = 9.1 ± 1.2 ng. per milliliter). Having built up in both strips maximum WT in a steady state with 12 v. per 5 cm. stimuli (*A1* and *B1*), DEFS was applied: 10, 8, 6, 4, and 3 v. per 5 cm. (*A2* and *B2*). In contrast to the postpartum uterus which responded to stimuli of 4 v. per 5 cm. or higher (*A2*), the pregnant uterus responded only to stimuli of 6 v. per 5 cm. or higher and failed to respond to the 4 v. per 5 cm. field (*B2*). In repeating the study, excitability amd threshold remained unchanged (*A3* and *B3*), illustrating that the differences in excitability and threshold between these two uteri (of different regulatory background) are stable.

Fig. 6 summarizes the results obtained in 12 postpartum, eight pregnant, and four progesterone-treated postpartum uteri. DEFS (from 12 v. per 5 cm. to 10, 8, 6, 4, and 3 v. per 5 cm.) reduced WT step by step in all uteri by activating fewer and fewer cells of the total cell population. Apparently DEFS decreases the ratio: active/inactive cells and reduces WT (through the elastic "yielding" of the inactive cells).[23]

Fig. 6 also illustrates that this decrease in WT resulting from DEFS was steeper in the pregnant and P-treated postpartum uteri than in the untreated postpartum uteri. This finding is evidence that: (1) the excitability of the pregnant (as compared to the

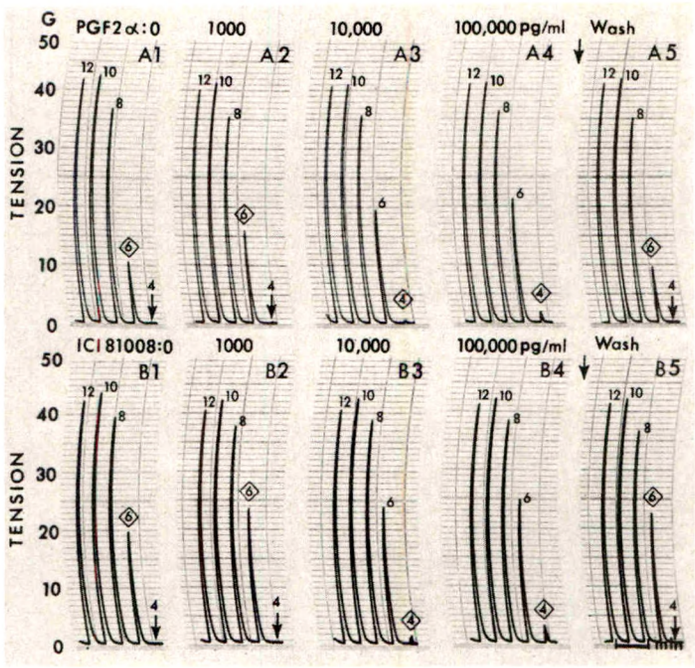

Fig. 7. The effects of $PGF_{2\alpha}$ and ICI 81008 on the excitability and threshold of the pregnant uterus. Uterus: approximately 25 days' pregnant. *A1* and *B1*, Excitability and threshold before treatment with PG's. Threshold was 6 v. per 5 cm. *A2, A3, A4,* and *B2, B3, B4.* The $PGF_{2\alpha}$ and ICI 81008 were administered in concentrations increasing from 1,000 to 100,000 pg. per milliliter. Only when the concentration of $PGF_{2\alpha}$ and ICI 81008 was increased to the excessive value of 100,000 pg. per milliliter (*A4* and *B4*) was the threshold distinctly lowered (from 6 v. per cm. to 4 v. per cm.). The PG-induced increase in WT at higher fields was also moderate. *A5* and *B5,* Washing the tissue with Krebs' solution promptly restored threshold to the pretreatment value (6 v. per 5 cm.).

postpartum) uterus is suppressed; (2) that this effect of pregnancy is due to a P action; (3) P increases while Pw decreases threshold. The difference in threshold between the pregnant (or P-treated postpartum) and the postpartum uteri was very highly significant statistically ($p < 0.001$).

The effects of $PGF_{2\alpha}$ and its analogue ICI 81008 on uterine excitability and threshold. Fig. 7 illustrates that when the pregnant uterus was exposed to increasing concentrations of $PGF_{2\alpha}$ and ICI 81008 the effects of these two compounds on excitability and threshold were similar. However both PG's were effective only at the unphysiologic concentration of about 100,000 pg. per milliliter (*A1, A2, A3, A4,* and *B1, B2, B3, B4*) and even at this high concentration they only lowered threshold from 6 to 4 v. per 5 cm. *(D).* A single washing of the strips with Krebs' solution suspended the effect of both PG's and increased threshold to its original value: 6 v. per 5 cm. *(E).* Apparently, the 25 days' pregnant uterus ($P = 9.1 \pm 1.2$ ng. per milliliter) is insensitive to PG's even at unphysiologic concentration.[2]

Fig. 8 illustrates that, in contrast to the pregnant uterus, the excitability and threshold of the postpartum uterus ($P = 0.7 \pm 0.2$ ng. per milliliter) were strongly affected by $PGF_{2\alpha}$ *(A1, A2, A3,* and *A4)* and ICI 81008 *(B1, B2, B3,* and *B4).* A concentration of $PGF_{2\alpha}$ or ICI 81008 as low as 10 pg. per milliliter lowered threshold from 4 to 3 v. per 5 cm. (*A2* and *B2*) and 1,000 pg. per milliliter reduced it to 2 v. per 5 cm. *(A4* and *B4).* Furthermore, as the PG concentration was increased from 10 pg. per milliliter to 1,000 pg. per milliliter, the same electric field provoked greater and greater WT, demonstrating that by reducing threshold PG's increase excitability. Apparently, the postpartum uterus is highly sensitive to PG's, while the pregnant uterus is insensitive. Fig. 8 also illustrates an additional finding of considerable therapeutic interest. In an earlier study[25] ICI 81008 was about 50 times more efficacious as an abortifacient than $PGF_{2\alpha}$. Since during normal pregnancy PG's cannot display their oxytocic potency, increased efficacy was explained[25] by a prolonged action on microcirculation and fetoplacental or luteal endocrine functions, resulting in Pw and consequent decrease in myometrial threshold and increased excitability. The effects of PG's on microcir-

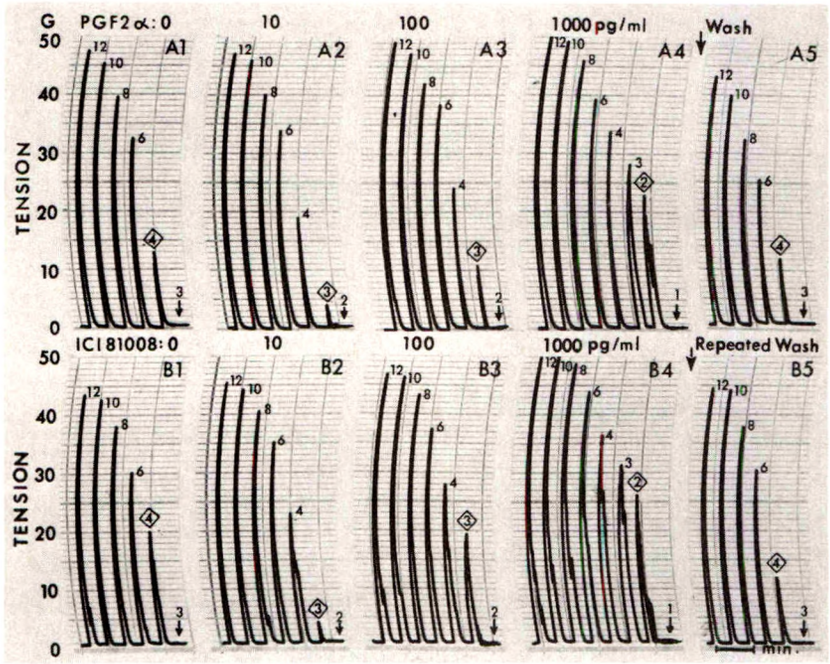

Fig. 8. The effects of $PGF_{2\alpha}$ and ICI 81008 on the excitability and threshold of the postpartum uterus. Uterus: approximately 12 hours; postpartum. *A1* and *B1*, Excitability and threshold before treatments with PG's. In comparison with the pregnant uterus (Fig. 7), threshold was low (only 4 v. per 5 cm.). *A2*, *A3*, *A4*, and *B2*, *B3*, *B4*, $PGF_{2\alpha}$ and ICI 81008 were administered in concentrations increasing from 10 to 1,000 pg. per milliliter. Threshold already decreased (from 4 to 3 v. per 5 cm.) at the PG concentration of 10 pg. per milliliter. As the concentration of PG's was raised, WT (induced by submaximal stimuli) increased, indicating increased excitability. At 1,000 pg. per milliliter PG concentration threshold decreased to 2 v. per 5 cm. *A5* and *B5*, A single wash with Kreb's solution suspended the effect of $PGF_{2\alpha}$ on excitability and threshold, while repeated washing was needed to suspend the effect of ICI 81008, indicating strong binding at target sites.

culation[26] and steroidogenesis[9–16] have already been demonstrated. Fig. 8 illustrates that in comparable doses ICI 81008 (*B1*, *B2*, *B3*, and *B4*) did not reduce threshold or increase excitability more than did $PGF_{2\alpha}$ (*A1*, *A2*, *A3*, and *A4*). This finding indicates that, despite the greater abortifacient efficacy of ICI 81008, the oxytocic potency of these two PG's is similar. However, threshold was restored by a single washing (with Krebs' solution) after $PGF_{2\alpha}$ (*A5*), while repeated washing was needed after ICI 81008 treatment (*B5*). This finding suggests that the binding of ICI 81008 at target sites is stronger than that of $PGF_{2\alpha}$.

Fig. 9 summarizes the results obtained by DEFS in 16 pregnant and 24 postpartum uterine strips. Both PG's affected the postpartum uteri significantly (*A* and *C*), while the pregnant uteri only slightly (*B* and *D*). However, the effects of $PGF_{2\alpha}$ and ICI 81008 on excitability and threshold were similar. Apparently, the high threshold of the pregnant uterus cannot be effectively reduced by either $PGF_{2\alpha}$ or ICI 81008 and thus during normal pregnancy a true oxytocic action cannot be promptly induced by these compounds. This finding exposed the importance of the premise that it is P which sustains high threshold during normal pregnancy and Pw (associated with parturition) which lowers threshold. The following study examined the validity of this premise.

The effect of progesterone on excitability and threshold. Fig. 10 illustrates that twin uterine strips, removed about 12 hours postpartum from a rabbit which when delivered received 5 mg. of P (in oil, intramuscularly), had excitability and threshold indistinguishable from those of 25 days' pregnant uteri (*A1*, *B1*). Also the effects of $PGF_{2\alpha}$ and ICI 81008 on the excitability and threshold of these uteri were characteristic of the 25 days' pregnant uteri (*A2*, *A3*, *A4*, and *B2*, *B3*, *B4*). Since these strips were excised postpartum, approximately 12 hours after the animals were exposed to progesterone treatment, the conclusion is inescapable that P was the regulatory agent which restored low excitability and high threshold (as well as pharmacologic refractoriness) in these uteri.

The relationship between threshold and spontaneous activity and the reversibility of the effects of

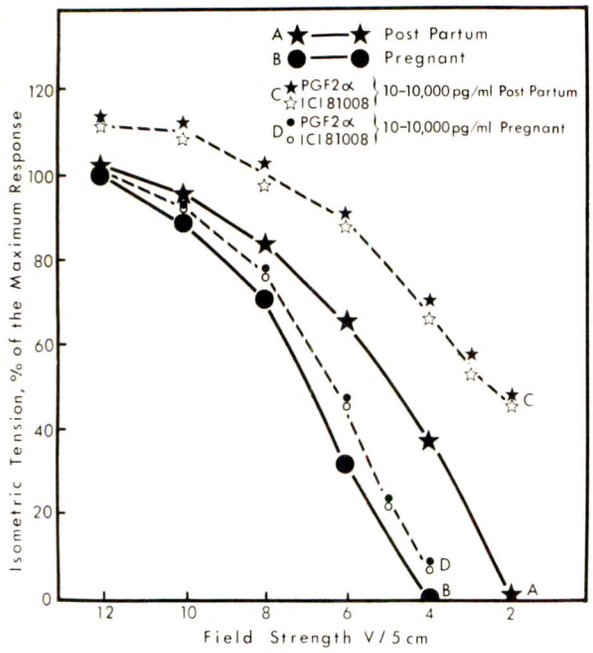

Fig. 9. The effects of $PGF_{2\alpha}$ and ICI 81008 on the excitability and threshold of the pregnant and postpartum uteri. A summary of the results obtained in 16 pregnant and 24 postpartum uterine strips. The WT values were measured within the entire range of 10 to 10,000 pg. per milliliter PG concentrations. However, at the same field strength of stimulation the values were averaged to demonstrate that at all levels of electric stimulation, both PG's significantly increased the excitability of the postpartum uteri (*A* and *C*) in contrast to that of the pregnant uteri (*B* and *D*).

$PGF_{2\alpha}$ and ICI 81008. Fig. 11 illustrates the relationship between threshold and spontaneous activity. After the build up of maximum WT *(A1)*, DEFS revealed that threshold is 4 v. per centimeter and that at this level of threshold there is no spontaneous activity under the present experimental conditions *(A2)*. Treatment of the uterus with 100 pg. per milliliter ICI 81008 promptly triggered spontaneous activity (which increased as the compound penetrated the tissue). WT also increased at all levels of electric stimulation indicating increased excitability as threshold decreased to 1 v. per 5 cm. The first washing did not suspend spontaneous activity *(A3)*, which was explained by the sustenance of low threshold: 2 v. per 5 cm. *(A4)*. Repeating the experiment showed *(A5 to A8)* that a total of six washings were needed to restore threshold to the pretreatment value of 4 v. per 5 cm. and to suspend spontaneous activity. Apparently the magnitude and frequency of spontaneous uterine activity is controlled (at least partly) by changes in threshold. The study also showed that through its effect on threshold ICI 81008 controlled the spontaneous activity of the uterus. Under the present experimental conditions the critical threshold value was ~ 3 v. per 5 cm.; when threshold was below 3 v. per 5 cm. spontaneous uterine activity appeared, while when threshold was above this value it was not generated.

Fig. 11 also illustrates *(A9)* that 100 pg. per milliliter $PGF_{2\alpha}$ also triggered spontaneous activity by increasing excitability and reducing threshold from 4 to 2 v. per 5 cm. However (in contrast to ICI 81008, $PGF_{2\alpha}$ was readily removed as indicated by the disappearance of spontaneous activity, decrease in excitability, and increase in threshold from 2 to 4 v. per 5 cm. by a single washing *(A10)*.

Apparently the effects of both $PGF_{2\alpha}$ and ICI 81008 were reversible. Both compounds were successfully removed from the same uterus by washing with Krebs' solution. However, six consecutive washings were needed to suspend the effect on excitability and threshold of 100 pg. per milliliter ICI 81008 *(A2-A8)*, while a single washing suspended the effect of 100 pg. per milliliter $PGF_{2\alpha}$.

Comment

The present studies were prompted by the recognition that threshold control is a basic regulatory process of considerable interest in reproductive medicine. The therapeutic control of threshold became a pressing clinical problem when it was realized[2] that the pregnant uterus responds only to stimulants when they are given in pharmacologic doses, and even then its response is an unphysiologic contracture. In order to "convert" this contracture response to a normal oxytocic response, for example, high level cyclic IUP (which approximates the maximum working capacity of the organ, IUP = 2WT/R), the uterus had to be *converted* first from a *refractory* to a *reactive* tissue by a marked reduction in P levels.[2–16]

The meaningful examination of threshold control presented technical problems. For, being made up from billions of cells which are significantly different from one another in electrophysiologic properties, even under well-defined regulatory conditions,[23, 24] the threshold of only few cells rather than that of the whole uterus could be characterized with intracellular microelectrodes. Therefore, a technique had to be developed which could quantitate threshold by "averaging" the excitability of all myometrial cells in the excised tissue and in so doing characterize the regulatory condition of the uterus. The in vitro method of "decreasing the electric field stimulation" (DEFS) provided a simple, reliable, and quantitative technique.[2, 17]

This method determined, in approximately 30

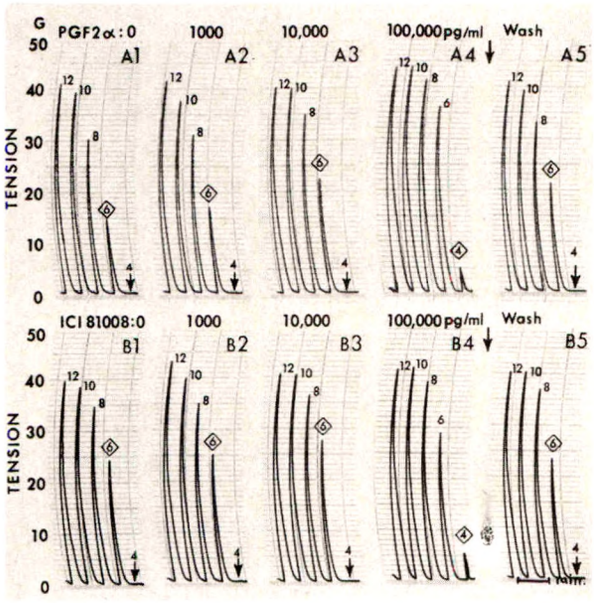

Fig. 10. The effects of $PGF_{2\alpha}$ and ICI 81008 on the excitability and threshold of the progesterone-treated postpartum uterus. Uterus: approximately 12 hours' postpartum, but animal received 5 mg. progesterone after parturition. *A1* and *B1*, Excitability and threshold before PG treatment. Threshold was 4 v. per 5 cm. *A2*, *A3*, *A4*, and *B2*, *B3*, *B4*, $PGF_{2\alpha}$ and ICI 81008 were administered in concentrations increasing from 1,000 to 100,000 pg. per milliliter. *A4* and *B4*, Only when the concentration of $PGF_{2\alpha}$ and ICI 81008 reached the excessive value of 100,000 pg. per milliliter was threshold lowered (from 6 to 4 v. per 5 cm.). The PG-induced increase in WT was also moderate. *A5* and *B5*, Washing the tissue with the Kreb's solution promptly restored threshold to the pretreatment value (6 v. per 5 cm.).

minutes after the exposure of the uterine strips to the in vitro environment: (1) the optimum electric field and maximum WT as reference points; (2) excitability, by changes in WT induced by a standard series of DEFS; (3) threshold, by the minimum field strength which triggered WT; (4) the effect on WT, excitability, and threshold of endogenous regulatory changes; (5) the effect on WT, excitability, and threshold (which together characterize pharmacologic actions) of exogenous stimulants and suppressors; (6) the relationship between threshold and spontaneous activity of the uterus; (7) the relationship between the binding of active compounds and the duration of their effects on WT, excitability, and threshold.

This method (which opened up other lines of investigation as well, for example, in uterine bioenergetics) provides *average* values for uterine excitability, threshold, and pharmacologic reactivity rather than describes single myometrial cells in terms of membrane and action potentials, pacemaker activity, etc.[23, 24, 27] DEFS is no substitute for the intracellular microelectrode technique and vice versa. Therefore, the two procedures should be used side by side for the in depth characterization of uterine function and regulation in those instances when one of them provides partial information only. Nor does DEFS substitute for the study of uterine function in situ. However (as shown by the present experiments), DEFS can characterize the regulatory conditions of the uterus as well as pharmacologic effects, prior to the in situ examination of new therapeutic agents in animal "models" and patients. In some instances DEFS already predicted the outcome of the in situ studies.[28, 29]

At the twenty-fifth day of pregnancy ($P = 9.1 \pm 1.2$ ng. per milliliter) uterine excitability was suppressed and threshold was high (6 v. per 5 cm.). In contrast, postpartum ($P = 0.7 \pm 0.2$ ng. per milliliter) excitability was high and threshold was low (4 v. per 5 cm.). That this significant difference in threshold between pregnant and postpartum uteri ($P < 0.001$) was an effect of P had been demonstrated by restoring high threshold through treatment with P in the postpartum uteri.

It could be argued that excitability and threshold (presently averaged by recording the WT responses of the uterus to DEFS) may not only depend on the excitatory characteristics of the individual myometrial cells of the examined tissue, but also on electric communication between the external and internal layers of these cells. For the electric current applied must penetrate promptly into the stimulated organ to activate its inner layers, or the outer layers must conduct the action potentials rapidly toward the inner layers to promote their participation in activity. Thus radial condition can increasingly affect WT as the stimulus decreases if W is so excessive that the stimulating current cannot penetrate it. This is a valid argument.

However, in the present studies, when 25 days' pregnant and ~ 12 hours[7] postpartum uteri were studied comparatively, W of the postpartum uteri was greater than that of the 25 days' pregnant uteri. If, therefore, radial conduction promoted WT by increasing the participation of the inner layers in activity, then the 25 days pregnant uteri of lesser W were promoted more than the postpartum uteri. Yet the decline of WT on DEFS was steeper and threshold higher in the 25 days' pregnant than in the postpartum uteri. Furthermore, when the animals received P treatment after having given birth, the W of these and the untreated postpartum uteri were similar. Yet the decline in WT of the P-treated postpartum uteri was steeper and their threshold higher than those of the untreated postpar-

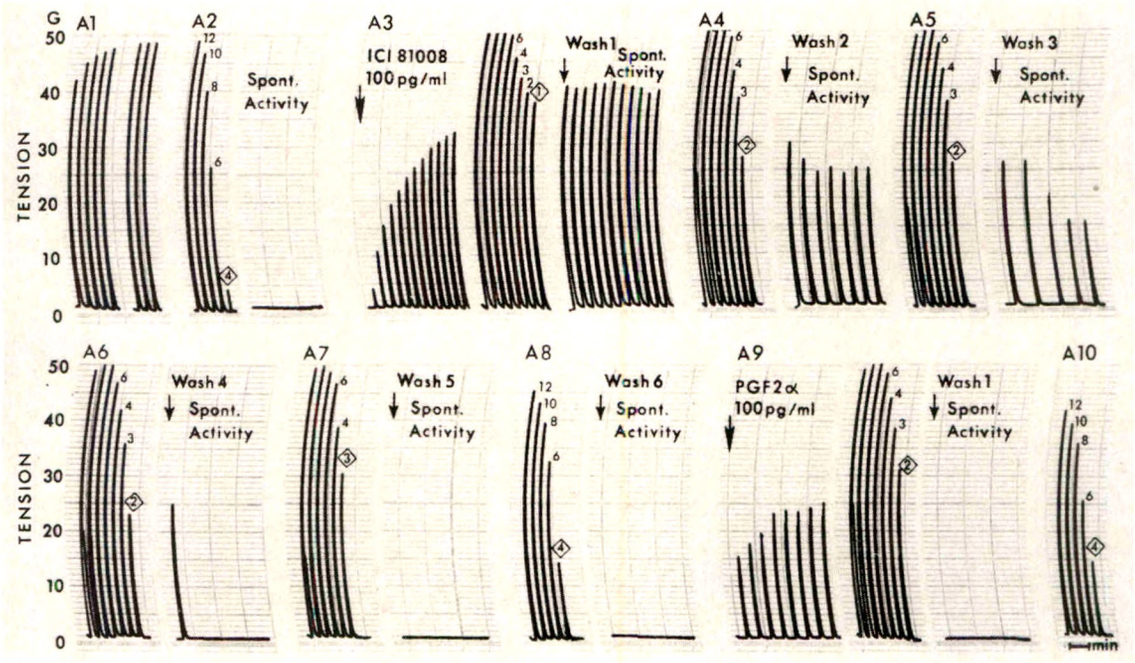

Fig. 11. The effects of ICI 81008 and $PGF_{2\alpha}$ on spontaneous activity, excitability, threshold and recovery. Uterus: approximately 12 hours' postpartum. *A1,* The preparatory steps before the study. *A2,* The effect of DEFS and the assessment of spontaneous activity. When threshold was 4 v. per 5 cm. there was no spontaneous activity (*A3*), but 100 pg. per milliliter of ICI 81008, by lowering threshold (from 4 to 1 v. per 5 cm.), induced it and increased excitability. *A3, A4, A5, A6, A7, A8,* Excitability and spontaneous activity decreased simultaneously when threshold was increased by the removal of ICI 81008 through repeated washing of the uterus. *A9,* The effect of 100 pg. per milliliter $PGF_{2\alpha}$ was similar to that of ICI 81008, but it was suspended by a single washing.

tum uteri. If, therefore, limitations in radial conduction did contribute to the decrease in WT when DEFS approximated threshold values, the 25 days' pregnant uteri of smaller W were affected less by this parameter. Therefore, if the threshold values of the 25 days pregnant and postpartum uteri were corrected for W, the differences between them should increase.

The observed difference in threshold between the pregnant and postpartum uteri is of considerable interest, specifically if the additional finding is considered that, when threshold is high, spontaneous activity is suppressed and the uterus fails in responding to physiologic doses of stimulants. For then it becomes apparent that while the uterus sustains maximum working capacity throughout pregnancy, this potential cannot be converted to high-level cyclic IUP by endogenous or even excessive exogenous stimulation until threshold is lowered by Pw. On the other hand, since the intrinsic uterine stimulant is also present throughout pregnancy, a mere Pw can promote activity by lowering threshold. Thus the present studies fully exposed the significance of endogenous Pw (which occurs near term and precociously in cases of threatened premature labor) and also of Pw exogenously provoked by luteectomy, hypertonic saline, or PG impact.

The present demonstration that in physiologic concentrations $PGF_{2\alpha}$ lowers threshold and increases excitability if threshold has already been lowered by Pw is a point of additional interest. So is the finding that the oxytocic potency of its synthetic analogue ICI 81008 (which is a considerably more potent abortifacient than $PGF_{2\alpha}$) is not greater, only its binding to myometrial sites is stronger and thus its action is prolonged.

Together, the present observations suppliment earlier findings and interpretations, regarding the mechanism of PG action. By showing that oxytocic action is controlled by threshold and threshold by P and that the oxytocic actions of $PGF_{2\alpha}$ and ICI 81008 are similar, the present studies exposed the significance of the effect of PG's on uterine microcirculation, fetoplacental and luteal endocrine functions, and consequently on the regulatory balance of the pregnant uterus. This information may be useful when protocols are designed for the clinical study of PG's.

However, perhaps the broadest and most immediate practical application of the technique of DEFS is in the

reliable screening of new oxytocic compounds and suppressors of therapeutic promise. For, once twin strips are in a steady state (and of course more than one pair may be used simultaneously if desired), the action of a potential uterine stimulant or suppressor can be characterized and quantitated in a few minutes. With the use of, for example, $PGF_{2\alpha}$ (a stimulant) and Naproxen (a suppressor of PG synthesis) as standards, the regulatory potency of new compounds can be characterized comparatively.

As already demonstrated, if the compound is active in vitro,[17] it is also active in situ[23, 25, 28] and the information obtained in animal "models" promotes the design and the predictability of the outcome of clinical trials.[29].

The author is grateful to Drs. A. L. Wapole and M. Dukes of the Imperial Chemical Industries, Limited, for their stimulating comments throughout this study and for the supply of the prostaglandin analogue, ICI 81008; and to Drs. E. M. Southern and G. D. Gutknecht of The Upjohn Co. for useful discussions and for the supply of $PGF_{2\alpha}$. The assistance of Professor M. Pulkkinen and his associates of the Turku University, Finland, in the various phases of this work is acknowledged, and the technical help of Elise F. Csapo, Gabriele Salau, and B. Hayden is appreciated.

Effect of ampicillin administration on estradiol, estriol, and cortisol levels in maternal plasma and on estriol levels in urine

S. SYBULSKI, M.Sc., PH.D.
G. B. MAUGHAN, M.D., F.R.C.S.
Montreal, Quebec, Canada

Ampicillin treatment in the last trimester of pregnancy had no significant effect on the levels of estradiol, estriol, or cortisol in maternal plasma. Urinary estriol excretion was, however, notably decreased during or following ampicillin treatment in six out of 10 patients. These results suggest that the plasma estrogen assays have greater validity than the urinary estriol assay in assessing fetoplacental endocrine function during a period of ampicillin treatment of the mother.

WE ROUTINELY assess the endocrine function of the fetoplacental unit in high-risk pregnancies by determination of estriol levels in maternal plasma and urine and by determination of estradiol levels in maternal plasma. In view of a recent report that ampicillin administration per se significantly depresses estriol levels in plasma and urine,[1] we wished to determine whether ampicillin exerts a similar effect on plasma estradiol. If it did not, the estradiol assay would be the assay of choice in high-risk pregnancies during ampicillin treatment, especially since we have found that maternal plasma estradiol levels accurately reflect the metabolic status of the fetoplacental unit in such pregnancies.[2]

Cortisol concentrations in the maternal plasma were simultaneously assessed to investigate the possibility that the reported ampicillin effects on estriol levels might be a reflection of maternal stress while treated. Relatively high levels of glucocorticoids in the maternal circulation may result in decreased levels of estrogens in maternal plasma and urine.[3]

Materials and methods

Noninfected patients who were hospitalized in the last trimester of pregnancy for threatened premature labor, mild toxemia, pruritus, or observation for other complications were treated with ampicillin. The steroid assays were performed for 7 consecutive days in most cases. Days 1 and 2 were control, following which a 500 mg. dose of ampicillin was given orally four times per day for 3 days, and days 6 and 7 were post-treatment controls. Any deviation from this schedule is indicated in the results. More than seven determinations of some steroids were performed in some patients and in others less than this amount.

Estriol levels in plasma and urine were measured by radioimmunoassay according to the method of Gurpide and associates.[4] Although this method actually measures total estrogens, estriol generally accounts for at least 80 per cent of estrogens produced in late pregnancy.

Estradiol and cortisol levels in plasma were determined by competitive protein-binding method employing human late pregnancy plasma as the source of the binding proteins, sex hormone–binding protein, and transcortin, as described in detail elsewhere.[5, 6]

Results

All steroid values observed in each patient are shown individually in Figs. 1 to 4.

Some degree of day-to-day fluctuation in plasma steroid levels is generally observed in hospitalized patients and it was observed in the present patients before, during, and after ampicillin treatment. In this context, Figs. 1 to 3 show that ampicillin treatment had no notable effect on the levels of estradiol, estriol, or cortisol in maternal plasma. This was confirmed by

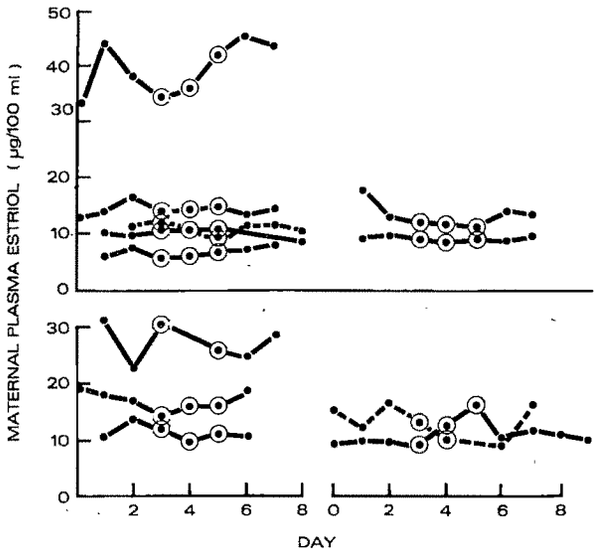

Fig. 1. Maternal plasma estriol concentrations in 11 patients before, during and after ampicillin treatment. Values during treatment are indicated by a dot in a circle.

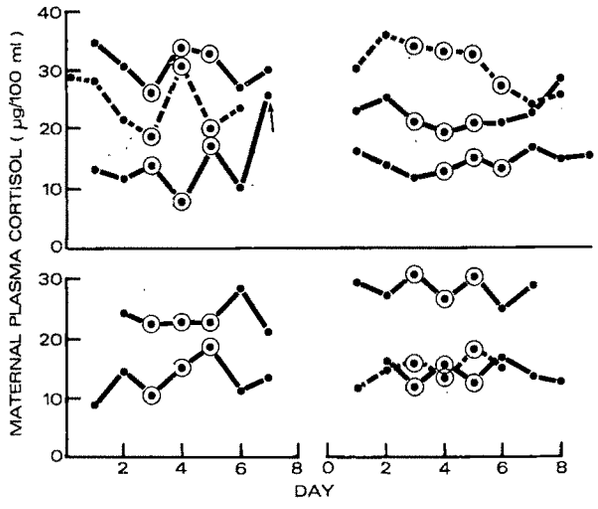

Fig. 2. Maternal plasma cortisol concentrations in 11 patients before, during and after ampicillin treatment. Values during treatment are indicated by a dot in a circle. The small arrow indicates that the patient was in spontaneous labor.

statistical evaluation of data from all patients pooled into before, during, and after ampicillin treatment categories, as indicated in Table I. The differences in mean values in these categories were not significant for plasma estradiol, estriol, or cortisol.

On the other hand, because of the wide range in interpatient values, pooling data for statistical purposes in the case of urinary estriol determinations obscured the fact that ampicillin treatment did affect urinary estriol excretion in some patients, as indicated in Fig. 4.

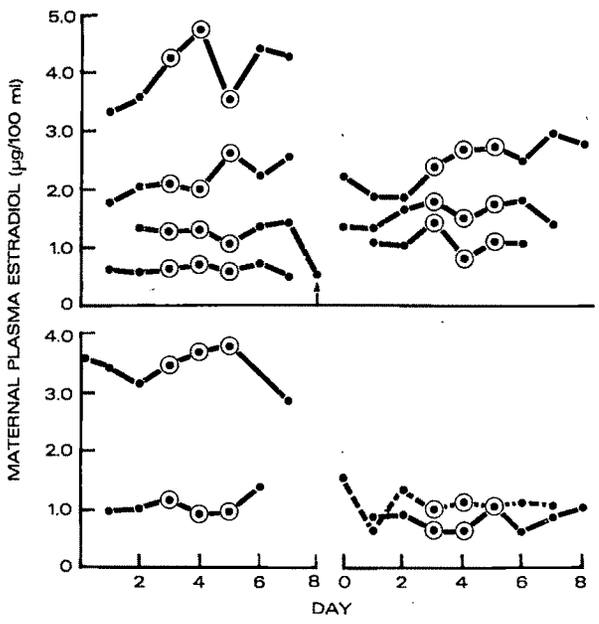

Fig. 3. Maternal plasma estradiol concentrations in 11 patients before, during and after ampicillin treatment. Values during treatment are indicated by a dot in a circle. The small arrow indicates time of onset of heavy bleeding associated with placenta previa.

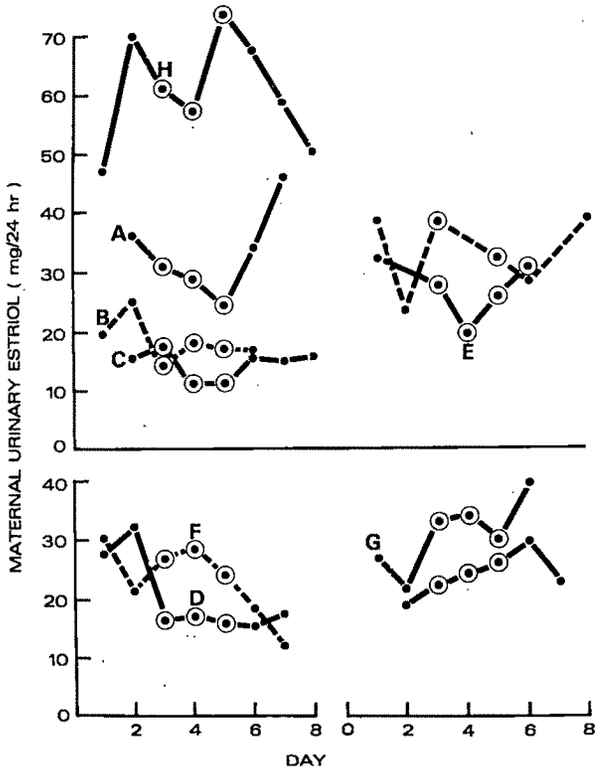

Fig. 4. Maternal urinary estriol concentrations in 10 patients before, during, and after ampicillin treatment. Values observed during treatment are indicated by a dot in a circle.

Table I. Effect of ampicillin treatment on estradiol, estriol, and cortisol levels in maternal plasma and on urinary estriol excretion

Steroid	*Steroid concentrations**		
	Before treatment	*During treatment*	*After treatment*
Plasma estradiol (μg/100 ml.)	1.74 ± 0.18 (26)	1.92 ± 0.20 (32)	1.85 ± 0.23 (22)
Plasma estriol (μg/100 mL)	16.3 ± 2.0 (26)	14.9 ± 1.6 (31)	15.7 ± 2.3 (21)
Plasma cortisol (μg/100 ml.)	21.6 ± 1.7 (23)	21.3 ± 1.3 (34)	20.4 ± 1.4 (22)
Urinary estriol (mg/24 hr.)	28.7 ± 2.7 (19)	29.1 ± 2.3 (32)	31.2 ± 3.5 (19)

*Values are the mean ± standard error; those in parentheses are the number of samples. The differences in mean steroid values observed before, during, and after ampicillin treatment are in each case not statistically significant.

A sustained decrease in values during treatment was observed in four of 10 patients (curves *A* to *D*). A fifth patient (curve *E*) showed an initial decrease in estriol excretion followed by an increase while treated. In another patient (curve *F*) estriol levels decreased markedly following treatment. Values in the four remaining patients, including the two afflicted with pruritus (curves *G* and *H*), were either unchanged or increased during treatment.

Comment

These results indicate that ampicillin treatment in the last trimester of pregnancy has no significant effect on the levels of estradiol, estriol, or cortisol in maternal plasma. The findings with respect to cortisol suggest that maternal stress which could affect fetoplacental function was not a factor in this study; excessive levels of cortisol in the maternal circulation can result in suppression of biosynthesis of estrogen precursors by maternal and fetal adrenals.[3]

An evident decrease in urinary estriol values during ampicillin treatment was observed in about half of the patients. Possibly ampicillin interfered with the enterohepatic circulation of estriol in these particular cases, causing greater excretion in the feces. This effect of ampicillin in pregnant patients has recently been reported by Tikkanen and associates.[7]

Although not all patients were affected (including the two patients with pruritus) the present results tend to agree with the findings of Willman and Pulkkinen[1] in regard to effect of ampicillin treatment on urinary estriol excretion but disagree with the latter authors' findings of a significant concomitant suppression of estriol levels in maternal plasma.

The present results indicate that the plasma estradiol and estriol tests have greater validity than the urinary estriol assay in high-risk pregnant patients during a period of ampicillin treatment.

Two patients were delivered soon after ampicillin treatment. Labor was normal and at term in one case; in the other, an emergency cesarean section was performed for placenta previa with bleeding at 37 weeks' gestation. Of the steroids measured only plasma estradiol reflected this complication. The newborn infants were apparently normal in both cases.

The urinary and plasma estriol determinations were done in the Endocrine Laboratory of the Royal Victoria Hospital. The authors thank Doctors A. DeLeon and J. Chow for assistance.

Human pregnancy-associated plasma proteins during the postpartum period

TSUE-MING LIN, PH.D.
SEYMOUR P. HALBERT, M.D.
WILLIAM N. SPELLACY, M.D.
STANLEY GALL, M.D.
Miami, Florida

The plasma levels of four pregnancy-associated plasma proteins (PAPP's) and pregnancy zone protein (PZP) were studied in women after delivery of a single viable infant by gel immunodiffussion methods. Data from 89 random samples and 85 serial specimens from five women revealed that both PAPP-B and HPL (PAPP-D) disappeared within a day after delivery. PAPP-A showed a rapid drop in the first 2 or 3 days post partum and became nondetectable in 4 to 6 weeks, with a half-life of 3 to 4 days. PAPP-C had a sharp decrease by the second postpartum day and was not detected 3 to 4 weeks later, with a half-life of 1 to 2 days. None of the PAPP's was detected again during the rest of the 14 postpartum weeks studied. In contrast, the PZP showed a much slower decrease or even a temporary increase during the first 2 weeks post partum; it remained readily detectable over the entire 14 weeks studied.

CERTAIN proteins become readily detectable in maternal plasma during gestation that are undectectable prior to pregnancy.[1–5] Four such pregnancy-associated or -specific plasma proteins (PAPP's) were revealed with immunologic methods in our laboratory.[6–8] They differed from each other in molecular weight, sedimentation rate, electrophoretic mobility, isoelectric point, as well as other properties,[7] and were not detected in cord serum. Three of them have been purified over 100-fold and monospecific antisera against them have been prepared.[9] By comparing the immunologic specificity of monospecific antisera to the PAPP's and possibly related proteins from other investigators,[9] it was revealed that one of the PAPP's (PAPP-D) is human placental lactogen (HPL). Another (PAPP-C) is identical to the pregnancy-specific β_1-glycoprotein (SP_1) described in 1971 by Bohn.[10] The other two (PAPP-A and PAPP-B) may represent newly discovered human plasma proteins since they were unrelated to many of the proteins which had been described in association with pregnancy, such as α_1-fetoprotein, oxytocinase, chorionic gonadotropin, pregnancy zone,[11] α_2-pregnoglobulin,[12] pregnancy-associated globulin (PAG),[13] Pal,[14] new serum α-macroglobulin,[15] Xh,[17] SP_3,[10] and pregnancy-associated α_2-globulin.[18] Evidence has been obtained which indicates that the latter eight actually represent the same protein.[19] For convenience and historical reasons, this will be referred to below as pregnancy zone protein (PZP).

During gestation, the plasma levels of these PAPP's rose steadily during the second trimester and increased steeply in the early part of the third trimester.[20] PAPP-A continued to rise until the end of gestation, whereas PAPP-C reached a plateau late in the third trimester. HPL (PAPP-D) showed a trend similar to PAPP-C. The quantitative pattern of PAPP-B could not be determined because of technical reasons, but it was detected with increased frequency as gestation progressed. The present report is concerned with measurement of the PAPP's, as well as the PZP in the plasma of women during the postpartum period.

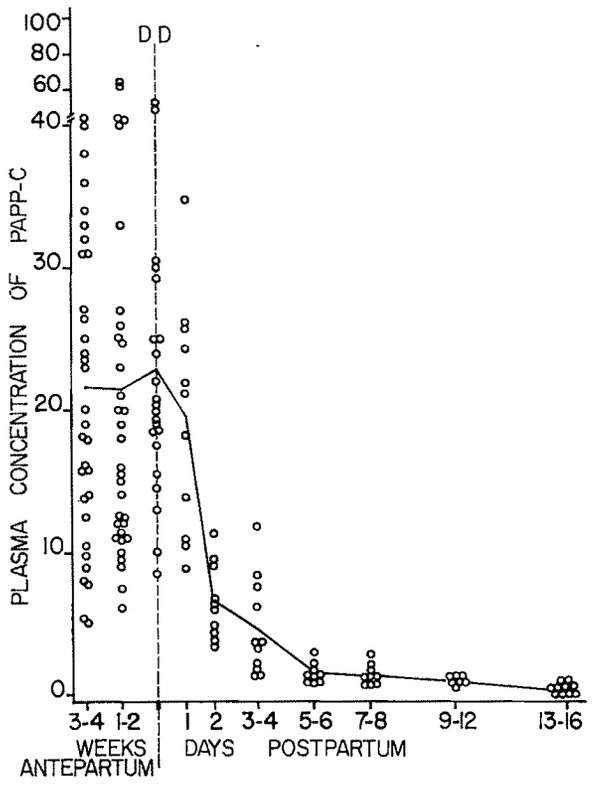

Fig. 2. Scatter diagram of PAPP-C concentration in early postpartum plasma. Means are connected with a solid line. *DD,* day of delivery.

Materials and methods

Two collections of plasma samples were obtained from the University of Miami Medical Center. The first consisted of 89 specimens from 55 women, representing single or repeat bleedings. They were obtained 0 to 16 days after term delivery of a single viable baby. These samples were assayed in duplicate for the concentration of PAPP's by the quantitative crossed-immunoelectrophoresis method described earlier.[20] The second group of 85 plasma samples were drawn serially from five normal women during the period between 6 weeks ante partum* and 14 weeks post partum. None of these received estrogen therapy during the first 4 weeks after delivery; one patient started estrogen-progesterone contraception (Norinyl) 8 weeks post partum. The concentrations of the PAPP's, as well as PZP, were measured in duplicate by Laurell's[21] "rocket" electroimmunodiffusion method with the monospecific antisera available, as well as by crossed-immunoelectrophoresis (for the detection of PAPP-B).[20] The former technique is the same as the latter, except that electrophoresis in the first direction is omitted. The values obtained by both methods showed good agreement in the case of PAPP-A, -C, and -D.

Poly- and monospecific rabbit antisera to the PAPP's for the assay system were prepared as described elsewhere.[9] Goat monospecific antiserum to PZP was generously donated by Dr. Berne of Indiana University.

A reference pregnancy plasma pool was concentrated fourfold by lyophilization to serve as a standard, and its contents of PAPP and PZP were arbitrarily assigned values of 100 units per milliliter, as described earlier.[20]

Results

Random samples. The data from these samples were grouped according to the time post partum, and charted in relation to the values previously obtained during late pregnancy.[20] As shown in the scatter diagram of Fig. 1, the plasma concentrations of PAPP-A increased until the day of delivery, then

*In this report, ante partum refers to the time before delivery.

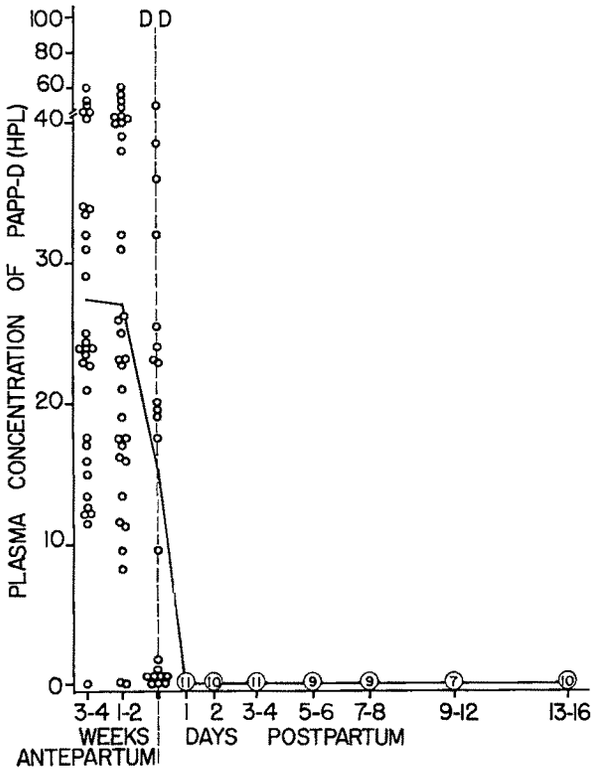

Fig. 3. Scatter diagram of HPL (PAPP-D) concentration in early postpartum plasma. Means are connected with a solid line. *DD,* day of delivery. Numbers in circles refer to the number of samples tested.

Table I. Detection of PAPP-B in the postpartum plasma samples by crossed-immunoelectrophoresis

Time of pregnancy	*No. with PAPP-B/ No. examined*	*Per cent*
Last month of pregnancy	32/65	49
Day of childbirth	11/22	50
1 to 16 days postpartum	0/67	0

showed a sharp drop in the first 2 days post partum, followed by a slower decrease to low levels during the rest of the period studied. It remained detectable in almost all specimens at the end of the second week post partum. The mean PAPP-A levels at 1 and 2 days post partum were 70 and 40 per cent of that found on the day of delivery, suggesting a half-life of 1 to 2 days for this pregnancy protein.

The PAPP-C levels 1 day after delivery were not much different from those seen in the last month of pregnancy. By the second day post partum, however, a sharp drop of more than 50 per cent occurred, which was followed by a more gradual decrease over the next 2 weeks (Fig. 2). By the end of the second week, PAPP-C was nondetectable in five of the 10 specimens tested. Both PAPP-B and HPL (PAPP-D) started to disappear rapidly on the day of childbirth and were not detectable 1 day after delivery or thereafter (Fig. 3 and Table I).

The rise in the PAPP's during pregnancy and their fall after delivery are diagrammatically summarized in Fig. 4, which incorporates the above data with those obtained earlier.[20] The median values, although often slightly lower, showed similar trends. PAPP-A was the last to increase during gestation, but it continued to rise until the day of delivery. PAPP-C began to rise earlier and less steeply, but reached a plateau during the last several weeks of pregnancy. Both PAPP-A and PAPP-C dropped sharply after delivery, but PAPP-C decreased more rapidly in the first week of the postpartum period. HPL (PAPP-D) rose steeply during the third trimester, reached its highest concentration during the middle part of the third trimester, and then dropped precipitously after delivery to nondetectable levels. Although PAPP-B cannot yet be quantitated because of technical reasons, it also appeared to increase during the last trimester, but like HPL (PAPP-D) it became nondetectable very rapidly after childbirth.

Serial sampling of individual women. Because of the rather large variation between women in the plasma concentrations of PAPP's shown above (Figs. 1 to 3) and in earlier studies,[20] it was felt of importance to serially determine the PAPP concentrations in individual women shortly before delivery and through the postpartum period. For this reason, serial samples from five patients were analyzed approximately biweekly during 6 weeks ante partum, daily during the first week post partum, and then weekly for an additional 13 weeks. The PZP was also analyzed in these specimens to determine if it correlated with any of the PAPP's.

Although the levels of these proteins showed the expected wide range of concentrations in the different women, in the same individual they did not show wide fluctuations, but revealed smoothly progressive changes over these time periods (Fig. 5). In the three instances where samples were available on the day of delivery and at 1 day post partum, both PAPP-A and PAPP-C showed a significant drop in the first day. HPL (PAPP-D) became nondetectable in all instances at 1 day post partum, as did PAPP-B. In all five patients, PAPP-A and PAPP-C showed a pattern of rapidly decreasing levels during the first 2 weeks, similar to that seen with the random samples. PAPP-C became uniformly nondetectable by 3 or 4 weeks; PAPP-A dropped to trace levels at 3 to 5 weeks and was no

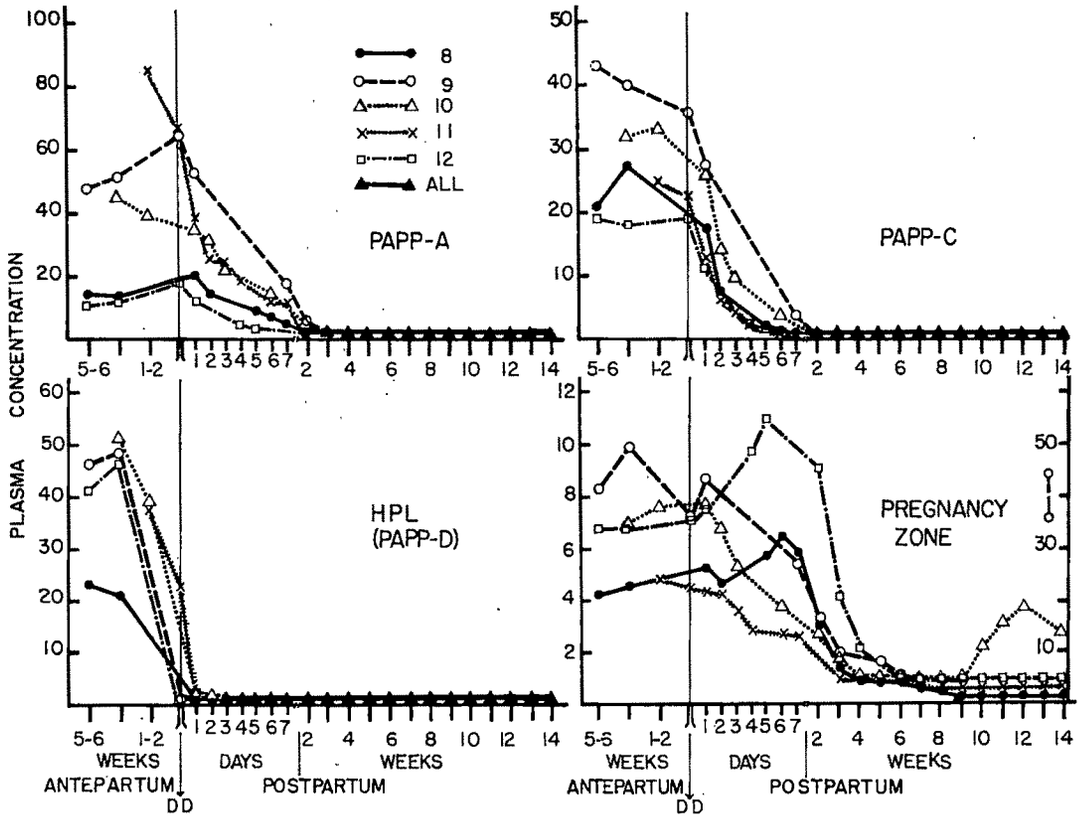

Fig. 5. Plasma concentration of PAPP-A, PAPP-C, HPL (PAPP-D), and pregnancy zone protein in serial samples from five women before and after delivery. *DD*, day of delivery.

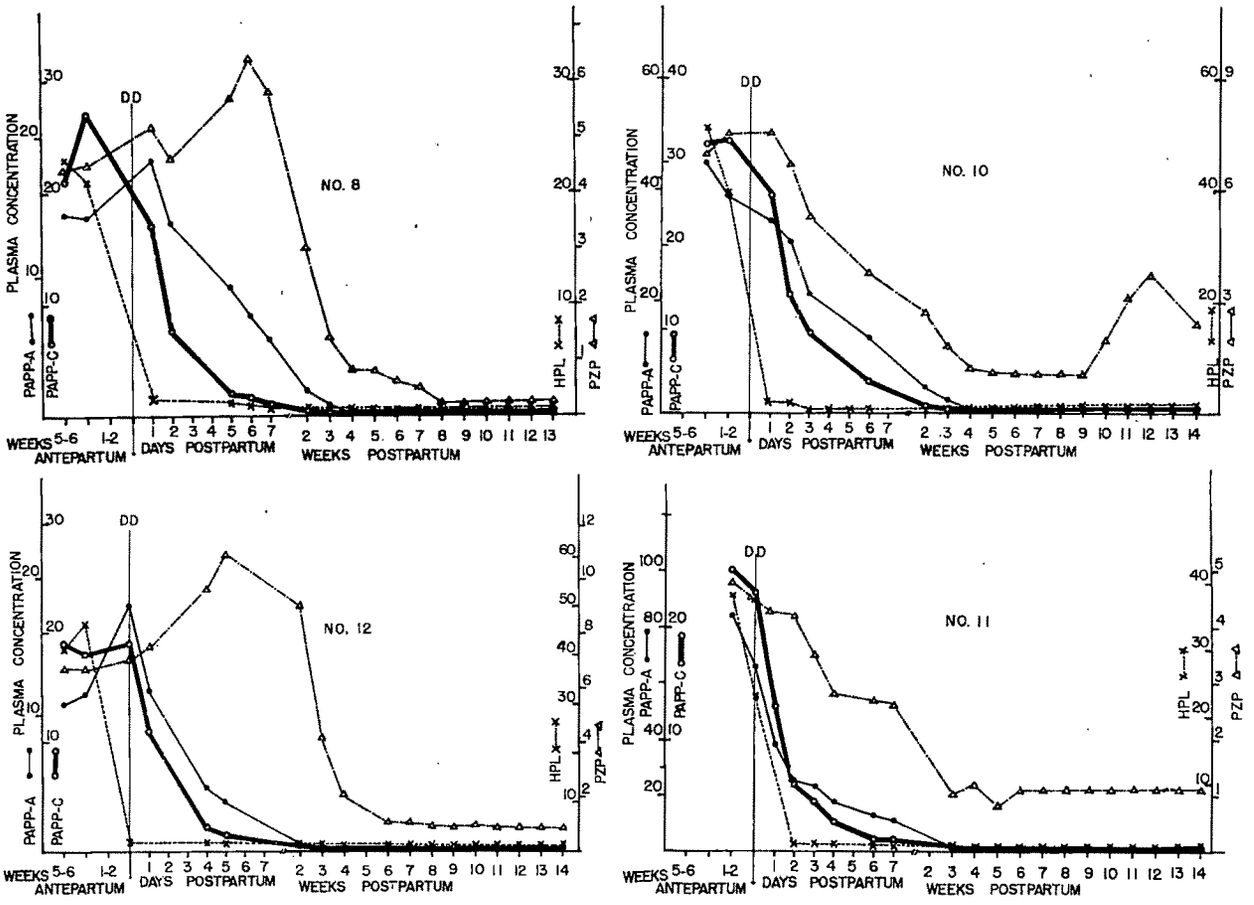

Fig. 6. Comparison of changes in plasma concentration among PAPP-A, PAPP-C, HPL (PAPP-D), and pregnancy zone protein in four women after delivery. The trends of these proteins in the fifth woman (No. 9) were similar to those in patient No. 11. *DD,* day of delivery.

longer detected in any case after 6 weeks. On the other hand, the PZP did not show any striking changes in concentration until the second and third weeks after delivery. Its level in two women (Nos. 8 and 12) even showed a temporary increase during the first week. The rate of decrease of PZP was also significantly slower than that seen with the PAPP's. In further sharp contrast to the PAPP's, PZP remained detectable by these methods during the entire period studied, up to 14 weeks post partum. A small rise in PZP was observed in one women (No. 10) during the period between the tenth and fourteenth weeks post partum, coinciding with the start of hormonal contraception. In four of the five women studied, the concentration of PZP was relatively low just prior to delivery, in relation to the reference specimen which represented a fourfold concentrate of a late pregnancy plasma pool.

The rates of change in the various PAPP levels and PZP in single individuals are shown in Fig. 6. It appeared that the decrease and disappearance of the PAPP's were sequential in all of the five women, starting with HPL (PAPP-D) and PAPP-B, followed by PAPP-C, and then PAPP-A. The time course of the changes in PZP concentrations showed no correlation with the rate of decrease of any particular PAPP in these individuals. By comparing the plasma levels in three women (Nos. 8, 10, and 11) during the first few days post partum, the half-lives of PAPP-A and PAPP-C were roughly estimated to be 3 to 4 and 1 to 2 days, respectively, the former being slightly longer than the value obtained from the random samples.

Comment

The rapid decrease and disappearance of all the PAPP's was shown to coincide crisply with the termination of gestation. Furthermore, none of the PAPP's increased or reappeared after becoming nondetectable during the 3 month post partum period. Bohn[10] also failed to detect pregnancy-specific β_1-glycoprotein (which is identical to PAPP-C) in any of the three serum samples collected 5 to 14 weeks after delivery. In sharp contrast, the PZP remained at relatively high

levels for the first 2 weeks post partum, although it showed a gradual decrease during this period. The PZP was still present in readily detectable concentrations during the rest of the 14 weeks studied. These latter data are in general agreement with the findings of Studd and associates,[4] Bohn,[10] Berne,[12, 22] and von Schoultz,[23] who detected PZP in women 2 to 3 months after delivery of normal infants. These findings suggest that the PAPP's are direct or primary responses to gestation, while the PZP is secondarily related to pregnancy. The elevation of PZP in patients with various malignancies is compatible with this concept, [12, 15] in contrast to the finding that none of the PAPP's has thus far been seen in the serum of cancer patients.[24] In any event, it is reasonable to assume that the PZP differs from all the PAPP's with regard to their biologic activities.

The smooth progression of PAPP levels in individual patients during the postpartum period suggests that the wide range of values observed in different women at the same stage of the gestational process is valid. This broad scatter of values indicates that any potential diagnostic usefulness of these measurements will require serial samples, or very extreme divergence from the normal range. It would be of interest to study the PAPP levels in individual women during several pregnancies to determine if a tendency toward low or high concentrations during gestation is characteristic of that individual.

Because the PAPP's do disappear so rapidly following delivery, it is reasonable to speculate that they may arise from the placenta or fetus. Since cord blood and amniotic fluid do not contain any PAPP's detectable with the technique used, the fetus is unlikely to be the source. Quantitative studies are currently being carried out to determine if the placenta synthesizes PAPP-A, -B, and -C, in addition to HPL.

The half-life of HPL (PAPP-D) has been shown to be 20 to 30 minutes.[25, 26] The present study confirmed the fast rate of disappearance of this hormone, which became undetectable by the methods used 1 day after the removal of the tissue of origin. The rapid disappearance of PAPP-B during the postpartum period suggests that it also may have a very short half-life. The half lives of PAPP-A and PAPP-C, as estimated with random samples, were similar to—but somewhat shorter than—those with serial samples. Because of the large variation in the PAPP levels among individuals, the estimates from serial samples may be more precise, although a much larger series will be required for an accurate determination. In addition, samples collected at closer time intervals just prior to delivery will be required for careful analysis of the changing PAPP levels during this critical period.

The association between abnormal glucose tolerance (hyperglycemia and hypoglycemia) and estriol excretion in pregnancy

In 2,000 consecutive patients having glucose tolerance tests in pregnancy hyperglycemia (≥ ninety-fifth percentile) was associated with increased placental weight ($p < 0.01$) but not with increased fetal birth weight. Patients with hypoglycemia (≤ fifth percentile) were more likely to have small-for-dates babies ($p < 0.01$). Perinatal death was related to maternal glucose tolerance, being reduced from 1.3 per cent in the total series to 0.6 per cent when normoglycemia was present ($p < 0.05$); it was significantly increased in the presence of maternal hyperglycemia ($p < 0.001$) and hypoglycemia ($p < 0.01$). A combination of abnormal glucose tolerance and subnormal estriol excretion detected pregnancies with significantly higher incidences of fetal and placental growth retardation, major fetal malformations, and perinatal deaths. Moreover, the combination of normoglycemia and normal estriol excretion (62.3 per cent of patients) was associated with a very favorable pregnancy outcome (0.4 per cent perinatal death rate). Hypoglycemia was at least as significant as hyperglycemia in terms of unfavorable pregnancy outcome, especially when associated with subnormal estriol excretion.

GLUCOSE TOLERANCE testing in pregnancy has principally been directed toward the detection of diabetes mellitus.[1] Because the glucose tolerance test has been regarded as an unsuitable laboratory investigation for routine performance in all pregnancies,[2] a policy of undertaking the test only in selected patients has led to publication of many means of selection of possibly diabetic patients.[3, 4] However, it is acknowledged that a number of patients with gestational diabetes will still be missed by such methods of selection.[4]

If the glucose tolerance test was more broadly interpreted and detected associations with pregnancy complications, then routine performance of the test in all pregnant patients may be justified. In the process all patients with gestational diabetes would be diagnosed.

Diabetes mellitus in pregnancy has an increased incidence of low estriol excretion,[5] while subnormal urinary estriol excretion in pregnancy is associated with an increased incidence of small-for-dates babies and placentas, perinatal death, and fetal malformations.[6, 7]

The purpose of the present study was to assess a new method of classification of glucose tolerance test results in pregnancy by defining hyperglycemia, hypoglycemia, and normoglycemia, and to evaluate the significance of urinary estriol excretion when glucose tolerance was abnormal in late pregnancy. The pregnancy outcome in each classification when the tests were performed in a consecutive series of patients is reported.

Materials and methods

Both glucose tolerance tests and urinary estriol excretion are routinely measured on all prenatal

patients at the Mercy Maternity Hospital. This series consisted of 2,000 consecutive patients, 1,000 clinic, and 1,000 private. The only patients excluded from analysis were 9 known diabetics, all of whose infants survived, and those with multiple pregnancies.

A standard 50 Gm. oral glucose tolerance test was performed at 32 to 34 weeks' gestation in the morning following an overnight fast. Plasma glucose was measured in capillary blood, obtained from a finger prick, by the glucose oxidase method using a Beckman glucose analyzer. Plasma glucose was measured on a fasting specimen and 1, 2, and 3 hours after the ingestion of glucose.

The ninety-fifth and fifth percentiles were calculated for each plasma glucose reading. These were separately evaluated for the clinic and private groups of patients,[8, 9] and are shown in Table I.

Hyperglycemia was diagnosed when the plasma glucose equalled or exceeded the ninety-fifth percentile on any of the four plasma glucose measurements. Hypoglycemia was diagnosed when the plasma glucose equalled or was less than any of the fifth percentiles. Normoglycemia was defined as being present when all four glucose levels during the tolerance test fell within the ninety-fifth to fifth percentile ranges.

Urinary estriol excretion was measured in all patients on one or more occasions from 30 to 34 weeks' gestation, the total number of assays performed in this study being 6,078. This was measured with the method of Brown and associates[10] and was regarded as subnormal when one or more values were obtained below a line joining 8 mg. per 24 hours at 30 weeks' gestation and 12 mg. per 24 hours at 40 weeks' gestation and thereafter.[11]

Large-for-dates infants were diagnosed when birth weight was above the ninetieth percentile and small-for-dates infants when below the tenth percentile according to gestational age for infants born in this community.[12] The ninetieth and tenth percentiles for defining large and small-for-dates placentas were those reported by Ratten and associates.[13]

A fetal malformation was regarded as major if it was of such severity that it interfered with the function of all or part of the infant. Perinatal death included any stillbirth after the twentieth week of pregnancy and deaths occurring in liveborn infants within 28 days of birth.

In this prospective series management of the pregnancy was unaffected by the finding of an abnormal glucose tolerance with the exception of those results indicative of gestational diabetes (maximum plasma glucose level of 180 mg. per 100 ml. or above and 2 hour level of 140 mg. or above).

Results

The 2,000 pregnancies were assessed for the incidences of low urinary estriol excretion, abnormalities of birth weight and placental weight, major fetal malformations, and perinatal death. The over-all results for the 2,000 patients are shown in Table II as well as the pregnancy outcome when evaluated according to whether urinary estriol excretion was normal or low.

Table III shows the pregnancy outcome according to the pattern of glucose tolerance (hyperglycemia, normoglycemia, or hypoglycemia) and according to whether estriol excretion was normal or subnormal.

Twenty-seven patients had both a hyperglycemic and a hypoglycemic level during the glucose tolerance test, and five of these (18.5 per cent) had subnormal estriol excretion. These patients are included in the results of both types of abnormal glucose tolerance. There were 14 tests diagnostic of gestational diabetes and in these patients there was one perinatal death, which was due to major malformations.

Comment

This classification of glucose tolerance tests in pregnancy has defined two types of abnormality—hyperglycemia and hypoglycemia—leaving a group properly defined as normal—normoglycemia.

The various definitions of gestational diabetes[14] attest to the confusion in what may be regarded as an abnormal glucose tolerance test. The concept of hyperglycemia and hypoglycemia in pregnancy has not been previously evaluated and was pursued to determine whether these were associated with pregnancy complications. The outcome of the pregnancies in those patients with abnormal glucose tolerance was

compared with that in the normoglycemia group.

Low urinary estriol excretion was seen to select pregnancies with a greatly increased incidence of small-for-dates babies ($p < 0.001$) and placentas ($p < 0.001$), with a reciprocal reduction in the incidence of large-for-dates babies ($p < 0.001$), but little alteration in the incidence of large-for-dates placentas (Table II). Furthermore, there was a doubled incidence of major malformations ($p < 0.05$) and a sixfold increase in perinatal mortality rate ($p < 0.001$) in pregnancies where estriol excretion was subnormal. This confirms the value of this investigation in prediction of pregnancy complications. These associations were seen to remain whether glucose tolerance was normal or abnormal (hyperglycemia or hypoglycemia) (Table III).

Glucose is an essential metabolite for fetal development and growth and presumably exerts much of its influence upon fetal growth via the insulin levels in the fetus responding to the amount of glucose transferring across the placenta. Although the placenta may prevent unlimited transfer of glucose to the fetus,[15] fetal glucose levels will qualitatively mimic those in the mother. In the presence of maternal hyperglycemia the increased levels of glucose transported to the fetus appeared to stimulate placental growth ($p < 0.01$) before fetal size was excessively stimulated ($p > 0.05$) (Table III). Placental hypertrophy, a characteristic of diabetes in pregnancy, is apparently an earlier effect of hyperglycemia than that of fetal macrosomia.[16] Karlsson and Kjellmer[17] were unable to show any relationship between the degree of hyperglycemia in the mother and the incidence of infants overweight at birth in their series of controlled diabetic pregnancies. However, relative glucose deprivation of the fetus, as may occur when there is maternal hypoglycemia, appeared to exert its influence principally by retarding intrauterine growth of the fetus (8.5 per cent in the normoglycemia group and 15.6 per cent in the hypoglycemia group were small for dates—Table III) ($p < 0.01$). With the ability of low urinary estriol excretion to detect intrauterine growth retardation, the combined application of both glucose tolerance testing and urinary estriol estimation selected groups of pregnancies where the incidence of small-for-dates babies ranged from 6.8 per cent when both tests were normal, to 38.1 per cent when estriol excretion was low in the presence of hypoglycemia (Table IV).

The association between hypoglycemia and small-for-dates babies and placentas was markedly increased when estriol excretion was low ($p < 0.001$ and $p < 0.001$, respectively). Moreover, there were no large-for-dates babies when estriol excretion was low in the presence of hypoglycemia (Table III).

Fetal malformations have been shown to be more common in pregnancies where estriol excretion is low, although with the exception of anencephaly or primary adrenal hypoplasia, this association is not causal but due to the high incidences of fetal growth retardation.[7] Although the incidence of major fetal malformations did not appear to be influenced by maternal glucose tolerance ($p > 0.05$ for both hyperglycemia and hypoglycemia), a trend toward a high incidence of malformations was noted when estriol excretion was low (Table III). This suggested that low estriol excretion was more selective for fetal malformations when seen in association with abnormal glucose tolerance.

Perinatal mortality rate was related to maternal glucose tolerance, being reduced from 1.3 per cent in the total series to 0.6 per cent when normoglycemia was present ($p < 0.05$). This was significantly increased in maternal hyperglycemia ($p < 0.001$), and hypoglycemia ($p < 0.01$) (Table III). The cause of fetal death in maternal diabetes mellitus is, as yet, not completely understood, but the low perinatal mortality rate in the normoglycemic pregnancies attests to the advantage of normal plasma glucose levels in pregnancy. The prognosis for the fetus of the pregnant diabetic is related to the degree of control of the maternal diabetes, and the results in this series support the principle that the goal for the management of the pregnant diabetic should be to keep her blood sugar level normal.[18] Karlsson and Kjellmer[17] have been able to show a dramatic reduction in perinatal mortality rates in diabetic pregnancies when the mean maternal blood glucose value was controlled at less than 100 mg. per 100 ml. (equivalent to 115 mg. per 100 ml. plasma glucose). Khojandi and colleagues[19] also concluded that perinatal mortality and morbidity rates were negligible when gestational diabetes was well controlled.

Evans and colleagues[20] reported a perinatal loss of 7 per cent when estriol excretion was normal and 23 per cent when low in their series of 93 diabetic pregnancies. In the present series (Table V) the combination of normoglycemia and normal estriol excretion (62.3 per cent of patients) selected a group of patients with a perinatal mortality rate of 0.4 per cent—the rate being 2.5 per cent when there was hyperglycemia ($p < 0.001$) and 1.6 per cent when there was hypoglycemia ($p < 0.05$). When estriol excretion was subnormal the perinatal mortality rate rose to 8.1 per cent when there was associated hyperglycemia, and was 9.5 per cent when hypoglycemia was present (Table V). Glucose tolerance testing and urinary estriol measurement were thus seen to be individually selective for pregnancies complicated by perinatal deaths, and by their combined use a high degree of selectivity was achieved, both for high and low degrees of risk.

Hyperglycemia	315	3.2	2.5	8.1
Normoglycemia	1,366	0.6	0.4	2.5
Hypoglycemia	346	2.6	1.6	9.5

Hypoglycemia is a biochemical abnormality not previously described in pregnancy, and inasmuch as the present data have revealed associated pregnancy complications, detailed analysis of a larger series is to be undertaken. More data are required before principles of treatment of hypoglycemia in pregnancy can be enunciated. We believe that hypoglycemia will be proved to be a significant cause of previously unexplained intrauterine deaths. It is hoped that this hypothesis proves true, because very simple measures could provide effective therapy.

We wish to thank our colleagues on the Medical and Nursing Staff of the hospital for their cooperation in this study and Mrs. J. Walstab for the statistical analysis.

Second-trimester spontaneous abortion, the IUD, and infection

STEVEN H. EISINGER, M.D.

Madison, Wisconsin

Nineteen cases of spontaneous second-trimester abortion associated with the intrauterine device (IUD) are reviewed and compared to 30 cases of spontaneous second-trimester abortion not associated with the IUD. Fifteen of the IUD's were Dalkon shields and four were Lippes loops. Sixteen of the 19 IUD-associated abortions began either with prolonged rupture of membranes or signs and symptoms of infection. Infection occurred in 18 or 19 of the cases (95 per cent) but only 30 per cent of the comparison group. Eleven major complications occurred in eight patients in the IUD group but only eight complications occurred among seven patients in the comparison group. It is suggested that when the IUD remains in utero during pregnancy, it may be a causal factor in second-trimester spontaneous abortion, and that intrauterine infection is the distinguishing characteristic of such cases. Mechanisms are suggested by which the IUD might cause infected abortion.

THE INTRAUTERINE device has come under recent suspicion as a cause of complications of pregnancy. In earlier reports, Scott[1] described ten deaths associated with the IUD. Two of these were definitely associated with pregnancy, although in both cases, the IUD had perforated the uterus. Lewit,[2] in a large cooperative study, showed high spontaneous abortion rates occurring in pregnancies with an IUD in utero. In a prospective study designed to show the influence on a pregnancy of removing an IUD, Alvior[3] showed that spontaneous abortion occurred in 48.44 per cent of cases when the IUD was left in situ but only 29.6 per cent of cases when the IUD (Lippes loop in this study) was removed early in pregnancy. Neither Lewit nor Alvior specified gestational ages of abortions occurring with an IUD in utero, nor were complications of these abortions described. Both studies concluded that an IUD should be removed early in pregnancy. Vessey and associates[4] have confirmed a high spontaneous abortion rate when IUD's remain in place.

More recently Shine and Thompson[5] followed 43 pregnancies occurring despite the presence of an IUD. Twenty-one (49 per cent) of these patients aborted spontaneously before 20 weeks. An additional four pregnancies or 9.3 per cent terminated with stillbirths. Febrile morbidity in the 21 spontaneous abortions was 33 per cent, far exceeding the hospital morbidity rate for all abortions of 4 per cent. Wiles and Zeiderman[6] followed eight patients with IUD's in utero. Seven patients had major maternal complications and six of these suffered fetal wastage. Dalkon shields outnumbered Lippes loops in this series seven to one. Hurt[7] confirmed the occurrence of septic pregnancy in five patients with Dalkon shields. Christian reported five deaths and seven other patients who were severely ill in the midtrimester with an IUD in place. All but two of these patients had shield-type devices. The report stresses "the insidious yet rapid manner in which these patients became ill," and points out the absence of early localized symptoms. Speculation is offered that the shield-type device predisposed toward early septicemia. Christian's[8] cases are gathered from different parts of the country and do not represent a series from a single locale. Information is not available concerning the prevalence of shield-type devices in the communities from which the patients came.

The A. H. Robins Company, [9] manufacturer of the Dalkon shield, has recognized the occurrence of

midtrimester septic abortion and has withdrawn the device from the market. It recommends prompt removal of the device in the event of pregnancy, and consideration of therapeutic abortion if the IUD cannot be removed. The entire topic has been well reviewed in a Symposium following the recent Food and Drug Administration hearings on IUD's.[10]

In this study a series of 19 midtrimester spontaneous abortions are presented, all associated with IUD's. For comparison purposes, 30 cases of midtrimester abortion not associated with the IUD were studied. In comparing these two groups of patients, the evidence strongly suggests that IUD's cause a large proportion of the midtrimester spontaneous abortions with which they are associated, and that infection is the distinguishing characteristic of these abortions.

Materials and methods

All cases of midtrimester spontaneous abortions associated with an IUD, which occurred in Madison hospitals from 1971 through February, 1974, were identified by computer and manual search of discharge diagnoses and by asking physicians to identify patients. Nineteen were found. For comparison purposes, all cases of midtrimester spontaneous abortion not associated with an IUD occurring from 1971 through 1973 were similarly identified. Thirty cases were found.

The second trimester is defined here as being from the fourteenth to the twenty-seventh week, calculated from the last menstrual period. Febrile morbidity is defined as a temperature of 100.4° F. or greater recorded on two occasions six hours or more apart.

Results

Incidence. Forty-five midtrimester spontaneous abortions were identified during the three-year period, 1971 through 1973, including 15 of the 19 IUD patients. In that time, 11,548 births were recorded. Thus one midtrimester abortion occurred for every 257 births, or 3.9 cases per 1,000 births. By comparison, in 1961 the rate of midtrimester abortion was somewhat lower—one per 308 births.

Patient characteristics. Age, parity, percentage of nulliparous patients, and gestational age of pregnancy were similar in the IUD group and the comparison group. However, 12 in the comparison group had experienced previous spontaneous abortions (40 per cent) but only two of 19 IUD patients (11 per cent) had previously aborted spontaneously.

The IUD. Dalkon shields and Lippes loops were the only IUD's represented in the study (Table I). In no case was the IUD inserted after the onset of pregnancy. In no case was uterine perforation by the IUD suspected. The IUD's were all recovered with the products of conception or from the uterine cavity subsequent to the abortion. It is of interest that in three cases, x-rays of the pelvis prior to the abortion failed to reveal the presence of the IUD.

Presenting signs and symptoms. In eight of 19 IUD patients (42 per cent) rupture of the membranes, proved by conventional tests, preceded the abortion by more than 12 hours, and was the first sign of any complication in six of these pregnancies. Rupture of the membranes for days was common and the longest period of ruptured membranes was three weeks. In the comparison group only three cases or 10 per cent presented with ruptured membranes. When patients in the IUD group entered the hospital, 12 (63 per cent) had a tender uterus, 11 (58 per cent) complained of fever and chills, 10 (53 per cent) had purulent vaginal discharge, only nine (47 per cent) had audible fetal heart tones, and eight (42 per cent) reported or showed evidence of bleeding. In the comparison group, there was a higher incidence of bleeding (16 patients or 53 per cent) but other presenting complaints were significantly less frequent. The most common presenting complaints in the comparison group were abdominal cramping, bleeding, and absence of fetal heart tones (Table II).

Febrile morbidity. Febrile morbidity was present prior to the abortion in ten (53 per cent) of the IUD patients, but only six (20 per cent) in the comparison group. Five additional IUD patients had either undocumented fever or low-grade fever (100.0° to 100.4° F.) prior to the abortion. Several IUD patients had high temperatures exceeding 103° F. Following the abortion an additional three patients (15 per cent) became febrile, making the total febrile IUD patients 13 (68 per cent). Of the comparison group, only one became febrile after the abortion, making the total 23 per cent. Two of the febrile comparison patients had undergone cervical cerclage earlier in the pregnancy (Table II).

Laboratory data. White cell counts and differentials were obtained in eight IUD patients. Leukocytosis with a left shift (average WBC, 13,400) was the rule. Cultures were obtained in 18 of 19 IUD patients, taken from the endocervix, amniotic fluid, uterine cavity, or products of conception. *E. coli* was the most common

Table II. IUD patients and non-IUD patients compared

	IUD Group 19 patients	*Non-IUD (comparison) group 30 patients*
Presenting signs and symptoms:		
Proved rupture of membranes 12 hours prior to delivery	8 (42%)	3 (10%)
Bleeding	8 (42%)	16 (53%)
Purulent discharge	10 (53%)	5 (17%)
Fever and chills	11 (58%)	5 (17%)
Tender uterus	12 (63%)	13 (43%)
Audible fetal heart tones	9 (47%)	7 (23%)
Febrile morbidity:

Fetal death	0	8 (27%)
Other	0	7 (23%)

organism isolated, but other dangerous pathogens were found as well. Blood cultures were obtained in eight patients, and four of these were positive. The organism was *E. coli* in every instance (Table III).

Mistaken diagnosis. On admission most of the patients were recognized to be experiencing a major obstetric complication. However, impending or septic abortion was not recognized in five IUD patients. Three were believed to have pyelonephritis, one patient was thought to have round ligament pain, and one patient was given an initial diagnosis of "cervicitis."

Treatment. Antibiotics were used in 18 of 19 IUD patients. Only nine of 30 (30 per cent) of the comparison group required antibiotics. Spontaneous labor occurred in about half of the IUD patients. Oxytocin stimulation prior to the abortion was required in ten IUD patients (53 per cent) and 13 comparison patients (43 per cent).

Operations were performed in ten IUD patients; D & C in nine patients (47 per cent) and hysterectomy in one patient with septic shock. In the comparison group, D & C was less often performed (seven patients—23 per cent but hysterectomy was necessary in three patients, and hysterotomy in two; all five major operations were done to halt severe hemorrhage.

Complications. No deaths occurred in this study. Of 19 IUD patients, four experienced excessive blood loss (estimated greater than 1,000 c.c.) and one of these suffered hemorrhagic shock. Two patients had septic shock, and one of these also had disseminated intravascular coagulation and a prolonged course of pelvic cellulitis. Late hemorrhage and lung infiltrate occurred in one patient each. In all, eight patients or 42 per cent experienced 11 major complications. In the compari-

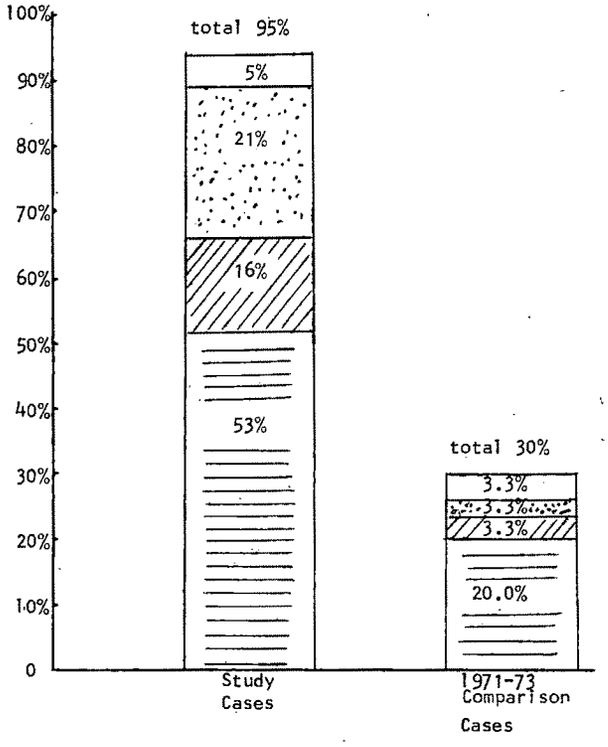

Fig. 1. The evidence for infection in 19 IUD patients and 30 non-IUD (comparison) patients who aborted spontaneously in the mid trimester. Clear background, pathologic evidence of infection only; stippled background, clinical evidence of infection only, i.e., purulent discharge, undocumented fever and chills, foul-smelling placenta, etc.; diagonal stripes, documented fever > 100.4° F. following abortion; horizontal stripes, documented fever > 100.4° F. before abortion.

son group, six patients had excessive blood loss, and one of these went into shock. Five of these patients underwent hysterectomy or hysterotomy. One patient had a prolonged course of pelvic cellulitis and pelvic thrombophlebitis. In all, seven of 30 patients in the comparison group (23 per cent) experienced major maternal complications. Fetal complications included two live immature fetuses in the IUD group and two severely deformed fetuses in the comparison group. No fetus in either group survived. Three patients in the comparison group aborted following placement of a cervical cerclage for incompetent cervix (Table II).

Major final diagnoses. All but one of the 19 IUD patients were discharged with a diagnosis indicating septic abortion. Three of these had a diagnosis of abruptio placentae as well. One patient had a diagnosis of abruptio placentae uncomplicated by infection. Of the 30 comparison patients, abruptio placentae accounted for 11 (37 per cent) and septic abortion nine (30 per cent). Intrauterine fetal death for various reasons accounted for eight patients (27 per cent) and the remainder of the diagnoses included incompetent cervix (2 patients), incompetent cervix with failure of cervical cerclage (3 patients), bicornuate uterus (1 patient), and premature labor of unknown etiology (1 patient) (Table II).

Comment

Does the IUD cause abortion? Direct evidence is not available from this study. Two related pieces of evidence, however, strongly support causality; first, that the onset of the abortion is different in the two groups of patients and, second, that a single unifying factor is common to all or most of the IUD patients.

Ten of the 19 IUD patients presented with signs and symptoms of infection as the first evidence that the pregnancy was complicated. Prolonged rupture of membranes, well known to predispose to infection, was proved in another six patients as the first sign of impending abortion.

Two patients aborted before they reached the hospital. Their presenting signs and symptoms are unknown. Only one patient presented with bleeding. In the comparison group, signs and symptoms of infection and prolonged rupture of membranes were uncommon modes of presentation.

The single unifying factor for the IUD patients is clearly infection. Febrile morbidity, the best single indicator of infection, was present in 13 of 19 patients or 68 per cent. Four patients, or an additional 21 per cent, had clinical evidence of infection such as purulent discharge, foul-smelling products of conception, or history of fever and chills without a documented temperature elevation. One additional patient had evidence of infection only on pathologic examination of the products of conception, that is, the placental tissue was shown to have acute chorioamnionitis in the absence of fever or clinical signs of infection. In all, 18 of 19 IUD patients or 95 per cent showed evidence of infection.

On the other hand, among the comparison group seven patients (23 per cent) were febrile. Of these, two patients had undergone cervical cerclage earlier in their pregnancy. One additional patient exhibited signs and symptoms of infection without become febrile. One more patient carried a diagnosis of chorioamnionitis on the basis of pathologic examination only. In all, nine of the 30 patients (30 per cent) showed evidence of infection and two of these had undergone cervical surgery (Fig. 1).

Thus, infection as a concomitant part of the abortion process is almost universally associated with the IUD. It is not, as the comparison group shows, a routine secondary complication of midtrimester abor-

tion. Since evidence of infection or ruptured membranes is present at the onset of abortion in the IUD patients, the IUD is strongly implicated as the cause of infected abortion.

It is possible that the difficulties of making an early diagnosis and the fulminating course of septic abortion in the IUD patients have been overemphasized. The diagnosis was straightforward in most of the IUD patients in this series. In five patients the initial diagnosis was incorrect, but was reversed in every case except one, soon enough to prevent permanent damage. Certainly, septic abortion is potentially a grave complication, yet only two patients in this series could be described as severely ill. One underwent hysterectomy for septic shock 24 hours after she was admitted with a mistaken diagnosis of pyelonephritis and a second patient had septic shock and disseminated intravascular coagulation. She was promptly treated with antibiotics and dilatation and curettage, but nevertheless developed a pelvic cellulitis requiring over a month of hospitalization and antibiotics. Most of the IUD patients were not severely ill and responded promptly to antibiotics and aggressive efforts to empty the uterus.

Whether a specific IUD is especially associated with infected abortion is an open question. The Dalkon shield has been under particular suspicion and the evidence implicating it seems to be increasing. In this series, although Dalkon shields outnumber Lippes loops 15 to four, the proportion of different IUD's in the general population is not known. Dalkon shields have been widely used in the Madison area.

The mechanisms whereby IUD's might cause septic abortion are a matter for speculation. With the Dalkon shield, the prongs are suspected to cause localized changes predisposing to infection. The relative rigidity of the Dalkon shield may cause shearing forces between the endometrium and the chorioamnion. Either the IUD tail may act as a nidus of infection as it is drawn up out of the vagina into the uterus by the enlarging pregnancy or it may act as a wick, drawing up contaminated vaginal contents. That this occurs with the Dalkon shield in vitro with dye and bacterial suspensions has been elegantly demonstrated by Misheli and associates.[10].

This study is believed to represent the total experience of this community with IUD-associated midtrimester abortions. If the Madison experience has validity in other communities, midtrimester-infected abortion associated IUD's is far more common than previously suspected. It is a danger which should be considered, and of which the patient should be warned, at every IUD insertion. The threat of infected abortion argues for the removal of an IUD in early pregnancy in every case. If simple removal is not possible, consideration should be given to therapeutic abortion. Should intrauterine infection in the presence of an IUD occur, a high index of suspicion will lead to proper diagnosis and effective treatment.

The author is grateful to Drs. B. M. Peckham and C. W. Horswill, the Medical Records Departments at the University of Wisconsin Hospitals, Madison General Hospital, and St. Mary's Medical Center for their generous aid in preparing this study.

Quantitation of uterine activity in 100 primiparous patients

FRANK C. MILLER, M.D., LIEUTENANT COLONEL, MC, USA
SZE-YA YEH, M.D.
BARRY S. SCHIFRIN, M.D.
RICHARD H. PAUL, M.D.
EDWARD H. HON, M.D.
Los Angeles, California

An on-line technique for quantitating uterine activity by measuring the total area under the intrauterine pressure curve was utilized during the labor of 100 primiparous patients. Uterine activity was measured in uterine activity units (one UAU = one Torr minute). UAU's were calculated for each patient in both cumulative and noncumulative fashions. The rate of uterine activity (UAU per unit of time) increased as labor progressed, yet the total UAU's expended at each centimeter of dilatation progressively decreased with advancing dilatation. Thus, the rate of cervical dilatation increased faster than could be accounted for by the increase in uterine activity. The implication being that the efficiency of uterine contractions increases with advancing labor. It no longer appears reasonable to refer to labor in terms of elapsed time. Information regarding the "pattern of cervical dilatation" and uterine activity appears to be much more meaningful to the evaluation of progress in labor. Quantitation of uterine activity may provide useful information for the ongoing management of labor. Quantitation of UA does provide a means of evaluating the effects of specific events such as medication, anesthesia, and manipulation on UA.

THE FORCES OF labor have been the subject of interest and clinical investigation for decades. Methods of evaluating uterine activity (UA) have progressed from manual palpation (of uterine contractions), to tocodynamometry, to the direct measurement of intrauterine pressure (IUP).

It seems reasonable to accept the premise that UA is related to progress in labor. Until recent years, the difficulty in accurately measuring UA precluded it as a clinical method for evaluating progress in labor. The most popular method of assessing adequacy of UA is the evaluation of progressive cervical dilatation. The graphic portrayal of cervical dilatation plotted against time was introduced by Friedman[1] in 1954. Utilizing this technique, an expected pattern of cervical dilatation during normal labor has been established which provides a means of recognizing abnormal progress. This serves to alert the physician to a potential problem but in no way identifies the underlying etiology. It has been claimed that slow progress in cervical dilatation is commonly associated with less than optimal UA.[2] Conversely, the cervical dilatation pattern may be abnormal despite apparently adequate UA in patients with fetal malpresentation or fetopelvic disproportion.[3] In order to intelligently interpret cervical dilatation patterns, one must be able to quantitate, in some manner, the strength of the uterine contractions.

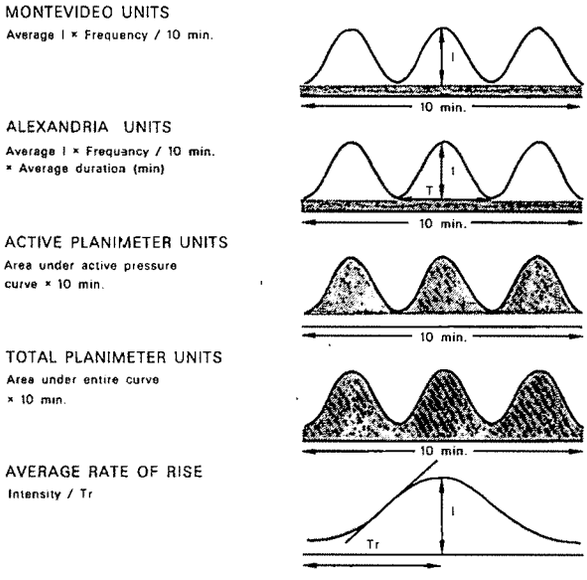

Fig. 1. Methods for quantitation of uterine activity.

Various methods have been utilized in an attempt to quantitate UA from intrauterine pressure recordings as shown in Fig. 1. Manual methods of calculation, such as the Montevideo and Alexandria units, are based on the measurement of the amplitude of the uterine contractions above base-line tone multiplied by the number of uterine contractions per ten minutes. (The Alexandria Unit also includes the average duration of the contractions in minutes.) The manual method has the disadvantage of being very time consuming. Planimeters can very accurately measure the area under the uterine pressure curve, but the method is also slow and time consuming. Analogue and digital computers can provide accurate measurements of UA by integrating the area under the entire uterine pressure curve or under only the "active area"; however, the equipment is expensive and cumbersome.

For the past three years, a simple on-lime technique for measuring the total area under the uterine pressure curve has been utilized in Women's Hospital, Los Angeles County—University of Southern California Medical Center.[4] This system integrates the total area (including uterine tone and contractions) rather than any fraction or segment of the intrauterine pressure. The entire area under the IUP curve was utilized since it seems reasonable that both tone and contractions may affect the rate of cervical dilatation. Additionally, it is technically much simpler to quantitate the total area than to evaluate the uterine contractions separately from the base-line tone. By quantitating UA in this manner, no comment can be made regarding the base-line uterine tone or the frequency and amplitude of uterine contractions. The equipment utilized is relatively inexpensive and easy to operate, and the data are quantitative and immediately available.

This paper presents our experience utilizing this on-line method for quantitating UA in 100 primiparous labors.

Material and methods

One hundred primiparous patients with the fetuses in the vertex presentation, whose labors were monitored in the Perinatal Intensive Care Delivery Unit, were selected for evaluation. Patients selected for fetal monitoring during labor in this unit are generally high-risk obstetric patients who have a higher incidence of obstetric complications than the normal patient population as shown in Table I. All patients studied had IUP measured with the use of a transcervical open-end fluid-filled catheter, connected to a Statham pressure transducer, positioned at the level of the anterior chest wall. The area under the uterine pressure curve was integrated with the use of a voltage-controlled oscillator (VCO). A digital print out of the uterine activity (measured in millimeters of mercury per minute, or Torr minutes) was obtained every ten minutes. A uterine activity unit (UAU) equal to one Torr minute will be used to express uterine activity in this study.[5]

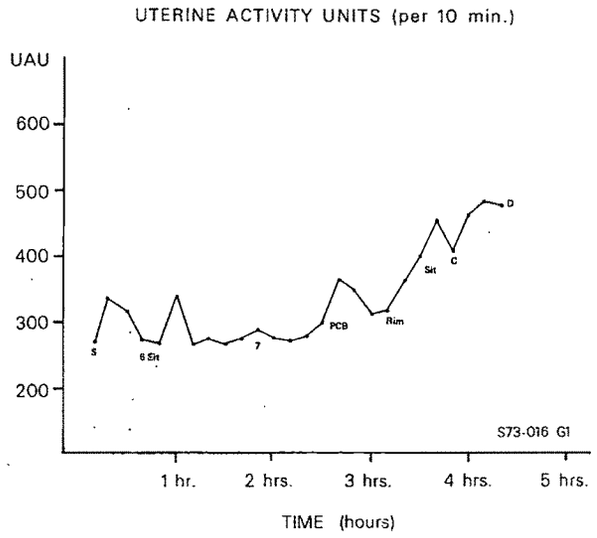

Fig. 2. The noncumulative uterine activity units per ten minutes from 5 cm. to delivery (one patient). The associated effect of events such as vaginal examination (5, 6, Rim, etc.), paracervical block *(PCB)*, and position change *(Sit)* on uterine activity are clearly shown.

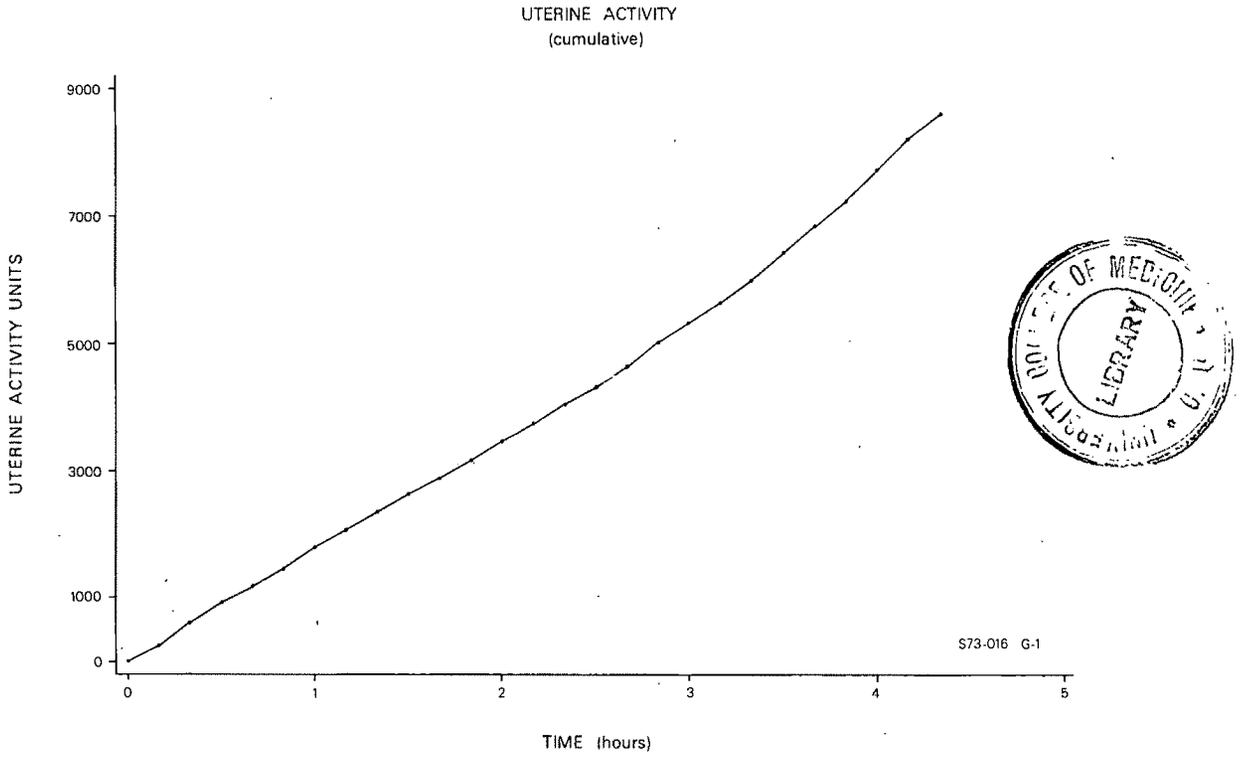
No attempt was made to alter the usual management of labor and delivery as performed in the Perinatal Intensive Care Delivery Unit. Individual variations in patient care were limited by protocols which provide strict guidelines for labor management in this unit. Patients received intravenous analgesia (Demerol and occasionally Demerol plus Phenergan) as clinically indicated. Paracervical block and/epidural anesthesia were used in selected cases. Magnesium sulfate dosage, when indicated, was given via continuous infusion pump. A policy of active labor management was practiced. If the cervical dilatation was not progressing and UA on clinical grounds was considered to be "inadequate," a low-dose intravenous oxytocin infusion was promptly instituted by use of an infusion pump. One half of all the patients received oxytocin at some time during labor; ten per cent of these for induction and 90 per cent for augmentation. Vaginal examinations were performed by one examiner in each patient for consistent assessment of cervical dilatation. All patients reached full dilatation. Two patients were delivered by cesarean section after two hours of good labor in the second stage with failure of descent of the presenting part.



Results

The cervical dilatation at the onset of monitoring ranged from 3 to 8 cm. (Table II). The longest monitored labor was eleven hours and fifty-six minutes, and the shortest was 56 minutes.

The uterine activity (reported in UAU's) was calculated for each patient in both cumulative and noncumulative fashions. The UAU's from the "normal" labor of a 16-year-old patient are shown in Fig. 2, plotted in a noncumulative fashion (UAU per ten minutes) from 5 cm. dilatation until delivery. UAU's progressively increased as labor progressed, although there were notable variations in the UAU's when successive ten-minute intervals were compared. The apparent effects associated with vaginal examination, medications, and position change on uterine activity are easily seen. The uterine activity from the same patient plotted in a cumulative manner (Fig. 3) forms a slope that is essentially linear with an increase in the slope near the end of the first stage and during the second stage of labor.

The variation of cervical dilatation at the onset of UA monitoring and in the length of labor make it difficult to compare UA at corresponding elapsed times in different patients. Delivery does provide a common end point and one may retrospectively plot UAU's for each ten minute interval for a relative comparison. A mean curve for the noncumulative UA for the six hours prior to delivery was plotted for the 100 labors (Fig. 4). There was a progressive increase in UAU's as labor progressed. The mean UAU's increased from 210 per ten minutes six hours prior to delivery to 375 per ten minutes at delivery.

Possibly a more useful way to evaluate UA is to calculate the UAU's required for each centimeter of cervical dilatation. The mean UAU's per ten minutes required to dilate the cervix from 3 to 4 cm., 4 to 5 cm., etc., were calculated. During these 100 labors, 428 vaginal examinations were performed in which there was a change in cervical dilatation. The dilatation had advanced 1 cm. since the previous examination in 318, 2 cm. in 76, and 3 cm. or more in 34. The UA data for changes of 3 cm. or more between examination was

LIBRARY

Fig. 3. Cumulative uterine activity units recorded every ten minutes from 5 cm. dilatation until delivery (one patient).

excluded because no accurate estimation could be made of the amount of UA expended at each centimeter of dilatation. When there was a 2 cm. change between examinations, the total UAU's were calculated and divided equally between the two centimeters. The mean UAU's per ten minutes at each centimeter of dilatation for all the patients in the study are shown in Fig. 5. The mean UAU's per ten minutes for patients grouped according to the cervical dilatation at the onset of monitoring showed progressive increases in each group as labor advanced. There were 268 examinations in which cervical dilatation advanced 1 cm. on two successive examinations. With this information a comparison of the mean UAU's per ten minutes at each centimeter can be made. Table III shows the number of examinations and the increases and decreases in mean UAU's with successive dilatation. The number of increases greatly outnumbers the decreases at each centimeter of cervical dilatation. Over all, the mean UAU's per ten minutes decreased in 23 per cent of examinations as labor progressed. However, in only five cases did the mean UAU's per ten minutes decrease twice in a row with progressive cervical dilatation. There were no patients with a decrease in the mean UAU's if cervical dilatation progressed more than 1 cm. between examinations (indicating rapid laxor progression). Although the rate of UA (UAU's per ten minutes) increased as labor progressed, the mean total UAU's required to effect cervical dilatation decreased with each successive centimeter of dilatation as shown in Fig. 6. The mean total UAU's were calculated by adding the mean UAU required to dilate each centimeter from 3 cm to delivery. Although there were only eight patients in the 3 to 4 cm. group, the 4 to 5 cm. group included these patients plus the 20 patients in whom monitoring was started at this dilatation, etc. A mean total of 11,536 UAU's was required to progress from 3 cm. to delivery in this group of patients. The UAU's necessary to accomplish delivery after complete dilatation were approximately one-fifth the total UAU's for the monitored labor.

The rate of cervical dilatation in centimeters per hour (slope of cervical dilatation) plotted at each centimeter of cervical dilatation for all 100 patients is shown in Fig. 7. It is obvious that as labor progresses, the slope of cervical dilatation progressively increases. The mean slope of cervical dilatation was then plotted against the mean UAU's per ten minutes at each centimeter of dilatation (Fig. 8). For this evaluation, the

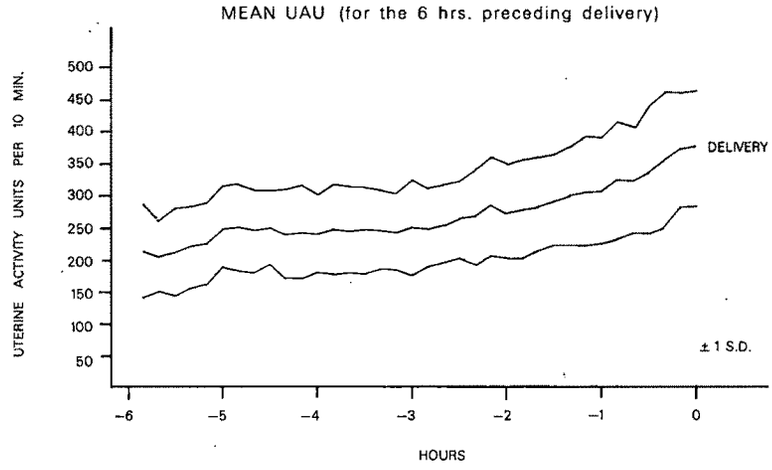


Fig. 4. Mean UAU's for 100 patients plotted retrospectively every ten minutes for six hours preceding delivery.

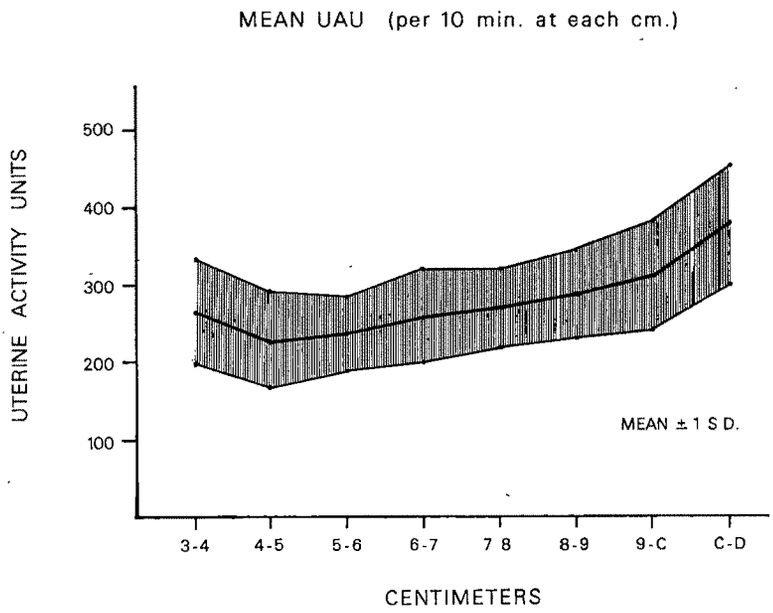

Fig. 5. Mean UAU's per ten minutes at each centimeter of dilatation for 100 patients.

data for changes of 3 cm. or more between examination were excluded for the reasons described earlier in the paper. With the exception of the 3 to 4 cm. group in which there were only eight samples, there was a direct correlation between the mean UAU's at each centimeter of dilatation and the slope of cervical dilatation.

When comparing UAU's in patients receiving oxytocin and those not receiving oxytocin, lower mean UAU's per ten minutes were found in patients receiving oxytocin at each centimeter of cervical dilatation. As labor progressed, these differences diminished, and at complete dilatation the mean UAU's were the same in the two groups (Fig. 9).

Comment

There are a number of factors that influence labor and any attempt to predict the course of labor with the

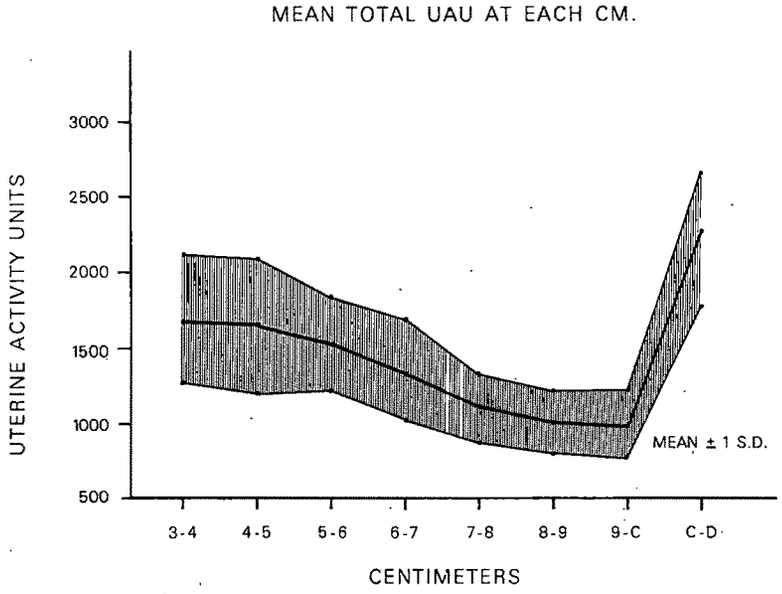

Fig. 6. Mean total UAU's expended at each centimeter of dilatation in 100 labors.

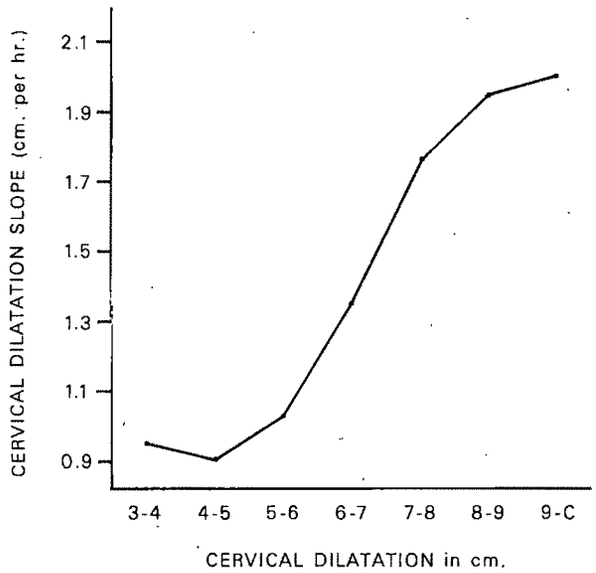

Fig. 7. The slope of cervical dilatation at each centimeter of dilatation (100 patients).

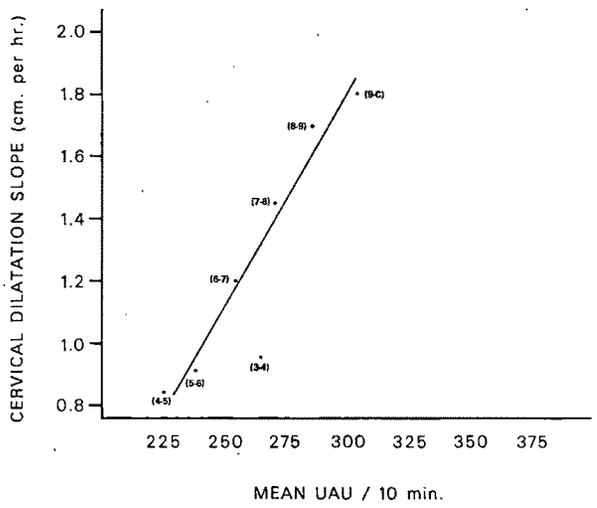

Fig. 8. The slope of cervical dilatation versus mean UAU's per ten minutes at each centimeter of dilatation (100 patients). (The numbers in parentheses indicate the centimeters of cervical dilatation.)

use of only one parameter is hazardous. However, in the absence of disproportion, progress in labor (cervical dilatation) will likely be proportional to the amount and quality of uterine contractions. Guidelines have previously been established for the expected rate of cervical dilatation per unit of time (hours) during normal labor. The amount of uterine activity required for normal labor has not been established. Until recently, instrumentation which could provide this information was not readily available for clinical use in the ongoing management of labor. Quantitation of UA from the IUP recording can provide this information.

Of the 11,536 UAU's required for labor from 3 cm. to delivery, approximately 20 per cent were required for the second stage of labor. Nine thousand three hundred and thirty-one UAU's were required to advance from 3 cm. to complete dilatation. Fifty-three per cent of this total was required from 3 to 6 cm. and

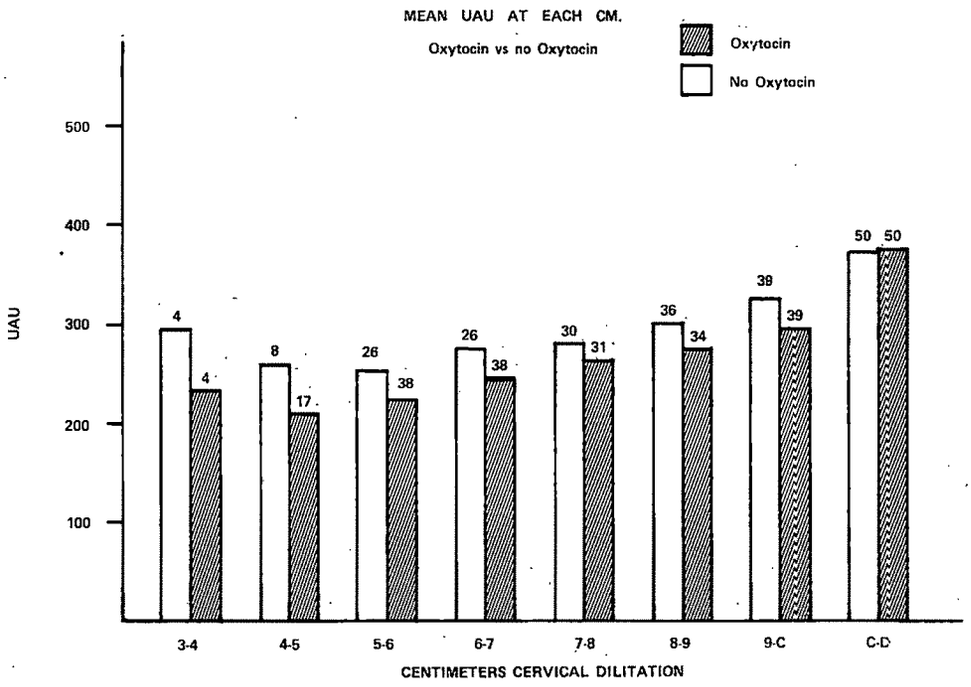

Fig. 9. The mean UAU's at each centimeter of dilatation comparing patients with and without oxytocin.

47 per cent from 6 cm. to complete dilatation. This is in contrast to the data of Burnhill[6] who found that 80 per cent of the "work" of the first stage was expended to progress from 3 to 6 cm. While the rate of uterine activity (UAU per unit of time) increased as labor progressed, the total UAU's expended at each centimeter of dilatation progressively decreased with advancing dilatation. Thus, the rate of cervical dilatation increased faster than could be accounted for by the increase in UA. It appears that much of the UA during the first stage relates to effacement and, once the cervix reaches a certain dilatation, there is rapid progression. This apparently coincides with the phase of maximum slope of cervical dilatation as described by Friedman.[7] The implication is that the efficiency of uterine contractions increases with advancing labor. There is a direct correlation between the slope of cervical dilatation and UAU's.

It no longer appears reasonable to refer to labor in terms of elapsed time. Information regarding the "pattern of cervical dilatation" is much more meaningful to the evaluation of progress in labor. Quantitation of UA might provide useful information to help in the ongoing management of labor. During the course of labor, the mean UAU's at any cervical dilatation can be calculated. The rate of UA (mean UAU's per ten minutes) can be compared to any centimeter of dilatation against the rate of UA for a preceding dilatation. If labor is not progressing adequately and the rate of UA is not increasing, appropriate therapy can be initiated to improve UA. If the mean UAU's are increasing, attention can be directed toward other possible causes of inadequate progress in labor.

Quantitation of UA provides a means of evaluating the effects of specific events such as medication, anesthesia, and manipulation on UA. This allows for an objective comparison of UA between individual patients and groups of patients. Quantitation also permits the use of a systems approach in the evaluation of labor.

Although the patients evaluated in this study do not represent "ideal" or "pure" study groups, the strength of the correlation between UAU's and the cervical dilatation pattern suggests that this might be a useful adjunct for assessing labor. Additional observations are necessary for assessing the correlations between UA and specific cervical dilatation patterns.

A method is now available which provides quantitation of UA for utilization in the evaluation of labor. The information is accurate and immediately available. Quantitation of UA provides objective data on which to base decisions for the ongoing management of labor.

VIII World Congress of Gynecology and Obstetrics

The VIII World Congress of Gynecology and Obstetrics will be held in Mexico City, Mexico, October 17-22, 1976.

Payment of the enrollment fee entitles both members of the FIGO and nonmembers to attend the scientific sessions and join in the social activities and to receive a copy of the Congress program and the book of abstracts.

Only active members of national federations, societies, or colleges affiliated with the FIGO may present free communications, scientific exhibits, and films or take part in scheduled discussions.

Registered accompanying persons are welcome at all social events as well as the tours especially organized for them.

For enrollment, form 1 must be completed and sent in with payment to the General Secretariat before July 31, 1976.

All payments must be made through bank draft to the order of "VIII Congreso Mundial de Ginecología y Obstetricia." The General Secretariat will mail back a receipt, exchangeable for the documents at the Congress Building as of Friday, October 15, 1976, from 9:00 A.M. to 5:00 P.M. Payment should be sent to General Secretariat, Avenida Baja California 317, México 11, D. F., Mexico.

Immunoglobulins and beta-1-C globulin in hydatidiform mole vesicles

HÉCTOR MÁRQUEZ-MONTER, M.D.
ROBERTO KRETSCHMER, M.D.
MARTHA LÓPEZ-OSUNA, B.S.
RAÚL BERLIOZ, M.D.
Mexico, D.F., Mexico

Qualitative and quantitative determinations of immunoglobulins (Ig's) and beta-1-C globulin were carried out in fluid vesicles of hydatidiform moles and carrier mothers. The mean concentration of IgG was 9.9 per cent, IgA had 14.3 per cent, in relation to maternal values. No IgM concentrations were detected in molar fluid. Beta-1-C globulin showed 60.5 per cent concentration in relation to mother's serum. It is suggested that in trophoblast of molar vesicles a selective transudate migration of Ig's by a mechanism of pinocytosis takes place to the vesicular fluid.

THE TROPHOBLAST is the first tissue to become differentiated in mammals.[1] Its functions include: hormone synthesis. nidation of the blastocyst in the endometrium, the early metabolic exchanges between mother and embryo. Immunologic isolation of the embryo has also been attributed to the trophoblast, accounting for the acceptance of the former as an allograft in the uterus.[2–4] This isolation, however, does not prevent maternal humoral antibodies from crossing the trophoblast in both directions. Immunoglobulin synthesis, on the other hand, occurs in the fetus at an early gestational age and some fetal immunoglobulins also pass through the trophoblast to the maternal circulation.[5] This dual exchange of immunoglobulins renders the evaluation of maternal immunoglobulins entering the embryonic circulation difficult. The fluid of vesicles of hydatidiform moles was chosen in order to study trophoblastic permeability to immunoglobulins because there is no embryo or embronic circulation in these pathologic pregnancies. Previous studies related to electrolytes and plasma proteins have been performed by McKay and associates,[6, 7] using this model. We hereby report the concentration of immunoglobulins in hydatidiform mole fluid vesicles. Values were compared with the same immunoglobulins in maternal sera.

Material and methods

Eleven recently delivered hydatidiform moles were obtained from the Hospital de Gineco-Obstetricia Number 2 of the C.M.N., I.M.S.S. Careful examination did not disclose embryos in these specimens. Grossly the moles were constituted by multiple vesicles with diameters ranging from 0.3 to 4 cm.; the largest vesicles were washed minimally in physiologic saline and were punctured with a needle for the extraction of fluid. Serum was also obtained from the patient at the moment of delivery. Unconcentrated vesicular fluid and the corresponding maternal serum were analyzed by microimmunoelectrophoresis,[3] using rabbit anti–whole-human serum and anti-human immunoglobulins (IgG, IgA, IgM) antisera. Quantitative determination of immunoglobulins and beta-C globulin in vesicular fluid and in serum was done by single radial immunodiffusion in agar plates.[9]

Results

Immunoglobulins G, A, and M, and beta-1-C globulin concentrations in vesicular fluid and sera are shown

*S = maternal serum; M = molar fluid.

in Table I, as well as the percentage of vesicular Ig's when compared to the maternal serum values. The mean concentration of IgG in molar fluid was 9.9 per cent of the maternal serum value (with a range of 1.8 to 25.6 per cent). For IgA, the mean concentration was 14.3 per cent of the maternal serum value with a range of 0 to 41.6 per cent. No IgM was detected in the 11 hydatidiform moles included in this study, whereas the concentration of IgM in the corresponding maternal serum was normal, except in one case where a low value of 34.5 mg. per 100 ml. was found. Finally, mean concentration of beta-1-C globulin was 60.5 per cent of the maternal value with a range of 10.6 to 22.4 per cent.

Immunoelectrophoretic analysis revealed a normal pattern for all the maternal sera except the case that showed low IgM (Fig. 1). All molar fluids revealed the presence of albumin, alpha-1, alpha-2, and beta-globulins, beta-1-C globulin, IgA, and a low concentration band of IgG in a slightly cationic position. No IgM precipitation band was found in the immunoelectrophoresis analysis of vesicular fluid. Those cases with concentration of IgG lower than 100 mg. per 100 ml. disclosed discrete duplication of the IgG band, probably a result of a progressive precipitation.[10]

Comment

Fetal serum of a gestational age similar to the hydatidiform moles included in this study (23 to 30 weeks), usually contains IgG of maternal origin amounting to 4 to 8 percent of the concentration in maternal serum.[11] Normally no IgA or IgM is found in fetal serum, although both can be found in cases of intrauterine infection. Fetal serum of this age contains approximately 15 mg. per 100 ml. of beta-1-C globulin, all of which is of fetal origin.

These data suggest—albeit no definite proof is offered—that immunoglobulins and beta-1-C globulin in hydatidiform mole fluids result from a transudation of maternal serum through a mechanism possibly including pinocytosis. First, because it contains IgA in considerable amount (19.3 per cent from the maternal values), and this immunoglobulin neither is synthesized by the fetus in normal conditions nor crosses the placenta in measurable amounts. If fetal infection is claimed to explain the presence of IgA in hydatidiform

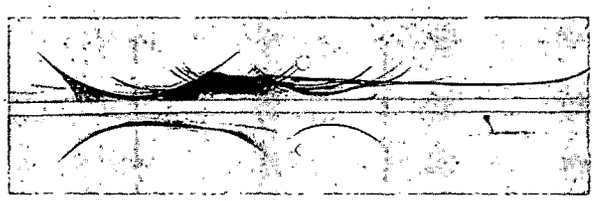

Fig. 1. Immunoelectrophoresis of molar fluid (lower) and maternal serum (upper) with whole antiserum.

moles, one has to consider that the same condition would also lead to the presence of IgM, and none of the cases revealed this immunoglobulin in the vesicular fluid. The high molecular weight of IgM, however, could explain its paucity or absence in a transudate fluid. On the other hand the presence of IgA could be due to a leakage of this immunoglobulin through an abnormal trophoblastic barrier of the hydatidiform mole.

The reasons for acceptance or rejection of
an oral contraceptive are many. Some are hers and
some are yours.
In the main, her reasons for rejection, often
highly subjective, are based on side effects—
and side effects are only partially predictable from
history and examination.
The ultimate test, then, of oral contraceptive
acceptability must be what happens when she takes it
since both your judgment and hers will be based on...
Real Life Experience

From real life...

A Woman satisfied her oral contraceptive

One important reason for patient satisfaction: Usually no G.I. discomfort

ZORANE 1/50 is a highly effective and generally well-tolerated oral contraceptive—providing the estrogen content and progestin:estrogen ratio that appears to be highly acceptable to the majority of women.

From clinical studies: In a study population of 1156 women, 25,983 cycles, the incidence of nausea and vomiting was 3.3%. Actual patient dropout rate* due to nausea and vomiting was 2.9% (33 subjects.) Overall patient dropout rate was 14.4% due to all adverse reactions. Serious reactions, as well as minor adverse reactions, have been reported following the use of all oral contraceptives. Before prescribing, the complete product information should be consulted for *special note, contraindications, warnings, precautions* and *adverse reactions*. Thereafter, the physician should remain alert to the earliest manifestations of any serious disorder. Should any occur or be suspected, the oral contraceptive should be immediately discontinued.

The woman profiled here is an actual ZORANE 1/50 user. However, not all women can be expected to have the same tolerance for side effects, should any occur. (Data on file, Lederle Laboratories)

*Dropout rates are based on total patient population (1,156); incidence reflects only those patients who completed one or more cycles (956).

Zorane 1.5/30 Norethindrone Acetate, 1.5 mg, and Ethinyl Estradiol, 30 mcg.

Zorane 1/20 Norethindrone Acetate, 1 mg, and Ethinyl Estradiol, 20 mcg.

Special Note: Oral contraceptives have been marketed in the United States since 1960. Reported pregnancy rates vary from product to product. The effectiveness of sequential products appears to be somewhat lower than that of combination products. Both types provide almost completely effective contraception. The dropout rate for medical reasons, as observed in clinical trials, with ZORANE 1.5/30 appears to be the same as that of higher dose combination products. The dropout rate due to irregular bleeding was somewhat higher, but dropouts were equally split between irregular bleeding and other medical reasons attributable to the drug. (ZORANE 1/20 only: The effectiveness is somewhat lower than that of the higher dose combination products. Both provide almost completely effective contraception. Dropout rate for medical reasons appears to be somewhat higher than with higher dose combination products, due particularly to irregular bleeding.) An increased risk of thromboembolic disease associated with use of hormonal contraceptives has now been shown in studies conducted in both Great Britain and the United States. Other risks, such as those of elevated blood pressure, liver disease, reduced tolerance to carbohydrates, have not been quantitated with precision. Long-term administration of both natural and synthetic estrogens in subprimate animal species in multiples of the human dose increases the frequency for some animal carcinomas. These data cannot be transposed directly to man. Possible carcinogenicity due to the estrogens can neither be affirmed nor refuted at this time. Close clinical surveillance of all women taking oral contraceptives must be continued.

Indications: For control of conception.

Contraindications: Thrombophlebitis, thromboembolic disorders, cerebral apoplexy, or a past history of these conditions; markedly impaired liver function; known or suspected carcinoma of the breast; known or suspected estrogen-dependent neoplasia; undiagnosed abnormal genital bleeding; pregnancy.

Warnings: If early signs of thrombotic disorders (thrombophlebitis, cerebrovascular disorders, pulmonary embolism, retinal thrombosis) occur or are suspected, discontinue use of drug immediately. (Studies indicated a higher risk of these conditions with use of these drugs, not persisting after drug stoppage and not enhanced by long-term use.[1-4]) If sudden partial or complete loss of vision occurs, or if there is sudden onset of proptosis, diplopia or migraine; or if examination reveals papilledema or retinal vascular lesions, discontinue medication. Safety of use in pregnancy has not been established, therefore rule out pregnancy in any patient who has missed two consecutive periods before continuing contraceptive regimen; if prescribed schedule has not been adhered to, consider possibility of pregnancy with first missed period. A small fraction of hormonal agents has been identified in the milk of mothers receiving these drugs; long-range effect to the nursing infant has not yet been determined.

Precautions: Pretreatment and periodic physical examinations of breasts and pelvic organs should include Papanicolaou smear. (Estrogens have produced tumors, some malignant, in 5 species of subprimate animals.) If endocrine and liver function tests are abnormal in patients taking these drugs, repeat tests after drug withdrawal for 2 months. With use of these drugs, pre-existing uterine fibromyomata may increase in size; and some conditions (*i.e.*, epilepsy, migraine, asthma, cardiac or renal dysfunction) may be influenced by fluid retention; observe carefully for such. With use of ZORANE 1.5/30 or ZORANE 1/20, alteration in menstrual patterns may be induced. Since the amount and duration of flow and cycle length may vary, this must be considered in attempting to determine if cause of bleeding is organic. (ZORANE 1/50 only: In breakthrough bleeding or all cases of irregular bleeding per vaginam, keep in mind nonfunctional causes and take adequate diagnostic measures.) With history of psychic depression, discontinue drug if depression recurs to a serious degree. Possible influence of prolonged ZORANE therapy on pituitary, ovarian, adrenal, hepatic or uterine function awaits further study. A decrease in glucose tolerance has been seen in some patients on oral contraceptives; carefully observe diabetics on such therapy. Patient age is no absolute limiting factor, although these drugs may mask onset of climacteric. The pathologist should be advised of ZORANE therapy when relevant specimens are submitted. Susceptible women may have an increase in blood pressure following use of contraceptive steroids.

Adverse Reactions Observed in Patients Receiving Contraceptives: Statistically significant association demonstrated between use of oral contraceptives and: thrombophlebitis, pulmonary embolism, cerebral thrombosis. Suggestive evidence, neither confirmed nor refuted, between use and neuro-ocular lesions (*e.g.*, retinal thrombosis, optic neuritis). Known to occur: nausea, vomiting, G.I. symptoms (abdominal cramps, bloating), breakthrough bleeding, spotting, change in menstrual flow, amenorrhea during and after treatment, edema, chloasma or melasma, breast changes (tenderness, enlargement, secretion), weight change (increase or decrease), changes in cervical erosion and secretions, suppression of lactation when given immediately post-partum, cholestatic jaundice, migraine, allergic rash, rise in blood pressure in susceptible women, mental depression. Reported association with use, neither confirmed nor refuted: anovulation post treatment, premenstrual-like syndrome, changes in libido, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, fatigue, backache, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, itching. *May Alter Laboratory Results in:* hepatic function (increased sulfobromophthalein retention and other tests), coagulation tests (increase in prothrombin, Factors VII, VIII, IX, X), thyroid function (increase in PBI_1, and butanol extractable protein bound iodine, and decrease in T^3 uptake values), metyrapone test, pregnanediol determination.

FETUS, PLACENTA, AND NEWBORN

Diagnosis of placental sulfatase deficiency

TORU TABEI, M.D., PH.D.
W. LEROY HEINRICHS, M.D., PH.D.
Seattle, Washington

Placental sulfatase deficiency has been found in four pregnancies (cases 1 to 4) with inappropriately low levels of urinary estriol excretion (less than 1.3 mg. per day near term gestation) associated with healthy neonates. The basis of the diagnosis in these cases was the greatly limited capacities for hydrolysis of ^{14}C-dehydroepiandrosterone sulfate (DHA-S) and ^{3}H-estrone sulfate (0.2 μCi each) to the free steroids during incubation of placental homogenates. Placental aromatase activities in vitro for free DHA and the concentrations of appropriate estrogen precursors in cord blood were normal or elevated. The defect was diagnosed prenatally in two of these cases on the basis of failure to increase the maternal excretion of urinary estriol (0.6 to 0.7 and 1.3 to 1.3 mg. per day, respectively) following acute instillation of DHA-S (250 mg.) into the amniotic fluid and on normal levels of estrogen precursors in cord blood. In comparison, a twofold increase in maternal estriol excretion was observed after infusing DHA-S into the amniotic cavity of a "high-risk" pregnancy having normal sulfatase and aromatase activities in vitro (case 5). These enzyme activities were also found to be similarly normal in another placenta from an undergrown fetus (case 6) and in six normal placentas. The clinical features of these pregnancies, the first ones described from the western hemisphere, are similar to reported cases: the newborn progeny are healthy males who appear to be developing normally. The prenatal diagnosis of the sex-specific placental enzyme defect has been made possible by the use of an intra-amniotic DHA-S loading test.
